PFNA II is a newer device used in fixation of intertrochanteric fracture. Previously, most surgeons used the dynamic hip screw as the choice of implant for intertrochanteric fracture. In this study the advantages of the device have been studied by means of operating time, blood loss and fracture union. Among the cases studied the mean blood loss was found to be very low when compared with that of dynamic hip screw (DHS) as quoted in the few studies. The operating time has been found to be reduced (statistically significant $p<0.001$) when this is compared with that of DHS.[10-14]

The blood loss in our study was lesser in this study when compared to most other studies that used DHS.[12-16] The difference in blood loss was statistically significant ($p<0.001$) with 95% C.I. Since this method of nail insertion uses small incisions and less soft tissue dissection, the mean blood loss is very less.

The simple operating steps reduces the duration of the surgery when compared to that of the DHS. The mean duration of surgery was less than 2 hours. This difference is statistically significant ($p<0.001$).[18-24] There was almost 100% union noted in this study than the previous studies, hence there is no worry for the operating surgeon about the fracture union.[13,27-31]

□□□□□□□□ □□

The PFNA II is an ideal implant for unstable intertrochanteric fracture since stable intramedullary fixation can be achieved with almost 100% union in the studied population. The PFNA II was easy and quicker procedure with minimally invasive technique and minimal blood loss when compared with previous studies that used the dynamic hip screws.

Limitations

Small sample size and short duration of follow up.

ABSTRACT

Background: Platelet rich plasma (PRP) has been a breakthrough in the field of medicine especially in the field of orthopaedics for enhancing bone and soft tissue healing. Plantar Fasciitis is a very common problem in the field of orthopaedics and are very difficult to treat and a challenge to orthopaedicians. The aim of our study was to find out the efficacy of autologous PRP in relieving pain in patients with plantar fasciitis.
Methods: In this study, 25 patients with plantar fasciitis (age above 18 years) were selected. The pain intensity was assessed with visual analogue score initially and during follow up. All subjects were given single autologous intralesional PRP injection and the results were assessed using difference in VAS.
Results: The mean pain score at presentation was 8.08. The mean pain scores at subsequent intervals of 1,2,4,6 months after injection were 4.32, 2.60, 1.88 & 2.00 respectively. ($P<0.05$ which is statistically significant). The maximum pain relief was seen at 4th month post PRP injection and the pain relief was sustained till the last follow up.
Conclusions: From our study we have found that intralesional autologous PRP is effective in relieving pain in patients with plantar fasciitis. PRP is biological and can be a safe adjuvant in the treatment of Plantar Fasciitis.

Keywords: Platelet rich plasma, Plantar fascitis, Visual analogue score

INTRODUCTION

Platelet rich plasma (PRP) has been a breakthrough in the field of medicine especially in the field of orthopaedics for enhancing bone and soft tissue healing. Plantar Fasciitis is a very common problem in the field of orthopaedics and are very difficult to treat and a challenge to orthopaedicians. Autologous PRP is a simple and cost effective means of treating plantar fasciitis by tissue regeneration.[1]

Plantar fasciitis is one of the most common causes of heel pain in adults. The cause of pain is due to collagen degeneration at the origin of plantar fascia. The plantar fascia is thickened fibrous fascia that originates from the medial tubercle of calcaneum and run forward to support the longitudinal foot arch.

The aim of our study was to find out the efficacy of autologous PRP in relieving pain in patients with plantar fasciitis.

METHODS

This is a prospective trial involving the patients in the department of orthopedics, PSGIMSR Coimbatore, Tamil Nadu, India from Jan 2015 to Jan 2016.

In this study, 25 patients with plantar fasciitis (age above 18 years) were selected. The pain intensity was assessed

with visual analogue score initially and during follow up. All subjects were given single autologous intralesional PRP injection and the results were assessed using difference in VAS.

Selection of patients

Patients with history of pain and localized tenderness on the medial calcaneal tubercle.[2] The classic sign is pain that occurs with few steps in the morning or at the start of walking which decreases as they warm up.[2]

Inclusion criteria

Patients clinically diagnosed to have plantar fasciitis, patients not responding to conservative treatment even after a minimum period of 3 months, both males and females of age 18 years and above.

Exclusion criteria

Less than 3 month duration of plantar fasciitis, patients without any trial of conservative treatment, recent local steroid injection (less than 2 months), infection or ulcer at the injection site, rheumatoid arthritis, seronegative spondyloarthritis, pregnant ladies, patients younger than 18 years, suspicion of diagnosis.

Methodology

Figure 1: Study design.

Method of preparation of PRP

PRP was prepared using double spin centrifugation method.

10 ml of venous blood is drawn from cubital vein. The blood is transferred into 2.7ml vaccutainer prefilled with acid citrate dextrose. Acid citrate dextrose will bind to calcium and prevents blood clotting with no known interference to platelet function and no contraindications for using in human beings. The blood is then transferred in the vaccutainer till the marking and centrifugation was done. Initially, with 1500 RPM for 3 minutes. After the initial rotations, blood was separated into plasma and RBC. The plasma will lie in the top with light yellow colour and was withdrawn and transferred into another container without mixing RBC. Later this container is again centrifuged with 2500 rpm FOR 3 MINUTES. After the 2nd centrifugation, the plasma is separated into 2 layers. The top half is platelet poor plasma and bottom half will be platelet rich plasma. The top half is discarded and bottom half is used for infiltration.

Technique of infiltration

Using a 21 Gauge, 1 and 1/2 inch needle, 1ml PRP is injected initially over the maximum tenderness point, and another 1 ml, was injected into the surrounding tissue with the same entry portal. This technique is known as peppering technique.

Pain scoring system

Visual analogue pain scoring system was used (Figure 2).

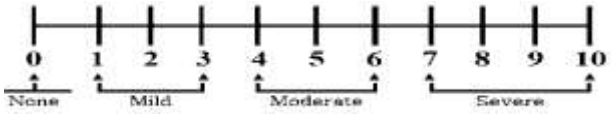

Figure 2: Visual analogue scoring system for assessment of pain.

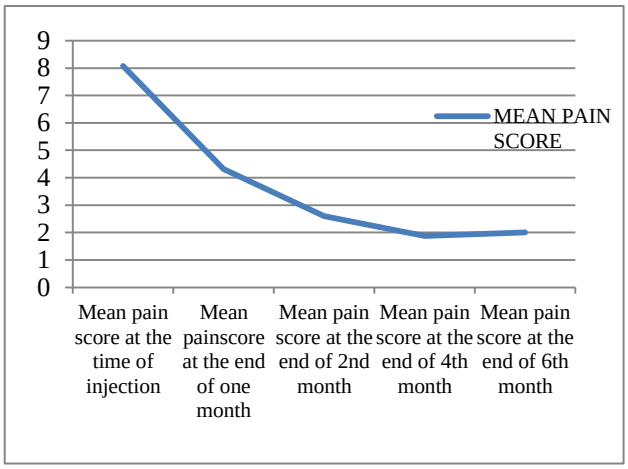

Figure 3: Mean pain score.

RESULTS

Patients were analyzed for pain relief subjectively at 0, 1, 2, 4 and 6 months. The results are given below.

Mean pain score

The mean pain score of patients with plantar fasciitis at 0, 1,2,4,6 months were 8.08, 4.32, 2.60, 1.88 & 2.00 respectively. While comparing the results at 0,1,2,4,6 months follow up, it was found that patients started getting pain relief at one month post injection ,which was statistically significant (p value <0.05). However the maximum pain relief was seen at 4th month post injection which was also statistically significant (p value <0.05).

Table 1: Showing mean pain scores at 0, 1, 2, 4 and 6 months intervals.

Patients receiving	Mean pain score at the time of injection	Mean pain score after	Mean pain score after	Mean pain score after	Mean pain score after
PRP		1 month	2 months	4 months	6 months
Plantar Fasciitis	8.08	4.32	2.6	1.88	2

Table 2: Showing Mean, T-Test and P-values at 0, 1, 2, 4 and 6 months intervals.

Pairs	Time interval	Mean	T-Test	P- Value
Pair 1	Pain at presentation & 1 month	4.32 ± 0.802	16.660; CI (3.29-4.22)	<0.00
Pair 2	Pain at presentation & 2 month	2.60 ± 0.645	33.309; CI (5.1-5.8)	<0.00
Pair 3	Pain at presentation & 4 month	1.88 ± 0.881	26.847; CI (5.72-6.67)	<0.00
Pair 4	Pain at presentation & 6 month	2.00 ± 0.957	24.877; CI (5.57-6.58)	<0.00

Statistical analysis

Statistical analyses were performed by SPSS for windows 19.0 software system version. Comparing the results at 0, 1, 2, 4, 6 months. P value for the test was taken as 0.05. Our study shows that the pain relief obtained following autologous PRP injection is statistically significant.

DISCUSSION

Platelet rich plasma (PRP) is also known as platelet rich concentrate, autologous platelet gel or platelet releasate. Platelet rich plasma is a portion of the plasma fraction of autologous blood with a concentration of platelets above the base line values.[3] In addition to platelet concentrate, autologous PRP contains complement of clotting factors and secretary proteins.[4] Normal platelet counts ranges between 150000/µL and 350000/µL, and average about 200000/µL in blood.[5] "PRP was introduced by M. Ferrari in 1987 as an autologous component in an open heart surgery to avoid homologous blood product transfusion".[6]

Platelets contain biologically active substance for blood clotting, such as coagulation factors, adhesive proteins and protease inhibitors. Platelets contain growth factors like TGF –beta 1, CGF, VEGF, and PDGF.[7,8] When activated these growth factors initiates the process of tissue healing by cellular proliferation and differentiation, chemo taxis, tissue debris removal, angiogenesis, and extra cellular matrix formation.[9,10] These properties of autologous PRP are used in the treatment of plantar fasciitis. An added advantage of autologous PRP is that it eliminates concerns about immunogenic reactions and disease transmission.[11]

Our study was a prospective study including 25 patients with plantar fasciitis (age above 18 years). The pain intensity was assessed with visual analogue score initially and during follow up. PRP was prepared by double spin centrifugation method and the platelet count in our samples ranged between three to six lakhs per cc. All subjects were given single intra-lesional PRP injection and the results were assessed using difference in VAS. In our study we did not use local anaesthetic agent which could bias our study by producing pain relief.

The results of our study matched with the results of the study by Ehab Mohamed Selem Ragab et al on 25 patients with plantar fasciitis, they concluded that average pain at the time of presentation was 9.1 and post autologous PRP injection was 1.6 at end of follow up (10.3 months).[1] Which was statistically significant (P <0.001).

In a comparative study by Ertugrul Aksahin et al they concluded that both PRP and corticosteroid treatment is equally effective in treating plantar fasciitis.[2]

The mean pain score at presentation was 8.08. The mean pain scores at subsequent intervals of 1,2,4,6 months after injection were 4.32, 2.60, 1.88 and 2.00 respectively. (P <0.05 which is statistically significant). The maximum pain relief was seen at 4th month post PRP injection and the pain relief was sustained till the last follow up.

The limitations of our study were that our study is not a randomized control double-blinded study, and the sample size was small and follow up was of shorter duration. The available data is insufficient to validate the efficacy of PRP in relieving pain in patients with Plantar Fasciitis. Further randomized control studies with large study population and the longer duration of follow up are needed to validate the efficacy of autologous PRP in the management of plantar fasciitis.

CONCLUSION

From our study we have found that intralesional autologous PRP is effective in relieving pain in patients with plantar fasciitis. PRP is biological and can be a safe adjuvant in the treatment of Plantar Fasciitis.

Functional outcome of Tibial condyle fractures treated by minimally invasive plate osteosynthesis

Dr. N Venkatesh Kumar, Dr. Arvind Kumar SM, Dr. Udayamoorthy S and Dr. Sanjeev S

DOI: http://dx.doi.org/10.22271/ortho.2017.v3.i1l.113

Abstract
Introduction: Tibial plateau fractures with intra-articular extension are very difficult to manage. Age, skin conditions, compartment syndrome and osteoporosis further increase the obstacles in the healing process.
Complex biomechanics of its weight bearing position and complex ligamentous stability and articular congruency are the main reason why these fractures are of concern to surgeon.
In our study we have evaluated the functional outcome of locking plate fixation of tibial condyle fractures using minimally invasive technique, a minimum period of 6 months after plate fixation by Rasmussen score and Knee society score.
Materials and Methods: Tibial plateau fractures treated by minimally invasive plate osteosynthesis using locking compression plate from January 2010 to January 2015 were taken into the study. All the patients who had completed the inclusion criteria were called for assessment of functional outcome of knee using Rasmussen score and knee society score.
Results and Discussion: In our study, we were able to get away with unilateral plating for type V and type VI fractures without any late complications like loss of reduction and malalignment.
Choice of the procedure/implant should be based on the fracture pattern, bone quality and intraoperative reduction.
Conclusion: Treatment of intraarticular tibial plateau fractures is still unsolved.
Our results in minimally invasive percutaneous plate osteosynthesis (MIPPO) technique is in par with the literature.

Keywords: Tibial fracture, Schatzker, osteosynthesis, implants

Introduction
The knee joint is complex and most commonly injured joint now because of increased motor vehicle accidents and sports related injuries. As it is a superficial joint, it is more exposed to external forces and gets easily injured. Tibial plateau fractures with intra-articular extension are very difficult to manage. Age, skin conditions, compartment syndrome and osteoporosis further increase the obstacles in the healing process.
Complex biomechanics of its weight bearing position and complex ligamentous stability and articular congruency are the main reason why these fractures are of concern to surgeon. The ideal treatment of high-energy tibial plateau fractures is controversial. Open reduction and stable internal fixation helps in maintaining the articular surface and restoration of the mechanical alignment which allows early mobilization of knee. But, techniques of open reduction and internal fixation compromise the soft tissues and the rate of wound infection is relatively high.
Various other methods of treatment like hybrid fixation and now plate fixation using minimally invasive technique have been suggested. Each method has its own advantage and disadvantages.The development of locking implants has allowed the use of minimally invasive technique for unilateral plating [37-39] with improvement in handling the soft tissue [40-43].
There are lot of studies which assess the general outcome of these fractures but there are only few studies which assess the functional outcome of these fractures which is more important to the patient. In our study we have evaluated the functional outcome of locking plate fixation of tibial condyle fractures using minimally invasive technique, a minimum period of 6 months after plate fixation by Rasmussen score and Knee society score.

Materials and methods

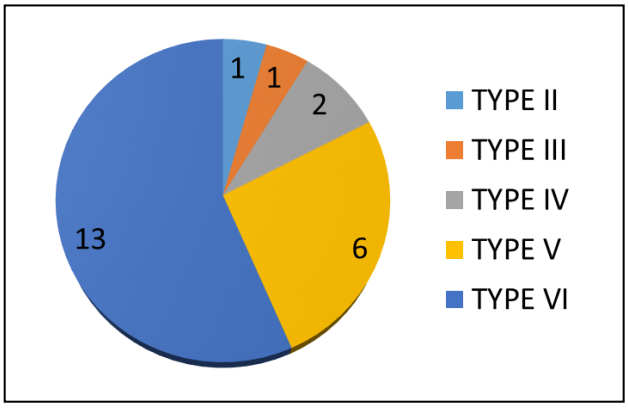
Tibial plateau fractures treated by minimally invasive plate osteosynthesis using locking compression plate from January 2010 to January 2015 were taken into the study.

Inclusion criteria

Age group: 18 years to 60 years all tibial condyle fracture treated by minimally invasive plate osteosynthesis.

Exclusion criteria

1) Skeletally immature patients,
2) Neurovascular injuries,
3) Concomitant lowerlimb fractures like patella, femur, ankle and pelvic fractures.
4) Open fractures



Methodology

This was both retrospective as well as a prospective study. For the retrospective study in-patients and out-patient records of the study population were collected from the medical records department and OT register. Age, gender of the patients, mode of injury, side of involvement, Associated injuries and medical comorbidities were documented. The Neurovascular status of the affected leg, compartment syndrome and any blisters or open wounds was noted. All Tibial condyles fractures were graded preoperatively using Schatzker classification. Patients were followed up postoperatively after a minimum period of six months after surgery. All the patients who had completed the inclusion criteria were called for assessment of functional outcome of knee using Rasmussen score and knee society score.

Results

n our study, 13 patients belonged to type VI, 6 patients belonged to type V, 2 patients belonged to type IV, 1 patient belonged to type III and type II respectively.

Total Number of Patients

Thirteen patients had right tibial plateau fractures and remaining ten patients had left tibial plateau fractures. Only fractures which were treated with MIPPO technique were taken for the study. RTA was the mode of injury in all the cases. In our study type VI Schatzker fractures was the commonest type. Functional assessment was assessed by Rasmussen score (subjective score) and knee society score (objective score). Average follow up period was 22.08 months.

Mean Follow Up

SL.NO	TYPE	AVERAGE FOLLOW UP (MONTHS)
1.	I	-
2.	II	17 (6-17)
3	III	18 (6-18)
4.	IV	32.5 (6-47)
5.	V	19.8 (6-27)
6.	VI	23.1 (6-53)

In type VI Schatzker there were thirteen patients of whom seven patients were treated by lateral plating and six patients were treated by medial plating. Mean Rasmussen score of type VI fractures was found to be 25.6, average knee society score was found to be 93.2 and mean range of knee flexion was found to be 118.8 degrees. All the patients were started on partial weight bearing from 8 weeks and full weight bearing by 12 weeks.

Average Scores by Knee Society and Rasmussen Score

Sl. No	Type	Knee Society Score	Rasmussen Score
1	1	-	-
2	2	98	27
3	3	96	29
4	4	94	26.4
5	5	81.3	22.8
6	6	93.2	25.6

Six patients belonged to type V Schatzker group. Mean follow up was 19.8 months (6-27). Lateral plating was done for 2 patients and medial plating was done for 4 patients. Average Rasmussen score was 22.8, mean knee society score was 81.3 and average range of knee flexion was found to be 118.3 degrees. Only one patient had flexion contracture of 10 degrees. All the patients were started on partial weight bearing at 8 weeks and full weight bearing was started at 12th week. Postoperatively there were no wound infections.

In type IV Schatzker fractures there were two patients. Mean follow up was found to be 32.5 months (6-47). All patients were treated by medial plating. Average range of flexion was found to be 122.5 degrees. Mean Rasmussen score was found to be 26.5. Mean knee society score was found to be 94. There was no wound infection and weight bearing was started at 12th week. In our study only one patient belonged to type III Schatzker fracture. Follow up was done at 18 months (6-18). He was treated by lateral plating and had Rasmussen score of 29. Range of flexion was found to be 120 degrees. Knee society score was found to be 96. No complications were noted.

In type II Schatzker there was only one case which met the criteria. Lateral plating was done. Follow up was done at 17 months (6-17). Rasmussen score was found to be 27, knee society score was 98 and range of knee motion was 125 degrees. No complications were noted. No bone grafts used in our study.

Discussion

Intraarticular tibial plateau fractures are complex fractures accounting for about 1.2% of all fractures. They affect knee function and stability which results in considerable morbidity. These fractures are caused by high velocity injuries and often associated with severe comminution and soft-tissue damage. The goals of treatment are to restore joint congruity, limb alignment and early mobilisation of joint. Stable internal plate fixation without damaging the soft-tissue envelope is very difficult to achieve, only fair results are seen in 20% to 50% in these fractures. Outcome after tibial plateau fracture fixation depends mainly on knee range of motion and strength of the quadriceps. Knee stiffness is more clinically relevant than instability in these fractures.

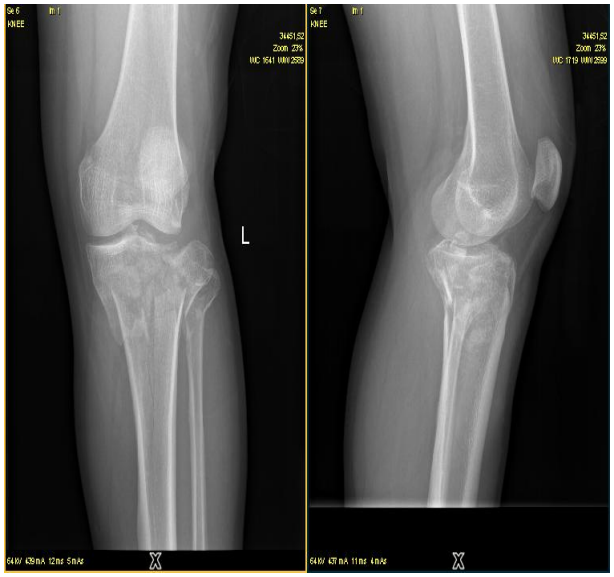
Open reduction and internal fixation (ORIF) with plates and screws enables direct fracture visualisation, reduction, and fixation, but there is high risk of soft tissue injury, stiffness and deep infection. The hybrid external fixator avoids soft tissue problems, but risks non-union, pin tract infections and poor patient compliance.

The concept of preserving the blood supply and atraumatic surgical technique led to the development of biological fixation techniques. Using this technique, soft tissue damage is reduced and shows higher union rate.

The development of locking implants has allowed the use of minimally invasive technique for unilateral plating [37-39] with improvement in handling the soft tissue [41-43].

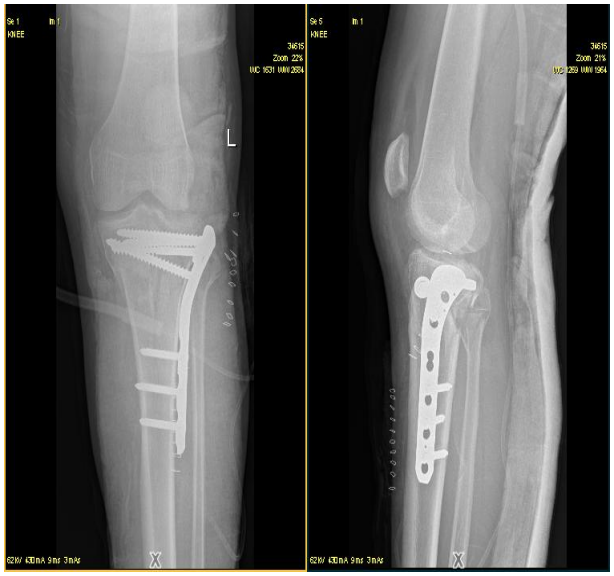
Laterally placed locking plates provide better stability in the presence of complex proximal 1/3rd tibia fracture with metaphyseal comminution and serves as an alternative to medial plate or external fixator for additional support of the medial column when a non-locking plate is used for bicondylar fractures. This plate allows fixation through single incision which avoids wound dehiscence, infection and prolonged immobilisation associated with extensile approaches.

MIPPO enables indirect fracture reduction and percutaneous sub muscular implant placement. Favourable outcome is not due to MIPPO but due to less extensive dissection of soft-tissue envelope and devitalisation of fracture fragments.



The aim of our study was to evaluate the functional outcome of tibial condyle fractures treated by minimally invasive percutaneous plate osteosynthesis. There is no universal scoring system for assessing the functional outcome for these fractures. Literature shows multiple scoring system like Rasmussen, knee society score and oxford knee score. In our study, we have evaluated the patients using Rasmussen score which is subjective score and knee society score which is an objective score. All these fractures were treated by a single plate either medial or lateral (11 lateral and 12 medial). In case of type V and type VI fractures, if needed the opposite condyle was fixed with percutaneous cancellous screws.

Mechanism of injury was road traffic accident for all these patients. The fractures were classified by Schatzker's classification. 13 patients belonged to type VI, 6 patients belonged to type V, 2 patients belonged to type IV, 1 patient belonged to type III and type II respectively. Even though, according to literature type II fractures were the most common, only one patient with type II fracture was included in our study as all other type II & type I fractures in the study period were fixed only by percutaneous screws hence excluded from the study. Type VI fracture with 13 patients (56.5%) were the most common in our study, next was type V (26.08) with 6 patients. Average followup period was 22 months (6-53). Hasnain Raza *et al*, in their study of assessing the functional outcome of tibial condyle fractures of 41 patients by minimally invasive plate osteosynthesis by Rasmussen functional score found excellent results in 18 patients, good in 19 patients and 4 patients had unacceptable results. The mean Rasmussen score was found to be 25.3 and range of knee flexion was 118 degrees. In our study mean Rasmussen score was found to be 26.1 and average range of knee flexion was found to be 120.9 degrees. Of which ten patients had excellent and good results each. Only 3 patients had fair results. This is comparable to the study done by Hasnain Raza. Mohammad Ali Tahririan, Seyyed Hamid Mousavitadi, and Mohsen Derakhshan [13] in their clinical study comparing the functional outcomes of tibial plateau fractures treated with nonlocking and locking plate fixation by knee society score, found a score of 80.2 for locking plate and 72.5 for non-locking plate. Average range of knee flexion was found to be 122.3 degrees for locking plate and 115.7 degrees for non-locking plate. In our study, locking plate was used for all the cases. Average knee society score was found to be 92.5 and average knee flexion was found to be 120.9 degrees. So, functional outcome in our study was marginally better than the locking plate group in that study and significantly better than the non-locking group. This shows the superiority of the locking plate in view of stable fixation and early range of motion when compared to non-locking plate. Chang-Wug Oh *et al* [18] in their study on double plating of (twenty three) type V and type VI proximal tibial fractures using minimally invasive percutaneous osteosynthesis found Eighteen patients with excellent, three patients with good and two patients with fair results. Average Rasmussen score was found to be 26 and average knee range of motion was found to be 123 degrees. In our study, nineteen patients belonged to type V and VI fractures. Average Rasmussen score of these type V and type VI fractures were found to be 24.2. Average range of flexion achieved by type V and type VI was found to be 118.5 degrees. Seven patients had excellent, ten patients with good and two patients had poor results. In their study of ten patients Kye-Youl Cho *et al* [5], used a single midline longitudinal incision and dual plating for the treatment of type V and type VI schatzker fractures. Their mean knee society score for the study group was 85 and the mean range of motion was 125 degrees. They had only one case with delayed wound healing as postoperative complication. In our study, average knee society score was found to be 87.25. One patient had 10 degrees of valgus malalignment in type VI fracture and one patient had flexion contracture of 5-10 degrees. But the functional outcome was not significantly altered when compared with others.



Dual plate gives better biomechanical strength and rigid construct thereby better control of both columns thus avoiding late collapse. There were no major wound problems in any of these studies. Weight bearing was started only at 8-12 weeks which was similar to our study. In our study, we were able to get away with unilateral plating for type V and type VI fractures without any late complications like loss of reduction and malalignment.

Choice of the procedure/implant should be based on the fracture pattern, bone quality and intraoperative reduction.

CASE 1:
Preop Xray

Immediate Postop Xray

After 6 Months

Clinical Picture

Conclusion

Treatment of intraarticular tibial plateau fractures is still unsolved. Our results in minimally invasive percutaneous plate osteosynthesis (MIPPO) technique is in par with the literature. There is no significant difference in the functional outcome between single plating in our study and dual plating of other studies at midterm followup. Choice of the procedure/implant should be based on the fracture pattern, bone quality and intraoperative fracture reduction.

ABSTRACT

Background: Neck of femur fractures are one of the devastating injuries in the old age. Their incidence is on the rise causing immense stress on the society. One of the most commonly done procedure is bipolar hemiarthroplasty. In our study we have evaluated the acetabular erosion after hemiarthroplasty, in neck of femur fracture patients after a minimum period of 2 years and have tried to correlate it with activity level of the patient. The aim of the study were early detection of acetabular erosion; to assess the functional outcome after minimum of 2 years after hemiarthroplasty by modified UCLA score; to correlate the functional activity level and radiological acetabular erosion.
Methods: This is a retrospective radiological and clinical study. The post hemiarthroplasty plain radiographs, showing AP view of hip joint taken in the Department of Radiodiagnosis, PSGIMS&R will be studied along with activity level assessment. By Convenient sampling method, all the patients undergone cemented bipolar hemiarthroplasty, for fracture neck of femur after minimum of 2 years were assessed both radiologically and clinically. Functional activity level was assessed by Modified UCLA scoring system.
Results: By this study we suggest an easy and effective way of evaluating acetabular erosion and clinical activity. There is significant increase in acetabular erosion as the duration after surgery increases.
Conclusions: By this study we suggest an easy and effective way of evaluating acetabular erosion and clinical activity. There is significant increase in acetabular erosion as the duration after surgery increases. The clinical activity is by and large not significantly altered as the erosion progress at mid-term follow up.

Keywords: Neck of femur fractures, Bipolar hemiarthroplasty, Acetabular erosion

INTRODUCTION

Neck of femur fractures are one of the devastating injuries in the old age. It is well recognized even from the era of Hippocrates. The accurate number of hip fractures worldwide is impossible to determine, but the global incidence in the year 2000 has been estimated at 1.6 million and the projections for the future suggest further increasing numbers. In addition to the suffering of the individual the economic strain on society due to hip fracture is immense.

Management of displaced intracapsular hip fracture in elderly remains controversial. Options include hemiarthroplasty or total hip arthroplasty. Total hip arthroplasty has shown better clinical outcome and lesser reoperative rate, but in the elderly frail population who often suffer from fracture of the neck of the femur, morbidity rates are high.[1]

Hemiarthroplasty is one of the commonest procedures done for neck of femur fractures. It provides pain relief and early mobilization. The Moore and Thompson prostheses have been successful implants in treating

fracture neck of femur. Disabling pain and acetabular erosions are frequent complications after the use of Moore prosthesis.[1] So in an attempt to retard the acetabular wear, prolong the life of the implant and delay the need for revision surgery the bipolar prosthesis was developed by Bateman in Toronto in 1974, which had the advantage of hip motion occurring at 2 interfaces, primarily at the prosthetic interface and secondarily at the metal cartilage interface, thus minimizing the articular wear.

This prosthesis was found to be very useful and results were encouraging. However in long-term studies show that the bipolar prosthesis starts acting as unipolar prosthesis with time and hence leads to some erosion. However not all patients with acetabular erosions were symptomatic.

In our study we have evaluated the acetabular erosion after hemiarthroplasty, in neck of femur fracture patients after a minimum period of 2 years and have tried to correlate it with activity level of the patient.

Aim and objective

1. Early detection of acetabular erosion.
2. To assess the functional outcome after minimum of 2 years after hemiarthroplasty by modified UCLA score.
3. To correlate the functional activity level and radiological acetabular erosion.

METHODS

Source of data

This is a retrospective radiological and clinical study. The post hemiarthroplasty plain radiographs, showing AP view of hip joint taken in the Department of Radiodiagnosis, PSGIMS&R during the period between June 2015 to May 2016 will be studied along with activity level assessment. A total of 22 patients were evaluated.

Mode of data collection

By convenient sampling method, all the patients undergone cemented bipolar hemiarthroplasty, for fracture neck of femur after minimum of 2 years were assessed both radiologically and clinically.

Inclusion criteria

All patients operated for neck of femur fracture with cemented bipolar hemiarthroplasty after a minimum period of 2 years.

Exclusion criteria

Exclusion criteria were surgical site hip Infection; any preexisting pathologies around the hip; previous hip surgeries; post-operative periprosthetic fractures; neurological conditions like CVA, parkinsonism.

X-ray technique

A plain anteroposterior view of the operated hip joint is taken and assessed for acetabular erosion grading (Figure 1) following the technique of SakrMazen, MD, Girard Julien, MD and FakihRiad, MD. Patient positioned in supine, using digital X-ray, cassette tube distance is set to 100 cms and the beam is centered directly over the hip.

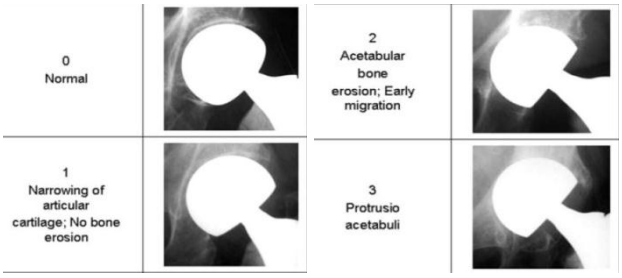

Figure 1: Grades of acetabular erosion.[2]

Activity level assessment[3]

Table 1: Functional activity level was assessed by modified UCLA scoring system.

Modified UCLA scoring system
1. Completely inactive, dependent on other and cannot leave the residence.
2. Mostly inactive or restricted to minimum activities of daily living
3. Sometimes going to social outdoor activities or visiting neighbours.
4. Regularly going to social outdoor activities or visiting neighbours.
5. Sometimes engaging in unlimited house works or shopping.
6. Regularly engaging in unlimited house work or shopping.
7. Regularly using staircase to climb.
8. Lifting or playing with small children.
9. Involving in heavy labour works.
10. Regularly using public transport.
Good --- 7 to 10 Fair-- 4 to 6 Poor--- below 4

Data analysis

Data collected were entered in Excel Spread sheet and analyzed using STATA statistical software package release 11. We used the two-sided independent-samples t test to compare means across dichotomous variables (i.e. men v. women); the one-way ANOVA test for comparison of means across multilevel variables. Simple calculations like Percentages, Proportions and Mean

values were derived. A type I error of 0.05 was considered in all analyses.

RESULTS

Table 2: Total number of participants according to gender.

Gender	Number of participants
Male	12
Female	10

Table 3: Total number of participants according to age.

Age in decades	Number of participants
60-69	9
70-79	11
80-89	1
90+	1

Total number of patient included in this study was 22. Total number of male patients 12, total number of female patients 10 and mean follow up age was 65 years. Right side hip involved was 11 and left side hip was 11. The mean follow up period was 3.54 years. The mean modified UCLA score was 6.22.

Table 4: Mean Modified UCLA score according to gender.

Gender	N	Modified UCLA score
Men	12	6.08±0.9
Women	10	6.4±0.7

The number of patients in Grades 0 and 1 acetabular erosion was 16 (72.70%) and in Grades 2 and 3 were 6 (27.30%).

Table 5: Mean acetabular erosion grade according to side affected.

Hip side	Number of participants
Left	11
Right	11

Table 6: Distribution of patients according to acetabular erosion grades.

Acetabular erosion grades	No. of patients	
Grade 0 and Grade 1	16	72.70
Grade 2 and Grade 3	6	27.30
Total	22	100%

The mean acetabular erosion when correlated with duration since surgery was statistically significant with p<0.001. Grade 0 & 1 has a mean value of 2.81 years and Grade 2 & 3 has a mean value of 5.75 years. This shows there was increased acetabular erosion as the duration post-surgery increases.

Table 7: Distribution of the study participants based on duration since surgery and grades of acetabular erosion.

Duration since surgery	Number of study participants	Erosion	No.	%
<4 years	18	0 and 1	16	88.9
		2 and 3	2	11.1
4 years	4	0 and 1	0	0
		2 and 3	4	100

Table 8: Mean duration since surgery (in months) according to acetabular erosion grades.

Acetabular erosion Grades	N	Duration since surgery
Grade 0 and Grade 1	16	2.81±0.32
Grade 2 and Grade 3	6	5.75±2.36

P<0.001.

The acetabular erosion grade when correlated with modified UCLA score was not clinically significant with p=0.71. In acetabular erosion Grade 0 and 1 the modified UCLA score was 6.33 and in Grade 2 and 3 the modified UCLA score was 6.18. Since the sample size was small the significance could not be correlated statistically. As the age of the patient increases there was a gradual reduction in activity.

Table 9: Mean Acetabular erosion grades according to duration since surgery (in months).

Duration since surgery	N	Acetabular erosion grades
<4 years	18	0.67±0.69
4 years	4	2.25±0.51

P<0.001

Table 10: Distribution of patients according to modified UCLA score.

Modified UCLA score	N	%
5	5	22.73
6	7	31.82
7	10	45.45
Total	22	

Table 11: Mean modified UCLA score according to acetabular erosion grades.

Acetabular erosion grades	Modified UCLA score
Grade 0 and Grade 1	6.33± 0.83
Grade 2 and Grade 3	6.18 ± 0.82

P=0.71(not significant).

Table 12: Mean modified UCLA score according to age in decades.

Age in decades	N	Modified UCLA Score
60-69	9	6.44±0.73
70-79	11	6.18±0.87
80-89	1	6±0
90+	1	5±0

Table 8 and shows description about Mean acetabular erosion grades according to duration since surgery (in months). This is statistically significant with P-value (<0.001) Erosion increases as the duration increases.

DISCUSSION

Incidence of fracture neck of femur is increasing gradually, probably due to increase in life expectancy of individuals.[4] The ideal treatment is still controversial[5]. Two common procedures done for elderly people are hemiarthroplasty and total hip arthroplasty. Some people advocate primary total hip arthroplasty for neck of femur fracture in elderly. Total hip arthroplasty results in more functional activity level and lesser reoperative rates but has more morbidity.

Hemiarthroplasty is more economical especially in developing countries like India and has lesser morbidity, but has a higher reoperation rate when compared to total hip arthroplasty.

The long term complications of bipolar hemiarthroplasty are acetabular erosion, aseptic loosening and infection.[6] Bipolar prosthesis is thought to have lesser incidence of acetabular erosion than unipolar prosthesis due to reduced movement occurring at acetabular prosthesis interface.

In this study we have tried to assess the acetabular erosion by radiological grading and functional outcome by modified UCLA scoring after a minimum period of 2 years after hemiarthroplasty.

Total numbers of patients assessed in this study were 22 and all underwent cemented bipolar hemiarthroplasty. The mean period of follow up was 42 months (range 2 years - 7 years). Six patients (27.30%) had a moderate to severe acetabular erosion and sixteen patients (72.70%) had minimal or no erosion. The grade of erosion was found to increase with follow up interval. With the follow up period of less than 4 years (18 patients) 16 patients (88.9%) had nil or minimal erosion and 2 patients (11.1%) had moderate to severe erosion. With follow up period of more than 4 years 4 patients had moderate to severe erosion. The mean follow up period in our study was 3.54 years and the significant acetabular erosion noted was 27.3% this could be compared with the study of Mazen et al, they had 33% erosion grade at the follow up period of 3 years.[7]

In this study all the patient's functional activity level were assessed by modified UCLA score, the mean modified UCLA score was found to decrease with increase in the age of the patients. Due to small study group the correlation of the modified UCLA score anti acetabular erosion was not statistically significant. One patient who had the longest period of follow up and maximum grade of acetabular erosion had a good level of functional outcome with modified UCLA score of 7. The pain did not restrict her functional activity.

Philips, London in his study found that the factors that had highest correlation were the level of physical activity and duration of follow up.[8]

Moon et al also found in their study that the progression of acetabular erosion correlated directly with the duration of articulation of the prosthesis within the acetabulum and this degeneration of articular cartilage becomes the cause of migration of bipolar cup, which is the major cause of failure of cemented bipolar arthroplasty. They also found the cause of degeneration to be multifactorial and it is accurately difficult to distinguish and measure the contributory level of each factor. They also found that all acetabular cartilage will show degeneration approximately 7 to 8 years after surgery.[9]

In our study all the 4 patients who had a follow up of more than 7 years had significant acetabular erosion. Hence the choice of total hip arthroplasty or a hemiarthroplasty in a fracture neck of femur may be determined by the life expectancy and the activity of the patient.

CONCLUSION

By this study we suggest an easy and effective way of evaluating acetabular erosion and clinical activity. There is significant increase in acetabular erosion as the duration after surgery increases. The clinical activity is by and large not significantly altered as the erosion progress at mid-term follow up.

Limitations of the study

Small study group, short period of follow up.

Funding: No funding sources
Conflict of interest: None declared
Ethical approval: The study was approved by the institutional ethics committee

Issues in management of fractures complicated by compartment syndrome

Venkatesh Kumar N, Arvind Kumar SM, Vetri Ganapathi and Sairamakrishnan S

DOI: https://doi.org/10.22271/ortho.2017.v3.i4e.44

Abstract
Introduction: Compartment syndrome has been identified as an acute devastating orthopaedic emergency and early fasciotomy is the only way to prevent any complications This retrospective study proposes to analyse the issues in management of fractures complicated by compartment syndrome occurring pre-operatively and post-operatively.
Aim: To study the issues involved in the rationale for deciding the method of fracture stabilization following fasciotomy. To study the problems, complications and functional outcome of fracture stabilization. To analyze and establish methods to the optimally manage the issues involved.
Materials and Methods: A review of patients admitted in the orthopaedic department at our institution who presented with or developed compartment syndrome and associated with fractures were chosen. Passive stretch pain and serve pain out of proportion were the main clinical indicators considered. Decision to perform fasciotomy was carried out based on the differential P value and were treated with double incision fasciotomy Patients were followed up every month for the first 6 months and then every 6 months. All the patients, who were reviewed, were functionally assessed based on Upper Extremity Functional Index (UEFI) and Lower Extremity Functional Scale (LEFS).
Results: A high suspicion of compartment syndrome must be maintained for all cases. The early diagnosis and treatment within 12 hours is critical to reduce morbidity and prevent any long term sequale. Compartment syndrome causes delay in bone healing. Risk of infection is not increased.

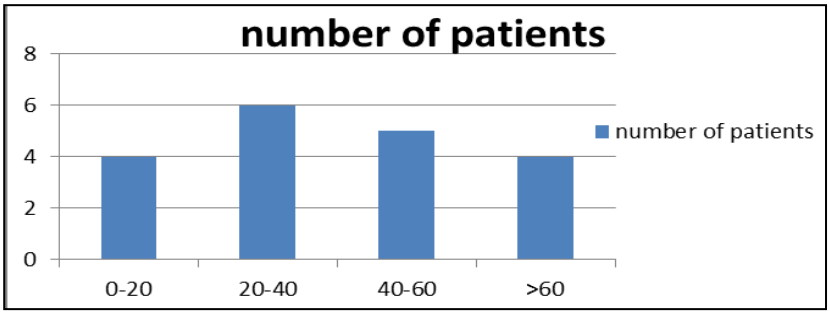
Keywords: compartment syndrome, fracture healing, faciotomy

Introduction
Compartment syndrome has been identified as an acute devastating orthopaedic emergency. Till date, compartment syndrome is one of the major complications in an injured limb. And early fasciotomy is the only way to prevent any complications due to compartment syndrome. Delay in diagnosis had been identified as the only cause of failure of treatment.
This retrospective study proposes to analyse the issues in management of fractures complicated by compartment syndrome occurring pre-operatively and post-operatively.

Aim and Objectives
Aim
To retrospectively study the issues in management of fractures complicated by compartment syndrome occurring pre-operatively and post-operatively.

Objectives
- To study the issues involved in the rationale for deciding the method of fracture stabilization following fasciotomy.
- To study the problems, complications and functional outcome of fracture stabilization.
- To analyze and establish methods to the optimally manage the issues involved.

Materials and Methods
- A review of patients admitted in the orthopaedic department at our institution was carried out. Patients who presented with or developed compartment syndrome and associated with



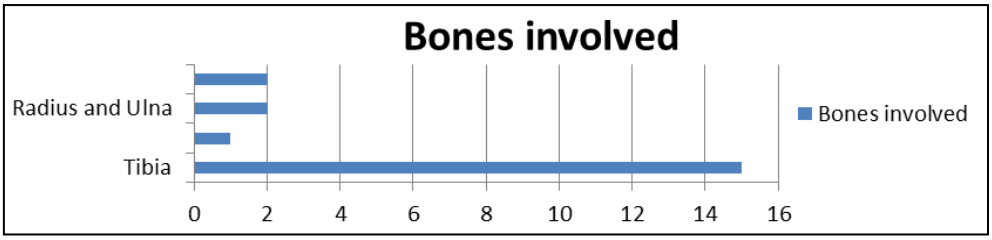
fractures were chosen.

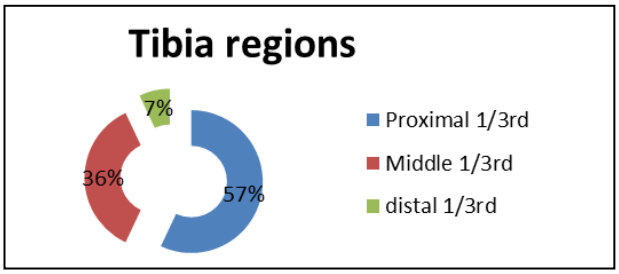
- Compartment syndrome was diagnosed clinically in all the cases, except one. Passive stretch pain and serve pain out of proportion were the main clinical indicators considered. Paraesthesia, paralysis and pulselesness were considered to be supportive of the diagnosis. Comportment pressure was measured in one patient who had a spinal injury. Decision to perform fasciotomy was carried out based on the differential p value. Differential P was calculated by the difference between the patients diastolic pressure and compartment pressure. Fasciotomy is indicated if the value was less than 30mm Hg[24].
- All the patients who had developed compartment syndrome of the leg were treated with double incision fasciotomy, anterolateral and posteromedial. Compartment syndrome of forearm was treated with single volar incision fasciotomy, while that of the thigh also was treated with a single lateral incision.
- The fracture were treated with external, internal or hybrid fixation.
- The fasciotomy wounds were taken up for secondary closure from 4-7 days after fasciotomy with split skin grafting.
- Patients were followed up every month for the first 6 months and then every 6 months. All the patients, who were reviewed, were functionally assessed based on Upper Extremity Functional Index (UEFI) and Lower Extremity Functional Scale (LEFS).
- Painless unprotected weight-bearing and presence of bridging callus on X-ray were together considered as signs of bony union.

Results

There were 21 patients who were diagnosed with compartment syndrome and underwent fasciotomy for the same. But compartment syndrome in 2 of the patients were not associated with fractures and hence excluded from the study.

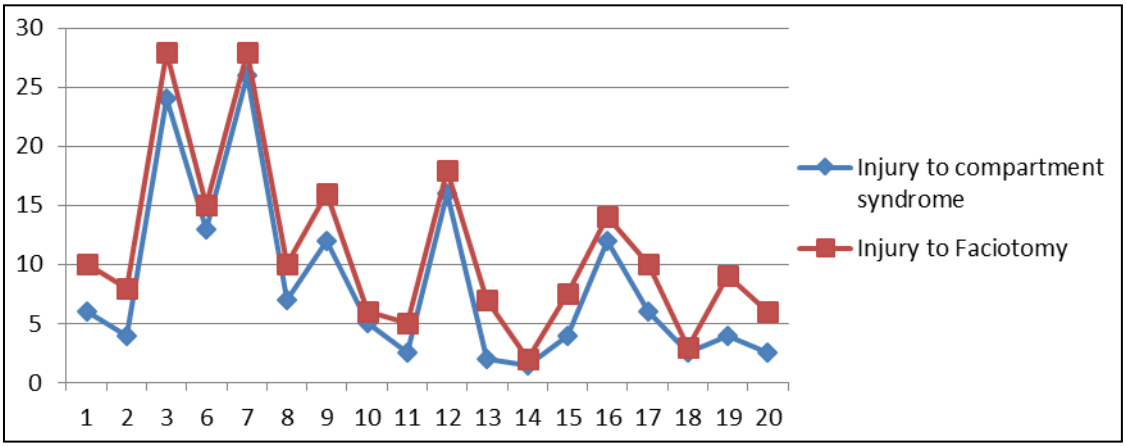
Incidence of compartment syndrome was found to be more common in physiologically young males, especially in the 3rd and 4th decades of life. This is probably due to the comparatively increased muscle mass in younger individuals.





Compartment syndrome is more frequently seen in fractures due to high velocity injuries, mainly in road traffic accidents. (Table 1)

Table 1



Mode of injury	No. of cases
Road Traffic Accident	16
Fall from height	2
Industrial injury	1
Trivial Fall	1

Fifteen of the fractures involved Tibia. Of the fifteen Tibia fractures, three involved the Tibial plateau and one involved a proximal Tibia epiphyseal injury and the rest involved tibioal diaphysis. Compartment syndrome frequently occurs in Tibia compared to all other sites. Occurance in Proximal one third Tibial is the commonest. (Graph 3, 4)

Of the remaining patients, one was a subtrochanteric fracture of the femur. The patient developed compartment syndrome of thigh probably as a consequence of the renal failure he was suffering from. Two were fractures of both bones forearm. One was a fracture around the elbow involving medial epicondyle and olecranon. One patient had additional injuries along with tibial fracture involving the ipsilateral femur and humerus and also compartment syndrome involving the forearm. One patient (Case 21) had sustained a D12 compression fracture with altered neurology of both lower limbs, along with a tibial plateau fracture (internally fixed in an institution outside). When he presented 10 days later, he had the altered neurology and also passive stretch pain with swelling of the affected leg.

The compartment syndromes were diagnosed by clinical monitoring. The delay in development of compartment syndrome following injury was 8.3 hours (1.5 hours to 26 hours, excluding case 21). The average delay in performing the fasciotomy after injury was 11.3 hours (2.5 hours to 28 hours).

There was delay in 2 of the cases (case 3 and 7) presenting to our institution as they received first aid in an outside institution primarily. Case 21, a 10 day old missed post-operative compartment syndrome, was not considered in the time of delay, because it was a case of established and missed compartment syndrome, on presentation from a different hospital. The patient's intra-compartmental pressure of all the compartments of the leg was measured using an electric arterial pressure monitor by an infusion technique. The differential P of the involved leg was found to be 10mm Hg, indicating the need for fasciotomy. Differential P of the other leg was found to be 40mm Hg.

All patients were clinically monitored for compartment syndrome from time of presentation, and also post-operatively. During the study, two distinct groups of patients were identified.

1. Patients who presented with compartment syndrome following a fracture.
2. Patients who developed compartment syndrome after surgical fixation of a fracture (cases 1, 2, 6, 8, 9 and 14)

Table 2: Grouping of patients with compartment syndrome

Compartment Syndrome Following	No. of Patients
Fracture	12
Surgical fixation of fracture (s0	6

Of the 12 patients who developed compartment syndrome after a fracture, 7 cases which were monitored from admission developed compartment syndrome. And they were taken up for fasciotomy with appropriate fixation.

Of the 18 cases considered, 6 of the fractures (cases 1, 2, 6, 8, 9 and 14), 5 tibial diaphyseal fractures and 1 ulna fracture, treated with intramedullary nailing developed compartment syndrome post-operatively. Pre-operatively, four of the fracture limbs were found to be edematous. All the 6 cases were diagnosed with compartment syndrome post-operatively after intramedullary nailing. The delay in establishing the diagnosis of compartment syndrome following intramedullary nailing was 8.5 hours (4 hours to 13.5 hours), caused probably by reduction of the fracture prior to intramedullary fixation. And the average delay in fasciotomy after intramedullary nailing was 11.8 hours (8hours to 16 hours).

Of the fifteen Tibial fractures, 6 were treated with intramedullary nailing (One-Unreamed nail), 4 were treated with Hybrid fixation, 3 were treated with external fixation and the Proximal Tibia epiphyseal injury (case 20) was treated with cancellous screw fixation. One patient with tibial plateau fracture was treated with hybrid fixator primarily. (case 17) the external fixation was converted to internal fixation primarily. (case 17) the external fixation was converted to internal fixation by means of intramedullary nailing after 3 weeks. One patient underwent internal fixation for tibial plateau fracture in an institution elsewhere before presenting to us. The subtrochanteric fracture was treated with Dynamic condylar screw and one of the forearm fractures was treated with K-wire fixation while the other was treated with Ulna square nail. And the elbow fracture was treated with internal fixation. The time lag in diagnosis, delay in fasciotomy and method of fixation of each case has been detailed in the master chart.

Except one, none of the cases had incidence infections or non-union. The patient who developed infection was a case of missed compartment syndrome.

All the patients were reviewed with an average follow-up of 33 months (6 months to 60 months). 2 patients (case 3 and 6) died due to unrelated causes. One patient (case 21) died due to sepsis leading to multi organ failure secondary to a 10 day old missed compartment syndrome.

The average time of healing in upper limb fractures was 11 weeks (9 to 15 weeks) and in lower limb fractures was 17 weeks (12 to 24 weeks). In two tibial fractures, the delay in healing needed bone grafting. Healing was relatively delayed in patients who had undergone fasciotomy 10 hours after the injury or internal fixation compared to those who had gone fasciotomy in less than 10 hours, in case of both upper and lower limb fractures.

3 patients (Case 1, 9 and 16) had neurological insult secondary to acute compartment syndrome. One patient (case 1) had weakness (Power 1/5) of the anterior compartment muscles of the leg at the time of diagnosis of compartment syndrome. He went on to recover partially (Power3/5) over a period of 3 months and then no further. Another patient had weakness (Power 3/5) of extensor hallucis longus at time of diagnosis of compartment syndrome and went on to recover in 3 weeks. One other patient (case 16) had developed severe volksmann ischemic contracture of the forearm due to delay in presentation to the hospital and hence delay in presentation to the hospital and hence delay in fasciotomy. The average in fasciotomy following injury in these cases was 13 hours (10 hours to 16 hours). Though the risk of infection is high, except one, none of our cases had any infection. Severe and extensive muscle necrosis of most of the muscles of the leg was found during fasciotomy of one of the patients (case 21), which ultimately led to sepsis and above knee amputation of the limb.

Two of the cases (case 7 and 9) had no signs of union at the end of 12 weeks both clinically and radiographically. The patients required bone grafting as a secondary procedure at 3 months to induce bony healing. The patient with volksmann ischemic contracture lost functionally of the upper limb, from elbow distally.

The functional outcome is decreased in patients who had undergone fasciotomy after 10 hours. However, younger patients showed better recovery even if they had undergone fasciotomy after 10 hours, compared to older patients.

Table 3

Patient Groups	Average functional outcome
Compartment syndrome after a fracture	85%
Compartment syndrome after fracture fixation	86%

The average functional outcome score of the cases, excluding those lost to follow-up is 68 and percentage of maximal function is 85%. The decrease in functional is 85%. The decrease in functional outcome score was due to the dysfunctional status of the affected limb in case 16. The percentage of maximal function increased to 91% on excluding case 16. The average percentage of maximal function of cases with post-operative compartment syndrome (cases 1, 2, 8, 9) was 86%, ompared to the 85% in cases primarily diagnosed with compartment syndrome (93% on excluding case 16). Mo significant difference was found in the functional outcome of both the group of patients.

Discussion

Compartment syndrome has been extensively studied. But difficulty and delay in diagnosis of the condition is the major problem encountered. The management of fractures associated with compartment syndrome also does not have fixed guidelines.

The study analysis nearly all the issues involved in management of the compartment syndrome and the associated fractures.

The study shows that compartment syndrome commonly occurred in physiologically young males, similar to all other studies [1, 21, 25, 37]. And high velocity injuries were also identified as the major cause of compartment syndrome as in most studies [1, 21, 25, 37]. Compartment syndrome of leg was the most common followed by that of forearm. And tibial fractures were the major cause of compartment syndrome of leg. McQueen et al showed that 36% of compartment syndromes follow tibial diaphyseal fractures.[22] Of all tibial fractures, proximal tibial fractures were most commonly involved. The higher incidence of compartment syndrome in proximal tibial fractures has been attributed to the vulnerable blood supply of the popliteal artery and the posterior tibial artery, due to the vessel bifurcation and enclosing tight osse of ascial canal.

Six of our cases developed compartment syndrome after the associated fracture was treated by surgical stabilization. McQueen et al found an incidence of 5.5% compartment syndrome in fractures treated by reamed nailing compared with 12.2 % in externally fixed fractures [22] The cause of compartment syndrome in post –operative cases has been postulated to be sudden decrease in compartment size following reduction of the fracture prior to intramedullary fixation

All diagnosis of compartment syndrome were made clinically. One patient was diagnosed with compartment syndrome 10 days after internal fixation of a tibial plateau fracture. The compartment syndrome was missed due to the spinal injury sustained by the patient and altered neurology below the thoracic level. All patients with tibial and forearm fractures were monitored clinically, for stretch pain and out of proportion pain, preoperatively from admission and also postoperatively.

Cases at risk of developing compartment syndrome were identified and monitored. Measure of intra-compartmental pressure was done only for patients under nerve blocks, with altered state of consciousness, with spinal cord injury and children who are not able to express themselves. In other patients, intra – compartmental pressure was measured only when clinical signs are inconclusive and to determine the need for fasciotomy. McQueen emphasized in numerous studies that diagnosis of compartment syndrome can be made only by continuous monitoring of the intra –compartmental pressure [4, 21, 22, 23, 24]. Continuous intra-compartmental monitoring is preferred to a single reading. However, Twaddle and Amendola stressed that continuous monitoring of all patients due to the need for equipment and manpower. They advised clinical monitoring to diagnose compartment syndrome and to measure intra compartmental pressure in a specified group of patients as mentioned above. And they observe that the judicious use of monitoring is required to prevent over diagnosing compartment syndrome.

Turen proposed that skeletal stabilization of fractures was needed immediately after fasciotomy to aid in the healing of soft tissues which was also concurred by Twassle and Amandola [36, 37]. Georgidas and Hake et al observed that closed fractures and uncontaminated open fractures, presenting with compartment syndrome, can be treated with primary internal fixation following fasciotomy, as there are low or negligible risks of infection and non-union.[9, 11] And this treatment protocol simplifies the bony and soft tissues cover must be obtained to cover the implant and fracture site.

Twaddle and Amendola observed that the stabilization technique used depends on the location and character of the fracture and the skill of the surgeon, but should minimize operative trauma to a limb that may already have had its

circulation compromised. Therefore, if possible, intramedullary nailing to stabilize the bone (and hence the soft tissues) is recommended. After the osteosynthesis has been completed, soft tissues coverage over the bone should be attempted [37].

All the fractures in our study were stabilized after fasciotomy by external fixation or internal fixation. Following fasciotomy, the fracture was considered to be an open one.

In metaphyseal and metaphyseal–diaphyseal fractures, we used external fixation as the method of choice for primary stabilization, We used external fixation for primary method of stabilization in 9 of the 15 tibial fractures. For juxta–articular fractures, we used external fixators or hybrid fixators. Hybrid fixators with inter fragmentary screw fixation were used in 4 cases of which 2 were tibial plateau fractures. The integrity of the articular surface was maintained by means of the hybrid fixators. The advantages of external fixation are the safety and ease of application, less devitalization of soft tissues and decreased operating time. Difficulties were faced early mobilization of the patient and wound care.

Of the 6 tibial diaphyseal fractures, 5 were treated primarily by means of external fixation. External fixation was used in diaphyseal fractures, when there was delay in fasciotomy and the viability of the muscles were in doubt and in cases without adequate soft tissues cover following fasciotomy. One of the cases treated with external fixator was taken up for intramedullary nailing at the earliest. The intramedullary conversion increased patient compliance. One tibial diaphyseal fracture was primarily treated with unreamed intramedullary nailing. Wound management was found to be easier after the internal fixation and the patient was also mobilizes early. Early mobilization, easy accessibility to the fasciotomy wounds for wound care, considerable decrease in the bulk of the implant and patient compliance are the advantage of intramedullary internal fixation.

Plate osteosynthesis was never considered in any of the tibial fractures, as the risk of devitalizing the already compromised soft tissues and infection were high.

Bony healing was delayed in all cases irrespective of method of stabilization. Time of bony healing did not differ much from that of post-operative compartment syndromes. In both the groups of patients, those who presented with compartment syndrome following an injury and those who developed compartment syndrome after internal fixation, the fracture was considered to be open. Both the groups had delayed bone healing. The average time of bone healing was nearly the same in bothgroups. And the functional outcome of both the groups of patients was nearly the same. Acute complications encountered in our study were neurological insult in three of the patients who underwent delayed fasciotomy of the three, one patient recovered completely, another patient had incomplete recovery, while the third patient had no neurological recovery. Incomplete recovery or total absence of recovery is due to the development of myonecrosis during the compartment syndrome and consecutive fibrosis of the muscles [27, 29].

Delay in diagnosis is primarily due to the delay in presentation to our centre.

Infection of the fasciotomy wounds and fracture site are expected. Fracture site is exposed during fasciotomy and the fasciotomy wound is left open for secondary closure increasing thechaces of infection. In our study, none of the cases developed infection at the fracture site of fasciotomy wound.

All the cases in our study, including the cases that developed compartment syndrome post-operatively, had delayed bone healing. This is probably due to loss of fracture haematoma during fasciotomies. But bone healing was further delayed I patients who underwent fasciotomy after 10 hours compared to those who underwent fasciotomy earlier. Similar results were also observed by Mullet [27]. Court-Brown and McQueen found that complication rates decreased to 4 % from 54 % with early fasciotomy [4].

Functional outcome was decreased I our patients who had undergone fasciotomy after 1 hours. Younger patients showed better functionality. The functional outcome of patients who had post-operative compartment syndrome was no different from those who had presented with compartment syndrome. The functional outcome of any case is determined mainly by the delay in fasciotomy followed by age than any other factor. Mullet et al found that younger patients had better functional outcome. This was attributed due to change in the muscle fiber composition and decreased muscle regeneration due to age [27].

Shortcomings of the study are the limited of number patients, the absence of a control group and also the analysis being done retrospectively. The chance of developing compartment syndrome has decreased considerably due to the early intervention following injury and advancement in monitoring patients early. In spite of these limitations zX, the factors influencing the outcome of the fractures associated with compartment syndrome were identified.

Orthopaedic surgeons must remain vigilant to identify compartment syndromes, both in in- patient and out- patient settings. Future development is likely to center around non-invasive methods of diagnosing acute compartment syndrome is being examined, like near infrared spectroscopy, which measures the amount of oxygenated hemoglobin in muscle tissues transcutaneously.

Conclusion

- A high suspicion of compartment syndrome must be maintained for all cases.
- The early diagnosis and treatment within 12 hours is critical to reduce morbidity and prevent any long term sequale.
- Compartment syndrome causes delay in bone healing.
- Risk of infection is not increased.
- External fixation is the method of choice in metaphyseal and metaphyseal-diaphyseal fractures and fractures without adequate soft tissue cover, when associated with compartment syndrome.
- Hybrid fixators with intra fragmentary screw fixation are used in juxta-articular fractures with communition.
- As bony healing is not compromised in any way, use of intramedulluary fixation is not contraindicated in diaphyseal fractures associated with compartment syndrome.

□□□r□d□□□□□□□□

Fracture neck of femur has been recognised since the time of Hippocrates and is a common orthopaedic problem in old age and they have a tremendous impact on both the health care system and society in general [1]. Despite marked improvements in the implant design, surgical technique and patient care, they still remain an unsolved fracture as for as treatment and results are concerned among the orthopaedic fraternity around the world [2]. Fractures of the neck of femur are on increase, which is not unexpected, as the general life expectancy has significantly increased during the few decades. These fractures may double within next 20 years and fracture rate doubles for each decade of life after 5th decade of life [□]. It's has been predicted that by the year of 2050, the number of hip fractures would triple.
This is the commonest fracture in old aged individuals because of osteoporosis and advancing age causing more brittleness of bone. So prolonged immobilization during such fractures in elderly will jeopardise the life span of the patient and further complicates the problem. This forces one to totally abandon complete immobilisation to achieve a bony union, or to resort early ambulatory procedures by surgery.
The blood supply to neck and head of femur is extensive, intricate and complicated. Healing process mainly depends on good blood supply. Non-union, avascular necrosis of femoral head and secondary degenerative arthritis are the principal complications of this fracture. The surgeon may have control over the problem of non-union, whereas he may have none over avascular necrosis and arthritis. This further handicaps the treatment of these fractures as the healing process is always in doubt. It's also a known fact that hip is a weight bearing joint and many performance based functions depend on hip joint. A successful operation at hip joint should provide painless, stable hip with wide range of movements.

Under these circumstances one has to decide whether the prolonged immobilization has to be employed to achieve bony union or quick ambulation by hemi-replacement arthroplasty, to achieve fair degree of function. Since early 1950's prosthetic replacement was introduced for solving the problems of Fracture neck of femur and vitallium intramedullary prosthesis received a hearty welcome, thus preventing Non-union and avascular necrosis. The Austin – Moore and Thompson prostheses have been successful implants in treating fracture neck of femur. Disabling pain and acetabular erosions are frequent complications after the use of Moore prosthesis [□]. So in an attempt to retard the acetabular wear, prolong the life of the implant and delay the need for revision surgery the bipolar prosthesis was developed by James E Bateman in Toronto in 1974, which had the great advantage of second joint, below the acetabulum. It was named bipolar prosthesis, since it had an outer head of metal which articulates with acetabulum and a second inner metallic head which articulates with High Density Poly-Ethylene (HDPE), lining the inner surface of outer head. So hip motion is to occur at 2 interfaces – primarily at the prosthetic interface and secondarily at the metal – cartilage interface, thus minimising the articular wear. This prosthesis was found to be very useful and results were encouraging [□].

But studies attempting to demonstrate the relative movements at the interfaces have yielded conflicting results. It's known that a friction produces particulate debris from the polyethylene liner and this was thought to be the cause of foreign body reaction causing stiffening up of the inter-prosthetic joint and also osteolysis and aseptic loosening of the implant. Recent studies have shown that over a variable period of time the bipolar prosthesis will become unipolar functionally due to stiffening up of the inter-prosthetic joint (IPJ).

This study represents the assessment of the inter-prosthetic joint movement in bipolar prosthesis done for fracture neck of femur at 6months and mid-term follow-up by radiological means. By this study we will be able to assess whether bipolar prosthesis really functions as it's name suggests or vice versa as the literature suggests.

M □□r □□□□□d M □□d □

□□r □□□d □□

Consist of 2 parts. Part I is a (prospective study) in which Patient's who undergone Bipolar hemiarthroplasty for fracture neck of femur at PSG Hospitals were included in the study after obtaining their consent during the period of December 2011 to June 2013.

Part II was a retrospective study where we took a data of patients who were operated earlier in our institute and had completed atleast 2 years of follow-up.

M □□d □□d □□□ □□□□□

By Convenient sampling method, the patients undergoing bipolar hemiarthroplasty for fracture neck of femur were assessed radiologically for amount of inter-prosthetic joint motion during post-opeartive period.□

□

□□ □□□□□d

- For all patients Life ortho care bipolar prosthesis was used (ISO – 13485 certified company). Implant made of 316 – Stainless steel. Femoral stem length is 150 mm, diameter – 8 mm. Outer head diameter varies from 37 to 53 mm with 2 mm increment. Inner prosthetic femoral head diameter was 26 mm and the lining between outer head and inner head is made of UHMWPE (Ultra High molecular Weight Polyethtylene). Neck shaft angle is 130 degrees. 2 types of prosthesis are available (Fixed only with collar, Modular with or without collar and Extra – long stem also available).
- No funding was received from the Implant Company for the purpose of this study.

□

□r □□□□□□□□□d □□

□r □□□□r □□□□□ □□□□□ □□□

All patients who are undergoing bipolar hemiarthroplasty□for fracture neck of femur are considered for the study after getting a written consent from them. All Patients were adequately worked up before surgery and all patients were taken up for surgery within 72 hours. Certain therapeutic measures such as Deep breathing exercises, Static Quadriceps exercises, ankle pumps were taught to the patient pre-operatively. A detailed history about the mode of injury and type of fracture were noted.

□

□□r □□□□□r □□d □r □□

All surgeries were performed on an elective basis using standard□aseptic precautions, Surgery was performed under spinal or general anaesthesia. Patient was positioned laterally lying on the unaffected side. For all the patient's lateral approach (Hardinge approach) was used in our series.

□

□□□□□□□r □□□□□r □□□□□

Throughout the post-operative period adequate care was taken□ to prevent abduction and external rotation of the limb. All patients received Quads strengthening X's and mechanical DVT prophylaxis during immediate post-operative period. All patient's were started on Full weight bearing ambulation as tolerated by the patient. Once initial pain subsided specific X-rays were done to assess the inter-prosthetic joint (IPJ) and outer bearing movement was assessed during immediate post-op (24 to 48 hours) , at 6 weeks and after 6 months with operated hip in neutral and maximum abducted positions.

□

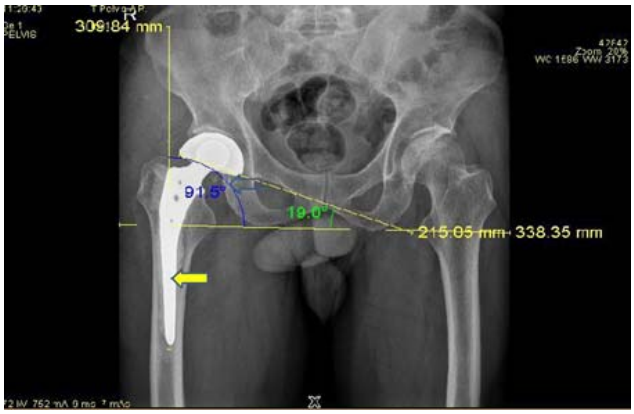
□r □□□□ □□□□□□□:

Two A.P x-rays of pelvis were taken. One with limbs in neutral position and neutral rotation and the other x-ray with affected limb in Maximum abduction are taken.

□

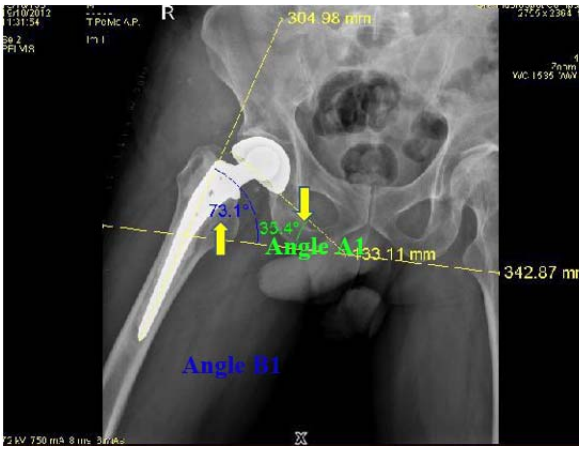
□d □□□□□□□□□□ □□□□□□ □□□

We followed the method of p lain radiographs, as described by Bochner *et al*.



On the X-ray in the neutral position, 3 lines are drawn as follows:

□□□□**1** □a line drawn tangential to the most inferior aspects of the ischial tuberosities which is used as a reference line.



□□□□**2** □drawn along the the inferior margin of the acetabulum

□□□□□□Drawn along the centre of the long axis of femoral stem.

- Angle A was defined as the intersection of the line drawn from the inferior margin of acetabular component and the reference line (line of ischial tuberosities).
- Angle B was formed by the intersection of the ischial reference line with a line drawn along the center of the long axis of the femoral stem.
- The same exercise was repeated on the maximum abduction anteroposterior radiograph also and the angles are marked as A^1 and B^1.

□□□□□□Operated Limb in Maximum Abduction

- Now, B^2 is the difference between angle B and B^1 which represents the total amount of Hip abduction of the operated limb.
- A^2 is the difference between angle A and A^1 which represents the amount of motion taking place between the acetabular component and the acetabulum (Outer bearing interface).
- As we have 2 variables ie. (B2 – total amount of abduction, A2 – motion at the outer bearing interface), the difference between B^2 and A^2 represents the amount of abduction taking place at the inner bearing (Inter-Prosthetic joint movement).
- Thus the total amount of abduction, movement at outer bearing interface and movement at inter-prosthetic joint were calculated and tabulated for each patient at each follow-up.

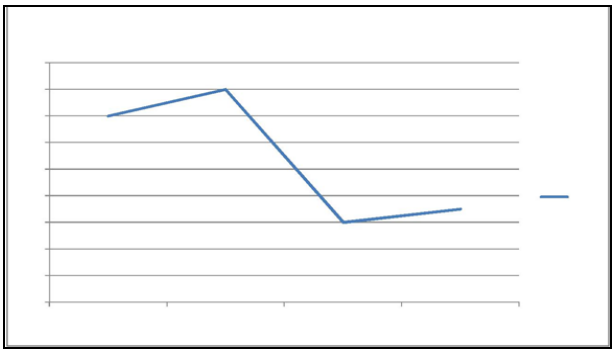
X-ray of pelvis with both hips (Abduction of operated hip) with bipolar prosthesis on right side showing Angle A1 – 43.3 and Angle B1 – 74.4 degrees.
A = 45.1, B = 83.4, A1 = 43.3, B1 = 74.4 (Degrees)
B2= 9 Degrees (Total Abduction)
A2 = 1.8degrees (Motion @ Outer Cup)
B2-A2 = 7.2 Degrees (Inter-Prosthetic Joint Motion)
A2 = 20% (Motion @ Outer Cup)
B2 - A2 = 80% (Inter-Prosthetic Joint Motion).
At the end of 6 months follow-up, in addition to Radiological assessment Functional outcome was also assessed with Oxford hip score.
Part – 2 (Retrospective study):
Patients in this group who had already undergone Bipolar H.A and completed 2 years follow-up were reviewed. The x-rays were taken in the similar fashion as described above. Functional outcome assessment was done using Oxford hip score. The retrospective study helped us to assess IPJ motion at midterm follow-up.

□

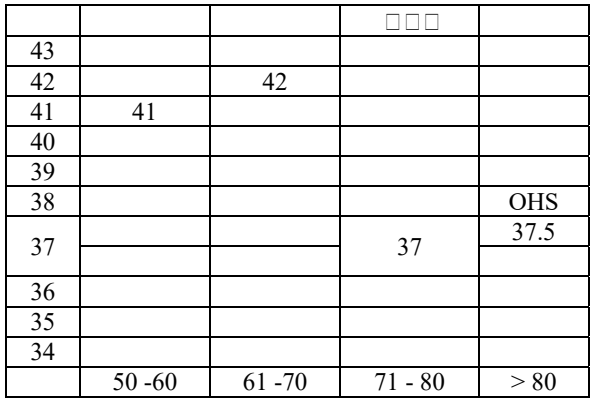
□ □□□**rd**□□ □□□□□□□**r**□□□□ □ □□

- It's useful to assess the outcome after surgical procedures by measuring 'patients' perceptions in adjunction to surgery. OHS assesses pain (6 items) and function (6 items) of the hip in relation to daily activities such as walking, dressing, sleeping etc.12 items with 5 categories of responses. Scores range from 0 to 4 (worst to best).
- Grading :
- 0-19 □ Worst, May indicate severe hip arthritis, requires some form of surgical intervention.
- 20-29 □ Fair, May indicate moderate to severe hip arthritis. Assessment by X-ray
- 30- 39 □ Good, May indicate mild to moderate hip arthritis. Non-surgical treatment, such as exercise, weight loss, and /or anti-inflammatory medication.
- 40-48 Excellent, May indicate satisfactory joint function. May not require any formal treatment.

Table 1: Radiologically Assessed Total Abduction, Outer Cup Motion And Inter – Prosthetic Joint Motion



Follow up	Patient's	Mean B^2 (in degrees)	Mean A^2 (in degrees)	Mean $B^2 - A^2$ (in degrees)	Mean A^2 (in%)	Mean $B^2 - A^2$ (in%)
Immediate						
Post-op	30	18	8	10	45	55
6 weeks	28	23	13	10	57	43
6 months	30	25	18	7	72	28



B^2 – represents Amount of Total abduction, A^2 – represents amount of movement between the outer cup and the acetabulum, $B^2 - A^2$ represents amount of IPJ motion.

Table 2: [illegible]

[illegible]	[illegible]	Mean [illegible]	[illegible]	Mean [illegible]	Mean [illegible]

□ □□□□□□□□□□□□

The basic advantage of the Bipolar prosthesis over conventional unipolar prosthesis is movement at the two interfaces ie. Between the prosthetic inner femoral head and polyethylene liner and between acetabulum and the outer head. It was proposed that the complications like acetabular erosions would be delayed or prevented by reducing wear due to sliding motion in the acetabular socket. The high molecular weight polyethylene (HMWPE) articulation also absorbs some of the impact forces during gait. This advantage of Bipolar over unipolar prosthesis has been accepted by many studies□but there have been some reports in the literature that cast doubt on the continuity of inter-prosthetic movement in a bipolar prosthesis over time. Various radiographic studies have been done in which the prosthesis was imaged in various non-weight-bearing and static weight-bearing positions to estimate the fraction of movement that is occurring at the inter-prosthetic joint in a bipolar prosthesis. Phillips[6]□ used radiograph in supine position, first in neutral and then in maximum abduction and adduction.

Verberne used image intensifier to do radiological examination. In this context we undertook the present study of evaluating the IPJ motion radiologically over a period of time at 6 months and at the end of 2 years. We had also tried to co-relate the amount of IPJ movement to Functional outcome to assess whether there's any improvement in the quality of life in patient's with good IPJ motion. We followed the method of plain radiographs, as described by Bochner *et al*. In our series the amount of IPJ movement was 55% during immediate post-op, 43% during 6weeks & 28% at the end of 6 months. The mean Inter – prosthetic joint movement at end of 2 years follow – up was 31% for patients in the retrospective group. So at the end of 6 months 66% of the patients had > 25% of Inter prosthetic joint movement in our prospective study and 80% had > 25% in the retrospective study. However we are not analyzing the same group of patients in the prospective and retrospective study & the sample size of retrospective study is small. This could have probably resulted in higher inter – prosthetic joint movement at the end of 2 years. Drinker and Murray reported that although some inner motion occurred in most implants, it was less than predicted. Philips TW (1987) had done a study on Fluroscopic movement in 100 patients who had undergone Bateman Bipolar arthroplasty. Out of these 100 patients Group I had 76 patients with arthritis of hip and Group II had 24 patients with neck of femur fractures. In 80% of group I patients, the prosthesis retained Bipolar function at the end of 4 years follow-up study as compared to only 25% of group II patients retained the bipolar functioning of the prosthesis□

Verbene G.H.M (1983), did a radiological study of movements of two components in Variokopf prosthesis in 20 patients with fracture neck of femur during Immediate, 1 month and 3 months post-operative period. He observed that the IPJ lost mobility and at 3 months it became almost completely stiff with inter-prosthetic joint motion of only 16.9% being retained.

Bochner RM, in a study 26 patients with Bateman's Prosthesis who were assessed radiologically for inter-prosthetic joint motion, concluded that bipolar function was retained at the end of 4 years and the motion was shared between both the joint interfaces [□]. In their study the inter-prosthetic joint motion at 6 months was 19%. In a study conducted Anil kumar rai, from Banaras hindu university, varanasi, india during the period march 2003 to january 2011 treated with BHU bicentric bipolar prosthesis, showed that in cases of fracture neck of femur, the percentage of total abduction occurring at the interprosthetic joint at 3 months was 33.74% (mean value of all the patients), which fell to 25.66% at 1.5 years and remained stationary till 6 years. So they concluded that some amount of IPJ motion is still preserved at the time of their mid-term follow-up of 6 years. Higher Inter-prosthetic joint motion was observed in the arthritic group as compared to fracture group. This could be explained possibly due to friction phenomenon.

The results of our study regarding the Inter – prosthetic joint movement was comaparable to other studies in literature. Verbene *et al*. showed only 16.9% inter-prosthetic Joint movement at the end of 3 months in 20 patients & Bochner *et al*. showed 19% movement at the end of 6 months in 18 patients. Our study had better inter-prosthetic joint movement of 28% at end 6 months. This result probably could have been due to lower sample size of the above 2 studies.

□

□□□□r □□□□□□□□□□□□□□□□□□□r □□□r □□□□□□□□□□□□□□ □□□□ □□□

1. Condition of the Acetabulum: In patients with normal articular cartilage of acetabulum, the outer cup probably slides more when compared patients with arthritis. This can probably due to friction at which the primary movement occurs in IPJ. Only at the terminal range of movements prosthetic femoral head impinges on the neck leading to movement of the outer cup.
2. The Inner femoral head size used by Verbene *et al* was 32 mm which could have probably decreased the IPJ motion, when compared to Bochner and Philips *et al* where they used 22 mm inner femoral head. In the study done by Philips TW they had suggested that lower the femoral prosthetic head size, then lower will be the friction between the Polyethylene liner & femoral head & decreased stress on outer metal cup, which will result in lower acetabular erosions.
3. In previous studies they had used prosthesis with High density polyethylene which is prone for formation of wear debris over time, which could have possibly played a role in decreasing the IPJ motion. The wear debris formed from UHMWPE is much lower than the HDPE used in those days which could have contributed to better IPJ movement.
4. Since in our study we had used Bipolar prosthesis consisting of UHMWPE liner & optimum size prosthetic Femoral Head, our patients had better inter-prosthetic joint movement when compared with Verberne *et al*. & Bochner *et al*. we also assessed the age of the patient co – relating with Inter –prosthetic joint movement, but we did not find any statistical signifance.

□□□□□□□ □□□□□□□□□□□□□□□□□ □□□□□ □□□ □□□□□□□ □□□**rd** □□ □□□ □□□**r** □□□□**d** □□□□□□□ □□□ □□□□□□□□□□□ □□□□□□□**M** □□□□□

Various criteria were used to assess the functional results following bipolar hemiarthroplasty. How best the patient is returned to the pre-fracture status has been the main criteria. In India our customs demand Squatting and sitting cross leged without difficulty. To achieve this patient should have good range of flexion, abduction, adduction and external roation at the hip and full flexion at the knee. Our final results at 6 months after bipolar hemiarthroplasty in our series were analyzed using Oxford Hip Score. The results were compared with the available western and Indian series where bipolar hemiarthroplasty was done for neck of femur patients.

Mukeherjee and Puri (1986)	55	29	49	18	4
Bavadekar and Manelkar (1987)	328	60		30	10
Arvade (1987)	104	70		16	14
Our series (2012 -13)	40	56	32	10	2

His table depicts the percentage of functional results following bipolar arthroplasty done for fracture neck of femur.

The difference between excellent and good results are minimal and therefore they can be gropued together as satisfactory results. In the series above Hinchey had 72.8%, Saxena [76]90.9%, Mukerjee and Puri 78%, Bavedekar 60% satisfactory results were achieved. In out series satisfactory results were achieved in 88% of our cases. Only 2% of the patients had poor results due to moderate /marked pain.

We found that there was no stastistical significance in between the age, sex Vs OHS. However we were able to analyse the relation between the IPJ motion and OHS. We found that there was significant increase in OHS in patients with IPJ motion of more than 25%. So we conclude that more the amount of IPJ motion preserved better will be the functional outcome in patients with bipolar arthroplasty done for femoral neck fractures

□

□

□□□□□□□□□

With this study we found that for effective functioning of bipolar prosthesis IPJ movement remains a vital cog in the success of the bipolar prosthesis. In this study we conclude that: There is good amount Inter-prosthetic joint movement of Bipolar prosthesis at short – term and mid - term follow-up. The functional outcome is also good when Inter-prosthetic joint movement is more than 25%.

□□□ □□□□□□□□□□□□□□□□□□□□**d**□

- In this study the patients in the prospective and retrospective are not the same. And hence the results show a trend rather than being specific.
- Sample size is small
- Long term studies are required

ABSTRACT

Background: The morphology of the proximal femur is a topic of extensive research. The hip joint is one of the most commonly replaced joint. The era of replacement has given rise to various implants that can be used to replace the proximal femur. This present study addresses these issues involving ethnic differences in the geometry of the proximal femur in Indians and its differences between people of various ethnicity.
Methods: The total population that was radiographed was 178 (n=178). There were 78 males and 100 females. The age of the participants were spaced from 25-75 years age groups. The parameters were measured.
Results: The canal flare index in South-Indians was an average of 3.23 with 70% of the study population having normal CFI (3-4.5), 30% of the population having a stove pipe configuration CFI (<3). Majority of the Indian population favour a un-cemented fixation (70%).
Conclusions: In summary all current implants have to be revised on population basis to fit the changing anthropometry of our proximal femur.

Keywords: Femur canal, South Indian population, Canal flare index

INTRODUCTION

The morphology of the proximal femur is a topic of extensive research. The hip joint is one of the most commonly replaced joint. The era of replacement has given rise to various implants that can be used to replace the proximal femur. The integral part of any replacement is to reproduce the biomechanics of the original joint in the prosthetic components in order to achieve good clinical outcome both in terms of patient and implant. Many of the conventional implant systems manufactured by various conglomerate companies are made in correlation with the sizes of the femora of Europeans.[1] The use of these implants in the Indian population, owing to its small size of the femur has been plagued with numerous complications like intra-op splintering of the proximal end of femur. It is also the bane of the Asian-Indian Orthopaedic surgeons to work with such ill-fitting implants.

Most implant systems are usually designed on the basis of European femora, which are believed to be larger than Asian population. The implantation of these prosthesis often results in problems like fractures of the proximal femur or less confirming prosthesis leading to loosening.[2]

This present study addresses these issues involving ethnic differences in the geometry of the proximal femur in Indians and its differences between people of various ethnicity. It also evaluates the adequacy of fit of the conventional femoral stems in Indian population.

The aim and objective of the study was to determine the proximal femur morphology in South Indian population determined with radiographs and from cadaveric dry bones and to determine the differences between anthropometry of South Indian population and other ethnic groups.

METHODS

This is a prospective study consisting of two fundamental parts, involved in assessing the anthropometric dimensions of the proximal femur. In the first part of the study we have evaluated anthropometry of 178 volunteers radiographically. The second part of the assessment was done with cadaveric femora obtained from the Department of Anatomy, PSGIMSR. 50 cadaveric dry femora were obtained and direct measurement of measurable anthropometric data was done. The study was conducted in PSGIMSR Coimbatore, Tamil nadu, India from August 2013 to August 2014.

Inclusion criteria were South Indian population and people of age 25 years and above. Exclusion criteria were no prior pathology in the femur- infection (old/healed/active), congenital anomalies, contractures and deformities around the hip, previous hip surgeries and open epiphysis.

Parameters templated

- Femoral head diameter
- Horizontal offset
- Neck shaft angle
- Endosteal diameter at a level 20 mm above lesser trochanter (D)
- Endosteal diameter at the summit of the lesser trochanter (E)
- Endosteal diameter at a level 20 mm below the lesser trochanter (F)
- Endosteal diameter at the level of the Isthumus (G-10 cm below lesser trochanter)
- Canal flare index.

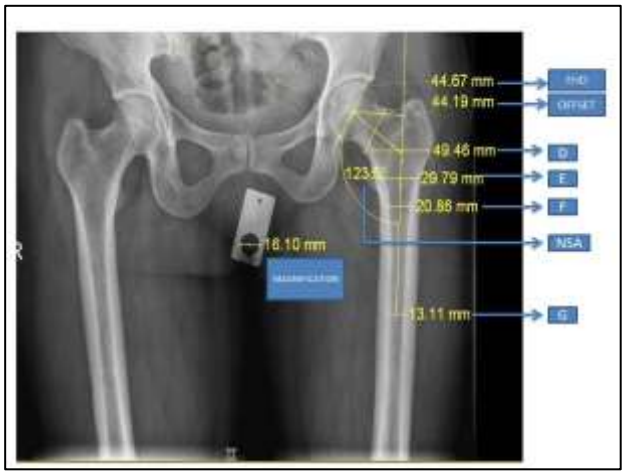

Figure 1: Radiograph templating.

Methodology of templating

Endosteal diameters

The endosteal width is measured at various locations based on reference lines which have been already defined as per Noble P C et al. The apex of the lesser trochanter is taken as the first landmark. The endosteal width at the level of the apex of lesser trochanter (E), endosteal width 20 mm above (D) and below (F) the lesser trochanter and 10 cm below the lesser trochanter (G) is measured. The mid-point of these endosteal width lines are connected to form the axis of the shaft of femur. One more point is taken measuring 10 cm distal to the apex of the lesser trochanter (G) which is considered as the isthumus. Endosteal width at that level is also measured.[3-5]

Femoral head diameter

The femoral head diameter is taken as the largest vertical diameter (superior-inferior) of head perpendicular to the axis of the neck of femur. The neck axis is drawn by drawing neck widths at 2 regions on the neck of femur, preferably in the trans-cervical and sub-capital region. The midpoints of these two lines are joined and extended further to form the axis of the neck. The femoral head diameter is measured perpendicular to this line taking the largest superior-inferior diameter of the femoral head.

Horizontal offset

The horizontal offset is also known as the actual femoral offset. The horizontal offset is measured as the distance between the centre of the femoral head to the axis of the shaft of femur. The x ray is taken in the said protocol mainly to reveal the proper and maximal offset of the femur.[6]

Neck shaft angle

The neck shaft angle is the angle subtended between the shaft axis and the axis of the neck of femur.[3,4,6]

Canal flare index

The ratio between the endosteal diameters 20 mm above the lesser trochanter (D) and at the level of isthumus (G) is called the canal flare index. Based on the values of canal flare index they were grouped in to normal (3-4.7) , champagne flute (high tapering in the proximal segment 4.7-6.5), stove pipe (a straight proximal femur relative to distal).[3]

The diameter of the magnification marker in the radiograph is determined for identification of the radiographic magnification error.

Cadaveric dry femora- study

The second part of the study involved with measuring the endosteal dimensions of cadaveric femur specimens. This was done to find out the true anthropometric parameters

of proximal femur in addition to knowing the fit of available femoral stems, So as to determine mismatch between implant and bone if any.

In our study we have taken 50 cadaveric femora. The cadaveric femora were cut at various positions so as to ascertain the endosteal dimensions at various regions of the cadaveric femur. The femora were cut using a motorized cadaveric cutting saw in the Department of Anatomy- PSGIMSR. The endosteal dimensions were measured using a Vernier calliper, at the regions mentioned below.

Figure 2: Cut sections of dry bones at various reference levels (left to right – D, E, F, G).

Figure 3: Method to measure neck shaft angle of cadaveric dry bone.

RESULTS

The mean femoral head diameter was 47.41 mm with a 95% confidence interval for the mean values, a standard deviation of ±4.5 mm. The mean offset in the study population was found to be 42.75±4.3 mm. The mean CFI was found to be 3.23±0.5.

Table 1: Results of radiographic study.

	Mean	SD	Minimum	Maximum
Age	47	10	25	75
Femoral head diameter	47.41	4.5	35	57
Medullary canal width				
D	43.79	5.2	33	61
E	27.35	4.3	17	43
F	19.92	3.5	12	31
G	13.88	2.8	9	23
Horizontal offset	42.75	4.3	34	53
Canal flare index	3.23	0.5	2	5
Neck shaft angle	126.03	4.6	114	137

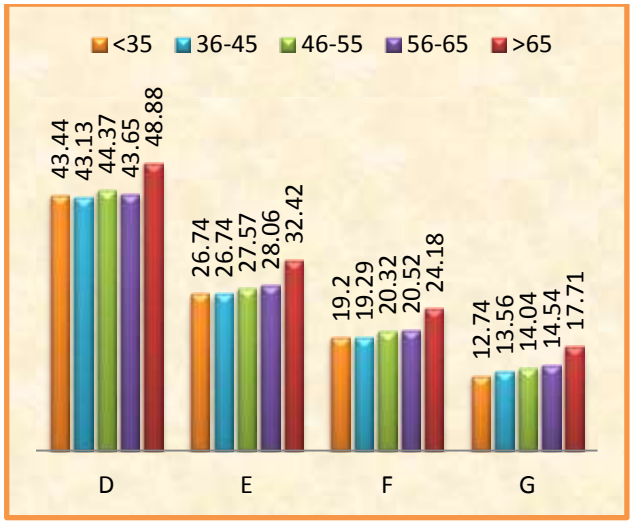

Figure 4: Mean medullary canal width at various levels matched with different age groups.

The above Figure 4 explains the difference in the medullary canal width as the age groups progressed there was a tendency towards increase in the mean width of the endosteal canal diameter.

Table 2: Age wise distribution of canal flare index.

Age group	Stove pipe(<3.0)	Normal (3.0-4.5)	Champagne	Total
<35	4	15	0	19
35-45	21	51	0	72
45-55	14	42	0	56
55-65	12	13	1	26
>65	2	3	0	5
Total	53	124	1	178
%	30%	70%	1%	100%

In the study population 30% had a stove pipe appearance of medullary canal with mean CFI <3. 70 % of the population had normal appearing femora with CFI ranging from 3-4.5 as shown in Table 2.

DISCUSSION

The aim of our study is to evaluate ethnic differences in the anthropometry of proximal femur of South Indians in comparison with other ethnic groups around the world.

The total population that was radiographed was 178 (n=178). There were 78 males and 100 females. The age of the participants were spaced from 25-75 years age groups. The following parameters were measured:

Femoral head diameter

The lowest femoral head diameter measured in our study was 35 and largest femoral head diameter in the study population was 57. The mean femoral head diameter was 47.41 mm with a 95% confidence interval for the mean values, a standard deviation of ±4.5 mm. The most prevalent head size in the given population was estimated in terms of mode for the given range, was found to be 49 mm.

Medullary canal diameters

Medullary canal widths were measured at various locations on the radiographs as described earlier in correlation to the prime seating points of the femoral stem. These levels are the standard reference points to address the changing geometry of the proximal femur. The mean and standard deviations were estimated for each parameter.

Mean canal widths at reference points-

- Endosteal canal width 20 mm above lesser trochanter (D)- 43.79±5.2 mm
- Endosteal canal width at the level of lesser trochanter (E)- 27.35±4.3 mm
- Endosteal canal width 20 mm below the lesser trochanter (F)- 19.92±3.5 mm
- Endosteal canal width at the level of isthumus (G)- 13.88±2.8 mm.

The distribution of endosteal canal widths at various levels were analysed with their age group wise distribution.

As the age groups progressed there was a tendency towards increase in the mean width of the endosteal canal diameter. This was most significant in the >65 years age groups. This was consistent with decreasing trend of canal flare index as age progressed.

Canal flare index

The mean and standard deviation for the same was calculated. The mean CFI was found to be 3.23±0.5. An age wise distribution of the canal flare index.

In the study population 30% had a stove pipe appearance of medullary canal with mean CFI <3.70% of the population had normal appearing femora with CFI ranging from 3-4.5.

There was progressive tendency towards stove pipe appearance of femoral endosteum as age progressed. Most strikingly noted in the >65 years age group with a mean canal flare index of 2.86. The younger age groups predominantly have a more normal type of femur. The distribution was found to be statistically significant in terms of distribution with progressive decline in the endosteal dimension as age progressed, and the femoral endosteum attaining a stove pipe like appearance ($p < 0.05$).

The gender wise distribution of the canal flare index was assessed, mean CFI in males was found to be 3.14±0.4, compared to the mean of 3.29±0.5 in the female pool. There were statistically significant differences in the gender wise distribution of the mean canal flare index ($P < 0.05$).

Horizontal offset

Horizontal offset calculated as the distance between the center of femoral head to the axis of the femoral shaft, which defines the abductor muscle tension was measured in all 178 subjects. The mean offset in the study population was found to be 42.75±4.3 mm.

Differences in anthropometric parameters of Indian femora vs. other ethnic population

The ethnic differences in the anthropometry of the proximal femur was assessed by matching the values of our present study with that of values previously measured in other ethnic populations. For the comparison we have taken the values of proximal femoral anthropometry of the Caucasian population according to the study by Noble P C et al (n-200), the importance of this study was its vitality in bringing up of the dimensions for creation of the various somatotypes for the cemented and un-cemented replacement armamentarium.[4] The study has allowed us to have sufficient arsenal for replacement at the same time allowing the implant to accommodate itself in to bulk of the femora. Anthropometric analysis of a Swiss population based on study by Rubin et al, French population by Massin et al, Malay population by Baharuddin et al, Thai population by Mahasavariya et al.[5,14-16]

Femoral head diameters

The difference in the femoral head diameters across various ethnic groups was assessed.

The present study showed mean femoral head diameters in the South Indian population to be 47.16±4.5 mm. The mean femoral head diameter of Indian population was compared with that of the Malay population 40.81±3.43 mm. The Malay population was found to have smallest femoral head diameters. The mean femoral head diameter of the present study was compared with the Thai population - 43.98±3.47, the Thai population had smaller femoral head dimensions. The mean femoral head diameter of the present study was compared with the Swiss population- 43.40±2.26 mm, the Swiss population had significantly smaller femoral head diameters. The mean femoral head diameters of the South Indian population was compared with the French population, they had lesser mean femoral head diameters- 45.60±4.20 mm compared to Indian population. There was no statistically significant difference in the mean femoral head diameters between Indian and Caucasian femora- 46.1±4.8 mm.

Canal diameters

The population mean endosteal dimensions were measured at four reference levels and assessed between various groups. The mean femoral head diameter at the four reference levels for the South Indian population was endosteal diameter 20 mm above lesser trochanter (D)- 43.79±5.2 mm, endosteal diameter at the level of lesser trochanter (E)- 27.35±4.3 mm, endosteal diameter 20 mm below lesser trochanter (F)- 19.92±3.5 mm Endosteal diameter at the isthumus (G)- 13.8±2.8 mm. There was no statistically significant difference between the endosteal diameters of South Indian and Malay population when matched against present study at the level of D (20 mm above lesser trochanter) and F (20 mm below the lesser trochanter). However at the level of G (isthumal diameter) it was found to be smaller in the Malay population (9.73±1.8 mm). These differences were statistically significant. There is no statistically significant difference in the mean canal diameters at the four reference levels when Indian femora were matched with the Swiss population indicating a close resemblance in terms of endosteal dimensions. There was no statistically significant difference between the endosteal diameters of the South Indian population (present study) and the French population. The endosteal widths of Indian femora was smaller by 2.0 mm in comparison to the Caucasian femora at all 4 reference levels which was statistically significant ($P < 0.05$). Even with a magnification error of 3 mm between present study and Caucasian study the endosteal dimensions are smaller by 2 mm in comparison to Caucasian femora. This suggests that the actual difference is much more.

Offset

The mean offset in the Indian population was 42.75±4.3 mm. The offset values of the South Indian population were compared with the Malay population- 31.50±5 mm. The offset of the Malay population was found to be significantly smaller than the South Indian population. The offset values of the South Indian population were compared with the Japanese population– 30.45±4.26 mm. The offset of the Japanese population was found to be significantly lower than the South Indian population. The offset of the South Indian population was compared with the French population who had a mean offset of 41±6.20 mm. The offset of the French population was close to that of the South Indian population and the difference was not statistically significant. The offset of the South Indian population was compared with the Swiss population who had a mean offset of 47±7.2 mm which was the highest among the ethnic groups in study. The mean offset of the South Indian population was 4.25mm lower than the Swiss population. This probably correlates with the bigger size of the femora among European population. There is no significant difference between the offset of South Indian population and Caucasian population- 43±6.8 mm.

Canal flare index

The mean canal flare index in the Indian population was found to be 3.23.The mean canal flare index of the South Indian population was compared to the Caucasian population which had a canal flare index of 3.8. The difference was statistically significant. The canal flare index of the South Indian population was compared with the French population who had a canal flare index of 3.6. The differences were found to be statistically significant between South Indian and French population, in terms of trending of the canal flare index. This probably suggests a better bone stock in the European population, with the European populations having more Champagne flute configuration of canal flare, therefore will favour more of an un-cemented fixation.

Neck shaft angle

The mean neck shaft angle was found to be 126 degrees in the present study of South Indian population. The verge neck shaft angle of the South Indian population was compared with the Japanese population. The Japanese population had an average valgus femoral angulation with mean neck shaft angle of 137 degrees in comparison to South Indian population.

The neck shaft angle of the South Indian population was compared with the Malay population. The mean neck shaft angle of the Malay population was 130 degrees. There was a slight inclination towards valgus mean femoral angulation in the Malay population when compared with the South Indian population in the present

study. There was no statistically significant difference between the neck shaft angles of present study and Caucasians -125 degrees. Analysis thus indicates more valgus femoral neck shaft angulations Asian population groups.

CONCLUSION

The canal flare index was found to be decreasing with age which is in correlation to the age related decrease in the femoral bone stock. The Asian and Indian femur bone is of much smaller sizes in comparison to European femurs.

Limitations of study

The radiographic study had a mean magnification of 3 mm. There was radiation exposure to normal subjects who have volunteered for the study. The age of the dry bones was not available.

Mechanical comparison of reconstruction nail and dynamic condylar screw in the treatment of unstable Subtrochanteric fracture *in vitro* study

Dr. Arvind Kumar SM, Dr. Yeluri Rama Krishna and Dr. B Arun Kumar

DOI: https://doi.org/10.22271/ortho.2019.v5.i4l.1748

Abstract
Background: Subtrochanteric femur fractures are severe injuries that are often associated with high-energy trauma in young age and a trivial fall in osteoporotic patients. These fractures constitute a major bulk of hip fractures and are difficult to treat.
Objective of this study was to determine the rigidity and strength of fixation and ultimate load of failure of certain composite femur models designed to simulate unstable subtrochanteric femur fractures fixed with DCS and Reconstruction nail.
Methods: Paired femora were osteotomized to produce like models of an unstable subtrochanteric femur fracture in vitro. The femora were fixed with the Reconstruction nail and a 95 degree dynamic condylar screw plate (DCS). Materials testing machine was used to apply compression to the femoral head through an adapter plate. Stiffness values were calculated from the load-deformation curves obtained.
Results: The Reconstruction nail-femur model was stiffer than the 95 degree DCS. The Reconstruction nail also had the highest ultimate load-to-failure than the 95 degree DCS.
Conclusion: Our findings suggest that the Reconstruction nail has greater stiffness and strength than the 95 degree dynamic condylar screw when tested in this model of an unstable subtrochanteric femur fracture.

Keywords: Subtrochanteric fractures, dynamic condylar screws, reconstruction nail

Introduction
Subtrochanteric femur fractures are severe injuries that are often associated with high-energy trauma in young age and a trivial fall in osteoporotic patients. These fractures constitute a major bulk of hip fractures [1]. These fractures are known to be difficult to treat successfully [2]. Anatomic and biomechanical variation in this region makes this area peculiar for the treating surgeons. The compressive stress in this area of the medial femur is as high as 1,200 pounds per square inch [3], which cause enormous stress on the fracture fixation devices. No single implant is ideal for all the Subtrochanteric fractures. Various implants used to address these fractures are 95 degree blade plate, 95 degree dynamic condylar screw, reconstruction nails and proximal femoral locking plate.
Through the years, numerous classification systems have been proposed for subtrochanteric fracture which have a prognostic importance and are of benefit in planning treatment.
Russell and Taylor [4] classified these fractures based on the involvement of the lesser trochanter and the piriformis fossa (Fig. 1). Intramedullary nail is the choice of implant in type I fractures as the fracture does not extend into the piriformis fossa. Extramedullary fixation with various plates is indicated in type II fractures in view of involvement of piriformis fossa. Loss of medial cortical contact and increased stress on the implant causes difficulty in treatment of Type IIB fracture.
Good results have been achieved using Dynamic condylar screw and reconstruction nail in unstable subtrochanteric fractures. The purpose of the present study is to compare the biomechanics of 95 degree dynamic condylar screw and reconstruction nail in resisting compressive loads in an unstable subtrochanteric fracture.

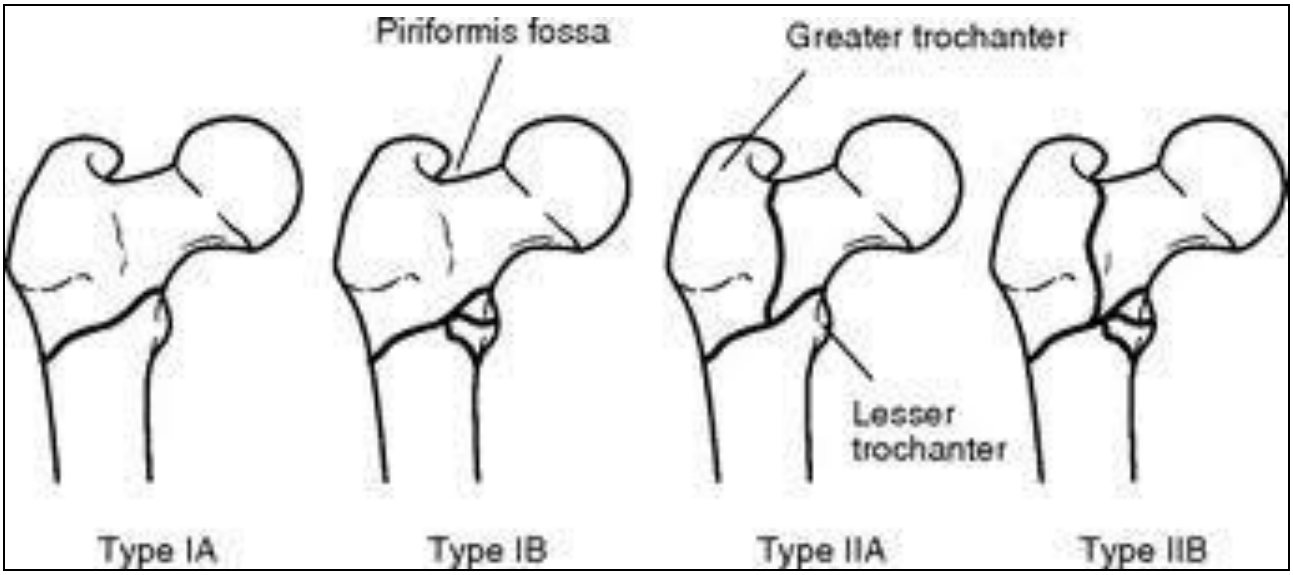

Fig 1: Russell Taylor classification of sub trochanteric fractures

Materials and Methods

Type of study: Observational study (in vitro)

Place: PSG IMS&R, Coimbatore

Selection: 3 Paired adult fresh cadaveric femora were used.

They were osteotomized to produce like models of an unstable subtrochanteric femur fracture. The femora were fixed with the Reconstruction nail and a 95 degree dynamic condylar screw plate (DCS).

The femora were placed into the materials testing machine with the femoral head placed in the metal mount over the base and the condyles superiorly held by the metal plate of the machine. The femora were placed vertically and loaded in compression to 500 newtons at a rate of one millimeter/second and a load displacement curve was obtained.

The Synthes 95 degree dynamic condylar screw plate (DCS) chosen (stock number S040-95-08) was a six-hole plate. A 75-millimeter lag screw was placed into the proximal fragment, and the plate was inserted over the lag screw and secured with the compressing screw. A 6.5-millimeter cancellous screw (70 millimeters long with a 32-millimeter thread) was placed into the most cephalad hole in
the plate. The next hole was left empty, and the last four holes were filled with bicortical 4.5-millimeter screws.

The Reconstruction nail used was 09x 380mm size (stock number SMPL, S182-09L-380) and the two proximal screws were of 6.4x95mm and 6.4x80mm size and locked distally with cortical screws.

The femora were prepared for the DCS and Reconstruction nail before the osteotomy was cut. The lag screw was placed over a guide wire in the specimen receiving the DCS. The osteotomies were cut in a similar manner in both the femora. A 30 degree osteotomy was cut, leaving a two centimeter defect on the medial side of the femur. The plates were then fixed to the distal fragment with 4.5-millimeter cortical screws. Failure was determined by a sudden change in the load deformation curve. Each of the femora was then radiographed and examined to determine the cause of failure.

The stiffness of each system was determined by measuring the slope of the load deformation curve. These stiffness values and the load-to-failure values were tabulated and averaged. The measurements were analyzed by analysis of variance to determine statistical significance.

Results

From Compression Testing of Simple Bone

At the peak load the bone suddenly fractured completely as shown in the figure 2

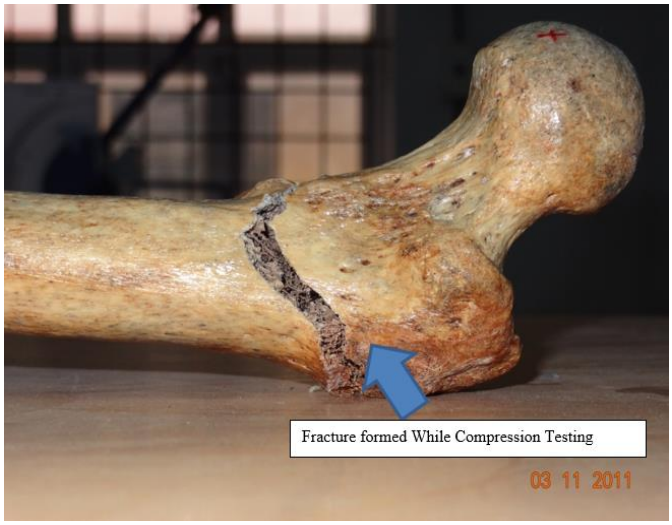

Fig 2: Fractured simple bone

The fracture is created due to the load application of load in the compression testing. When the bone is placed at a 6 degree angle as like in the human body

The fracture happened as shown in the fig 2. if the one is placed perpendicular loading arm the fracture is in the middle also breaking load also increases.

The peak load from this compression testing of the simple bone is given as he force value for Finite element analysis using ANSYS for study of the stress distribution over bone while compression loading.

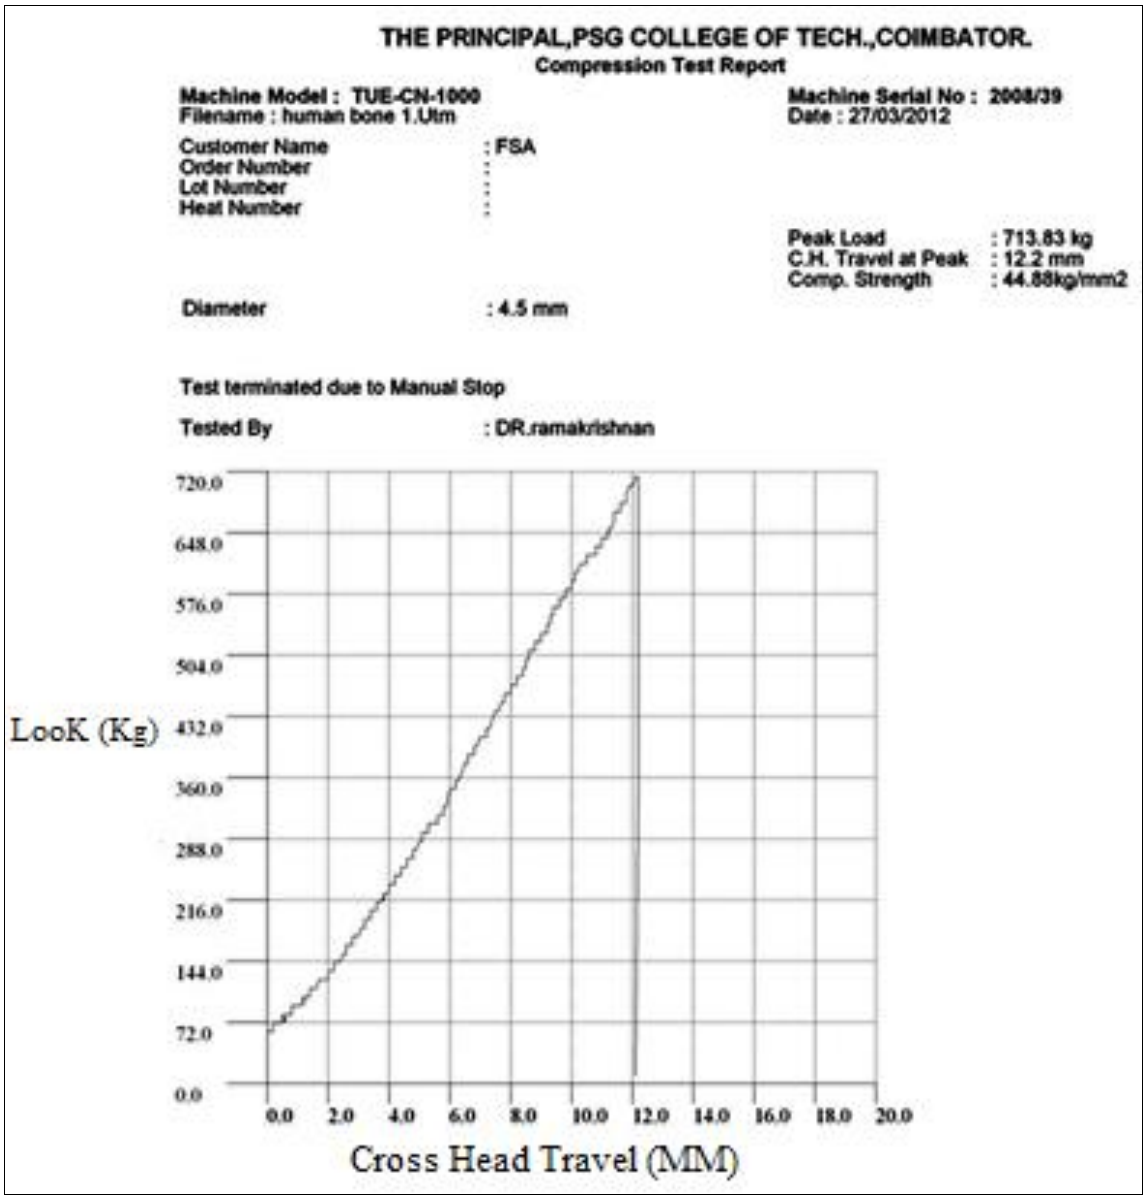

Fig 3: Load deformation curve for simple bone

The peak load at which bone Breaked is 713.83 kg and cross head travel that is deflection of the specimen is 12.2mm. The final result compressive strength is 44.88kg/mm2 was shown in the Fig 3

For testing dynamic condylar screw (DCS) Implant

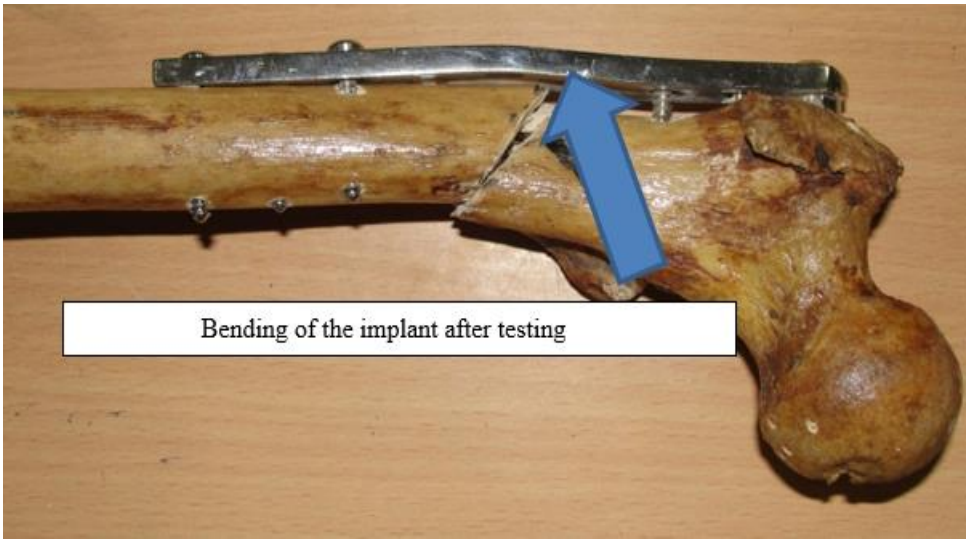

Fig 4: Failure of the DCS Fixed Bone

While testing, the bones shattered into pieces are brought together shown in fig 4 the fractured part i.e., artificial fracture created for testing the implant stability is the one first get affected and broken early while loading. At initial loading bone itself takes all the load so its obvious for fractured part to gets affected

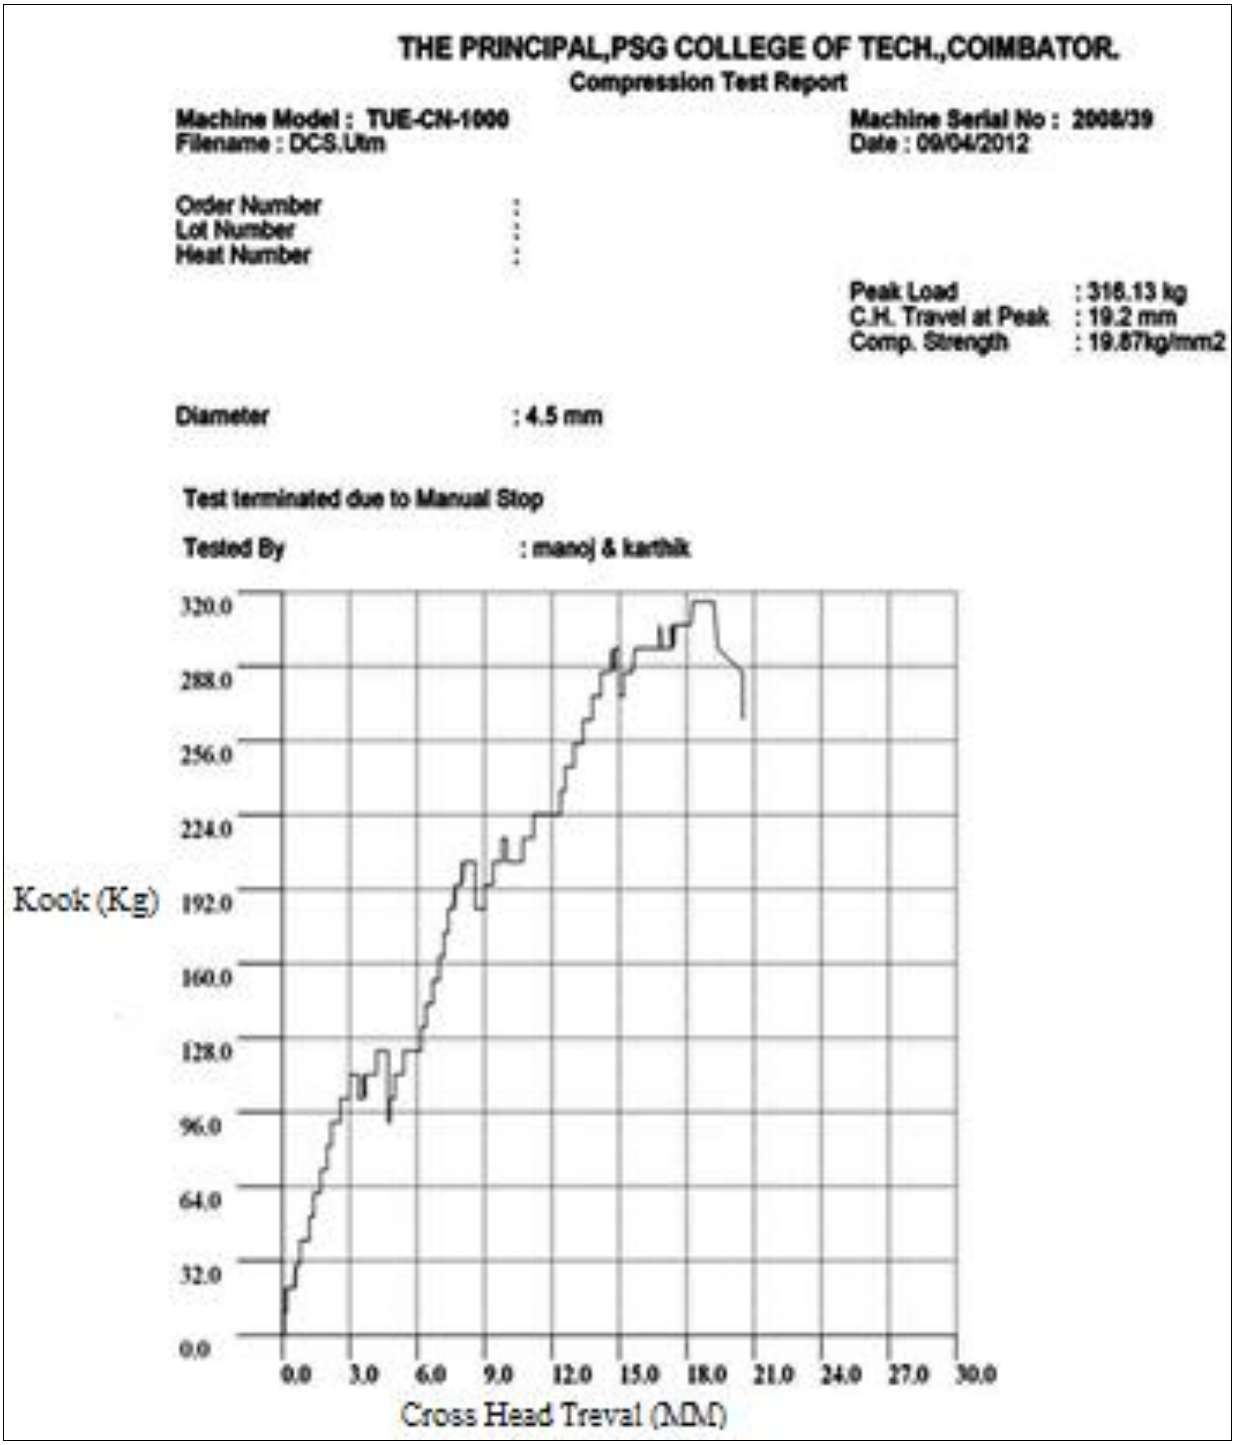

Fig 5: Load deformation curve obtained for DCS

The peak load at which implant failed is 316.13kg and cross head travel that is deflection of the specimen is 19.2mm. The final result compressive strength is 19.67kg/mm2 was shown in the fig 5.

For testing proximal femoral nail (PFN) implant

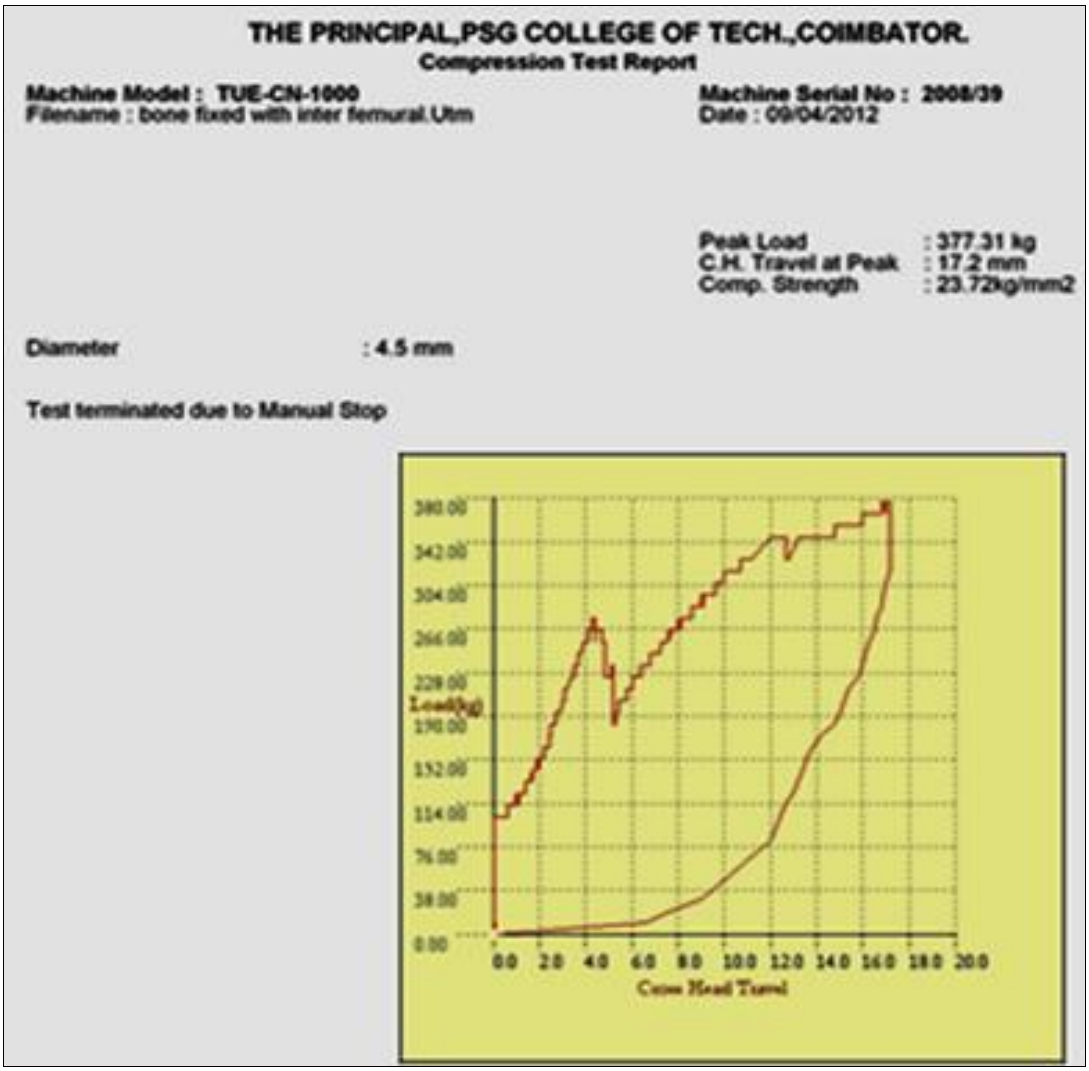

Fig 6: Load deformation curve obtained for PFN

The peak load at which implant failed is 377.31kg and cross head travel that is deflection of the specimen is 17.2mm. The final result compressive strength is 23.72kg/mm2 was shown in the fig 6

In both implant testing the loading is terminated manually at peak loads because of the significant deformation in the bone and implants is considered as failure of the implant. Compressive strength are generated based on the peak load. Simple bone's compressive strength is maximum because loading is done till the complete breaking of the bone

Fig 7: Failure of Proximal Femoral Nail fixed bone

The figure 7 & 8 shows the failure of the PFN fixed bone. PFN implant never showed any deformation while loading only the bone started to crack is considered as failure of the implant.

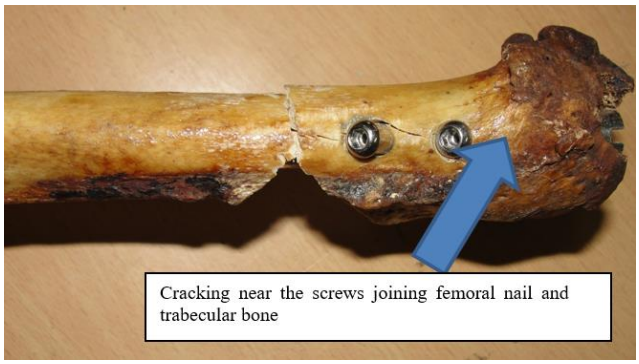

Fig 8: cracking of bone

Reconstruction nail femur composite demonstrated a stiffness of 665 newtons/millimeter and the DCS femur composite demonstrated a stiffness of 373 newtons/millimeter. Using ANOVA test the statistics were analsed. These differences were statistically significant ($p< 0.00001$).

The Reconstruction nail femur composite also had the highest load-to-failure (3773 Newton's), and for the DCS femur construct it is 3,161 newtons. These results were also statistically significant ($p< 0.00001$). The sudden change in the load-deformation curve coincided with an obvious deformation of the implant. Table 1

Discussion

Subtrochanteric fractures of the femur demands a vital place

in orthopedic traumatology, given the high rate of complications associated with their management due to the high loading forces and immense stresses in this area. An ideal implant should achieve stable fixation with no interference with the vascularity and hold the fracture till it unites. Fixation is a race between fracture healing and implant failure. Irrespective of the mode of fixation emphasis is laid on the medial cortex reconstitution as described in the study by Senter B *et al*. [5]. Intramedullary devices require less surgical exposure, enable early weight bearing and exert less biomechanical stresses (as the lever arm is moved medially) [6-8] However technical difficulties are observed in upto 63% of the cases [9, 10].

Comminuted subtrochanteric femoral fractures are often caused by high-energy trauma [12, 13] Fractures may extend into the greater and the inter-trochanteric regions [11]. Open reduction further devitalizes fragments, damages the vascular supply or soft tissues, and increases the risks of non-union, infection, and implant failure [12] whereas indirect reduction does not [19]. One case of implant failure (12.5%) is observed in fractures fixed with DCS by open reduction compared to failure rates of 20 to 23% in different studies [14, 15].

In this study the inference from the each load deformation curve is as follows.

Inference for DCS Curve

Graph indicates the increase in deformation as the load increases at the load of 122kg first failures takes place in the fractured section of the bone first drop in graph indicates this failure.

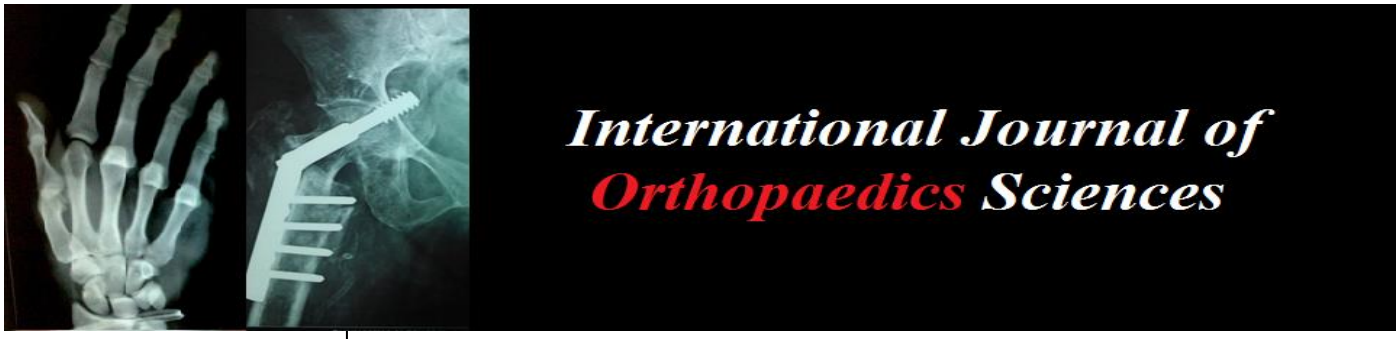
At the load of 204kg fracture gets more affected is noticed by propagation of crack all around the bone with crisping sound.

Implants start to bend at the load of 298kg that is considered as the failure of DCS fixed bone.

Inference for PFN Curve

As the load increases the deflection in the bone also increases. Drop in the deflection curve at 270 kg indicates the first failure at the fractured section of the bone after the first failure the continuous loading results in cracking of the bone at the fractured section at 350kg

Conclusion



Taking into consideration that the femoral nail implant is way tougher than the DCS implant the failure can be verified with the fracture of the bone only.

Since the inter femoral nail fails at load higher than the DCS implant it can be inferred that:

- The inter femoral (PFN) is found as more stable implant followed by dynamic condylar screw (DCS) to treat unstable sub trochanteric fracture.
- The rate of displacement of the head also is less at a higher force when compared with that of the DCS and hence it can be inferred that PFN also resists displacements.
- In the failure pattern the implant did not break in PFN but only the fracture occurred between the two screws hence again confirming that PFN is a rigid implant.

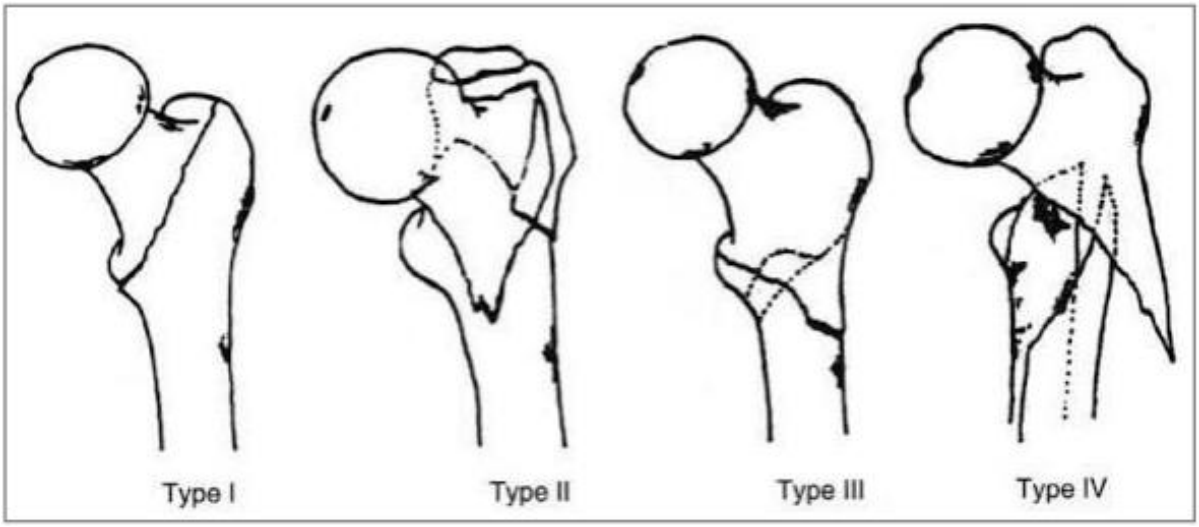
A modified dynamic hip screw in unstable intertrochanteric fracture: A retro-prospective study

Sandeep MMR and Dinakar Rai

DOI: https://doi.org/10.22271/ortho.2020.v6.i3m.2291

Abstract
Background: Intertrochanteric fractures occur mostly in elderly patients, and the outcome may be extremely poor if there is prolonged bed-rest.
Many treatment modalities have come up in management of these unstable intertrochanteric fractures. Sliding Hip Screw Fixation is still the gold standard in treatment of stable intertrochanteric fracture. In unstable comminuted intertrochanteric fractures, there is high incidence of failure in view of excessive collapse seen with Dynamic hip screw.
In order to limit the collapse we have done a modification on Dynamic Hip Screw implant. The aim of this study is to assess fracture healing, collapse and implant failure, in unstable intertrochanteric fractures (Boyd and Griffin type-2) treated by modified DHS fixation.
Methods: 23 patients who were operated with modified DHS for unstable intertrochanteric fracture were selected using random selection and following parameters were noted from the records.
Results: Out of 23 patients in this study, 20 patient showed fracture healing (87%) with or without minimal collapse and 3 patient had non-union (13%) at the end of 5 months follow up. Ultimately all fractures united at the end of 1 year followup.
Conclusion: Modified Dynamic Hip Screw has showed improved results as compared to normal Dynamic Hip Screw in treating communited intertrochanteric fracture, which limits the collapse at fracture site.

Keywords: Intertrochanteric fractures, modified DHS, collapse



Introduction
Intertrochanteric fractures occur mostly in elderly patients, and the outcome may be extremely poor if there is prolonged bed-rest. The best treatment for trochanteric fracture remains controversial [1-3]. Many methods have been recommended [4-6]. Early mobilization of these patients reduces the morbidity and mortality rate.
Intertrochanteric fractures with severe communition and displacement are commonly seen in elderly patients. Most of the elderly patients have poor bone quality due to which fractures are often associated with complications like non-union, implant failure and femoral head perforation.
Management of unstable intertrochanteric fractures is challenging because of excessive collapse, loss of fixation, implant failure, lag screw cut out and in addition osteoporosis also adds to the complication resulting in unpredictable outcome.
In order to limit the collapse we have done a modification on Dynamic Hip Screw implant. In this study we are assessing the outcome of unstable intertrochanteric fractures treated with modified dynamic hip screw fixation designed by us.
Boyd and Griffin (1949) classified fractures in the trochanteric area of femur into 4 types. Their classification included all fractures from extra capsular part of neck to a point 5cm below the lesser trochanter. Their classification is useful in planning treatment and estimating prognosis [7].

Type 1: Fractures that extend along the intertrochanteric line from the greater to the lesser trochanter. Reduction usually is simple and is maintained with little difficulty. Results generally are satisfactory.

Type 2: Comminuted fractures, the main fracture being along the line, but with multiple fractures in the cortex. Reduction of these fractures is more difficult because the comminution can vary from slight to extreme. A particularly deceptive form is the fracture in which an anteroposterior linear fracture occurs, as in type 1, but with an additional fracture in the coronal plane, which can be seen on the lateral radiograph.

Type 3: Fractures that are basically subtrochanteric with at least one fracture passing across the proximal end of the shaft just distal to or at the lesser trochanter. Varying degrees of comminution are associated. These fractures usually are more difficult to reduce and result in more complications during surgery and convalescence period.

Type 4: Fractures of the trochanteric region and the proximal shaft, with fracture in at least two planes, one of which usually is the sagittal plane and may be difficult to see on routine anteroposterior radiographs. If open reduction and internal fixation are used, twoplane fixation is required because of the spiral, oblique, or butterfly fracture of the shaft.

Aim of the study

The aim of this study is to assess fracture healing, collapse and implant failure, in unstable intertrochanteric fractures (Boyd and Griffin type-2) treated by modified DHS fixation.

Objectives

1. To assess fracture healing, collapse in management of communited intertrochanteric fracture with modified Dynamic Hip Screw.
2. To look for implant failure- migration of implant, implant loosening, implant cutout or non-union.

Materials and Methods

Study Design: Retrospective observational study population: Patients diagnosed to have intertrochanteric fractures and treated with Modified DHS Study Area : PSG Hospitals.

Inclusion criteria

1. Boyd and griffin classification type-2 fractures only
2. Patients willing for treatment and given written informed consent.

Exclusion criteria

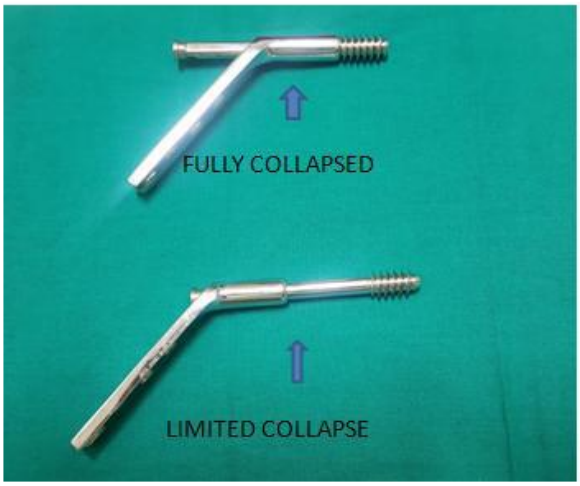
1. Boyd and griffin classification type-1, type-3 and type -4
2. Pathological fractures
3. Infection
4. Treated after 3 weeks of trauma.
5. Patients medically unfit for surgery.
6. Compound fractures associated with vascular injuries, ipsilateral femoral shaft fractures and pelvic fractures.
7. Patients not willing for treatment.

23 patients who were operated with modified DHS for unstable intertrochanteric fracture were selected using random selection and following parameters were noted from the records.

The criteria taken into consideration were fracture healing , collapse of fracture fragments, implant failure

About Modified Dynamic Hip Screw

One of the cause for failure of Dynamic Hip Screw is over collapse at fracture site [8].



In this study, we have used modified dynamic hip screw to limit the over collapse which is undesired in unstable intertrochanteric fractures. In this implant we have done modification in the shaft of lag screw, we have reduced the length of keyed screw system, so that we can have a maximum of 1 cm collapse, hence there will be limitation in collapse unlike the original implant.

Modified lag screw versus Normal lag screw

Before collapse

After collapse

Results

In this retro-prospective study a total of 23 patients were assessed. Pre-operative

AP radiographs of pelvis was taken for all the patients who were treated by modified dynamic hip screw fixation. All patients who underwent treatment were of age from 38 years to 90 years. Out of 23 patients in this study, 13 patients were male (56.5%) and 10 patients were female (43.5%). Only boyd and griffin type-2 fractures were taken in view of standardisation. Post-operatively follow up xray were taken at 1st month, 3rd month and 5th month and the outcome was assessed.

Factors assessed were

1. Fracture healing
2. Fracture collapse
3. Implant failure

Fracture Healing

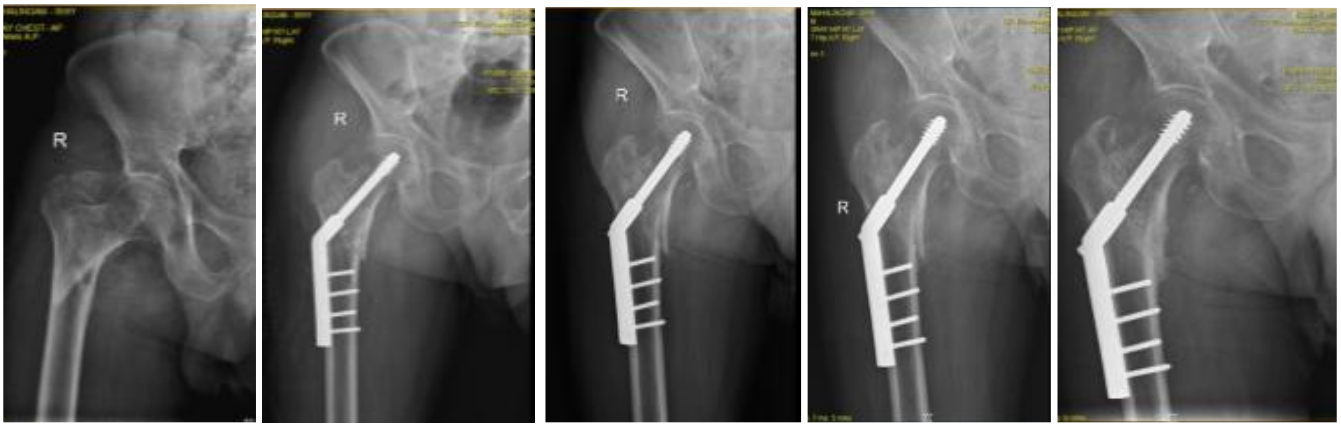
1st month 3rd month 5th month

	1st month	3rd month	5th month
Union	8(34.8%)	20(87%)	20(87%)
Non union	15(65.2%)	3(13%)	3(13%)
Total	23(100%)	23(100%)	23(100%)

Out of 23 patients in this study, at first month follow-up, 8 patients showed fracture healing (34.8%), at third month follow-up, 20 patients showed fracture healing (87%), at fifth month follow-up, 20 patient showed fracture healing (87%) and three patient had non-union (13%)

Fracture Collapse

	1st month
Minimal collapse	16(69.6%)
No collapse	7(30.4%)
Total	23(100%)



Out 23 patients in this study, at first month follow-up, 7 patients showed no Collapse (30.4%) and 16 patients showed minimal collapse (69.6%) [less than 1 cm], however the collapse rate remained same for all patients till end of this study.

Implant Failure

	1st month	3rd month	5th month
No implant failure	19(82.6%)	19(82.6%)	19(82.6%)
Lag screw migration not breaching cortex	4(17.4%)	4(17.4%)	4(17.4%)

At the end of 5 months followup out of 23 patients, 4 patient had implant migration not breaching cortex (17.3%).

Radiographs

Pre op Post op 1st month 3rd month 5th month

Discussion

Intertrochanteric fractures are mainly treated by surgical intervention. Despite longterm experience in many centres, there have been factors still contributing to pooroutcome of managing unstable intertrochanteric fractures.

Controversies persist because there is lack of proper per-

operative risk factors assessment that affect the outcome in these fractures treated by various methods. Failures of Dynamic hip screw in unstable intertrochanteric fracures are due toover collapse at fracture site [8].

In this study, we have used modified Dynamic Hip screw for treating comminuted intertrochanteric fractures, we have used this implant to limit the over collapse at fracture site.

Fracture united in 20 patients with minimal collapse and 3 patients had no signs of union at the end of 5 months. But all fractures united at the followup period of 1 year, lag screw migration occurred in 4 patients who started early weight bearing.

Nordin S in their study on treatment of intertrochanteric fractures with Dynamic Hip Screw, 83.3 percent of patients had fracture healing at one month [9]. In our seriesonly 34.8 percent of patients showed fracture healing at first month, however at the endof fifth month 87% fractures went on to heal. This delay in fracture healing relates to the modification in design of implant which limits the collapse at fracture site.

Sadowski cal *et al.* in their study on treatment of unstable intertrochanteric fractures with sliding hip screw, implant failure and non-union was noted in 7 of 19patients (38%) who had been treated with the sliding hip screw [10]. In our series, implant migration was noted in 3 out of 23 patients (13%) but no breaching of cortex occured. This results compare favourably and highlights the advantage of modified Dynamic Hip Screw in treatment of communited intertrochanteric fractures.

Conclusion

Modified Dynamic Hip Screw has showed improved results as compared to normal Dynamic Hip Screw in treating communited intertrochanteric fracture.

1. Fracture healing was slow in comparing with regular Dynamic hip screw.
2. Modified Dynamic hip screw significantly limits the collapse at fracture site.
3. When modified Dynamic Hip Screw is used in managed of communited intertrochanteric fracture, weight bearing mobilisation should be delayed to improve the outcome.

Limitations

Small sample size

Other forms of fixation of trochanteric fractures were not compared in this study.

ABSTRACT

Background: Platelet rich plasma (PRP) has been a breakthrough in the field of medicine especially in the field of orthopaedics for enhancing bone and soft tissue healing. Plantar Fasciitis is a very common problem in the field of orthopaedics and are very difficult to treat and a challenge to orthopaedicians. The aim of our study was to find out the efficacy of autologous PRP in relieving pain in patients with plantar fasciitis.
Methods: In this study, 25 patients with plantar fasciitis (age above 18 years) were selected. The pain intensity was assessed with visual analogue score initially and during follow up. All subjects were given single autologous intra-lesional PRP injection and the results were assessed using difference in VAS.
Results: The mean pain score at presentation was 8.08. The mean pain scores at subsequent intervals of 1,2,4,6 months after injection were 4.32, 2.60, 1.88 & 2.00 respectively. ($P<0.05$ which is statistically significant). The maximum pain relief was seen at 4th month post PRP injection and the pain relief was sustained till the last follow up.
Conclusions: From our study we have found that Intra-lesional autologous PRP is effective in relieving pain in patients with plantar fasciitis. PRP is biological and can be a safe adjuvant in the treatment of Plantar Fasciitis.

Keywords: Platelet rich plasma, Plantar fascitis, Visual analogue score

INTRODUCTION

Platelet rich plasma (PRP) has been a breakthrough in the field of medicine especially in the field of orthopaedics for enhancing bone and soft tissue healing. Plantar Fasciitis is a very common problem in the field of orthopaedics and are very difficult to treat and a challenge to orthopaedicians. Autologous PRP is a simple and cost effective means of treating plantar fasciitis by tissue regeneration.[1]

Plantar fasciitis is one of the most common causes of heel pain in adults. The cause of pain is due to collagen degeneration at the origin of plantar fascia. The plantar fascia is thickened fibrous fascia that originates from the medial tubercle of calcaneum and run forward to support the longitudinal foot arch.

The aim of our study was to find out the efficacy of autologous PRP in relieving pain in patients with plantar fasciitis.

METHODS

This is a prospective trial involving the patients in the department of orthopedics, PSGIMSR Coimbatore, Tamilnadu, India from Jan 2015 to Jan 2016.

In this study, 25 patients with plantar fasciitis (age above 18 years) were selected. The pain intensity was assessed

with visual analogue score initially and during follow up. All subjects were given single autologous intra-lesional PRP injection and the results were assessed using difference in VAS.

Selection of patients

Patients with history of pain and localized tenderness on the medial calcaneal tubercle [2].The classic sign is pain that occurs with few steps in the morning or at the start of walking which decreases as they warm up.[2]

Inclusion criteria

Patients clinically diagnosed to have plantar fasciitis, patients not responding to conservative treatment even after a minimum period of 3 months, both males and females, age- 18 years and above.

Exclusion criteria

Less than 3 month duration of plantar fasciitis, patients without any trial of conservative treatment, recent local steroid injection (less than 2 months), infection or ulcer at the injection site, rheumatoid arthritis, sero-negative spondyloarthritis, pregnant ladies, patients younger than 18 years, suspicion of diagnosis.

Methodology

Figure 1: Study design.

Method of preparation of PRP

PRP was prepared using double spin centrifugation method.

10 ml of venous blood is drawn from cubital vein. The blood is transferred into 2.7ml vaccutainer prefilled with acid citrate dextrose. Acid citrate dextrose will bind to calcium and prevents blood clotting with no known interference to platelet function and no contraindications for using in human beings. The blood is then transferred in the vaccutainer till the marking and centrifugation was done. Initially, with 1500 RPM for 3 minutes. After the initial rotations, blood was separated into plasma and RBC. The plasma will lie in the top with light yellow colour and was withdrawn and transferred into another container without mixing RBC. Later this container is again centrifuged with 2500 rpm FOR 3 MINUTES. After the 2nd centrifugation, the plasma is separated into 2 layers. The top half is platelet poor plasma and bottom half will be platelet rich plasma. The top half is discarded and bottom half is used for infiltration.

Technique of infiltration

Using a 21 Gauge, 1 and 1/2 inch needle, 1ml PRP is injected initially over the maximum tenderness point, and another 1 ml, was injected into the surrounding tissue with the same entry portal. This technique is known as peppering technique.

Pain scoring system

Visual analogue pain scoring system was used (Figure 2).

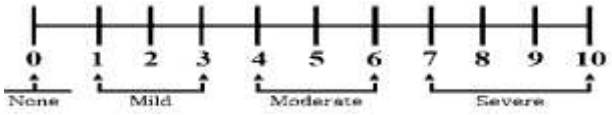

Figure 2: Visual analogue scoring system for assessment of pain.

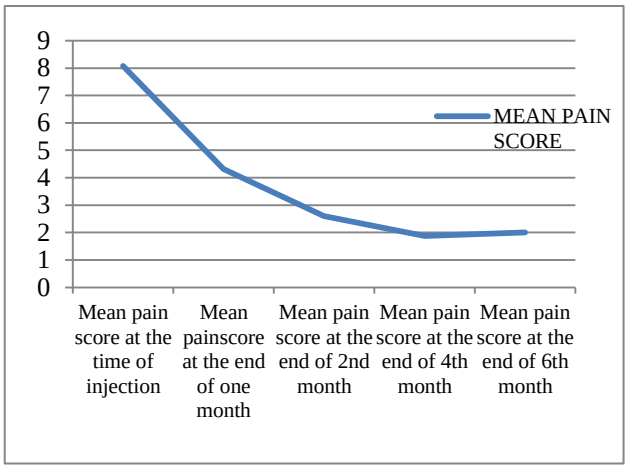

Figure 3: Mean pain score.

RESULTS

Patients were analyzed for pain relief subjectively at 0, 1, 2, 4 and 6 months. The results are given below.

Mean pain score

The mean pain score of patients with plantar fasciitis at 0, 1,2,4,6 months were 8.08, 4.32, 2.60, 1.88 & 2.00 respectively. While comparing the results at 0,1,2,4,6 months follow up, it was found that patients started getting pain relief at one month post injection ,which was statistically significant (p value <0.05). However the maximum pain relief was seen at 4th month post injection which was also statistically significant (p value <0.05).

Table 1: Showing mean pain scores at 0, 1, 2, 4 and 6 months intervals.

Patients receiving	Mean pain score at the time of injection	Mean pain score after	Mean pain score after	Mean pain score after	Mean pain score after
PRP		1 month	2 months	4 months	6 months
Plantar Fasciitis	8.08	4.32	2.6	1.88	2

Table 2: Showing Mean, T-Test & P-values at 0, 1, 2, 4 and 6 months intervals.

Pairs	Time interval	Mean	T-Test	P- Value
Pair 1	Pain at presentation & 1 month	4.32 ± 0.802	16.660; CI (3.29-4.22)	<0.00
Pair 2	Pain at presentation & 2 month	2.60 ± 0.645	33.309; CI (5.1-5.8)	<0.00
Pair 3	Pain at presentation & 4 month	1.88 ± 0.881	26.847; CI (5.72-6.67)	<0.00
Pair 4	Pain at presentation & 6 month	2.00 ± 0.957	24.877; CI (5.57-6.58)	<0.00

Statistical analysis

Statistical analyses were performed by SPSS for windows 19.0 software system version. Comparing the results at 0, 1, 2, 4, 6 months. P value for the test was taken as 0.05. Our study shows that the pain relief obtained following autologous PRP injection is statistically significant.

DISCUSSION

Platelet rich plasma (PRP) is also known as platelet rich concentrate, autologous platelet gel or platelet releasate. Platelet rich plasma is a portion of the plasma fraction of autologous blood with a concentration of platelets above the base line values.[3] In addition to platelet concentrate, autologous PRP contains complement of clotting factors and secretary proteins.[4] Normal platelet counts ranges between 150000/µL and 350000/µL, and average about 200000/µL in blood.[5] "PRP was introduced by M. Ferrari in 1987 as an autologous component in an open heart surgery to avoid homologous blood product transfusion".[6]

Platelets contain biologically active substance for blood clotting, such as coagulation factors, adhesive proteins and protease inhibitors. Platelets contain growth factors like TGF –beta 1, CGF, VEGF, and PDGF.[7,8] When activated these growth factors initiates the process of tissue healing by cellular proliferation and differentiation, chemo taxis, tissue debris removal, angiogenesis, and extra cellular matrix formation.[9,10] These properties of autologous PRP are used in the treatment of plantar fasciitis. An added advantage of autologous PRP is that it eliminates concerns about immunogenic reactions and disease transmission.[11]

Our study was a prospective study including 25 patients with plantar fasciitis (age above 18 years). The pain intensity was assessed with visual analogue score initially and during follow up. PRP was prepared by double spin centrifugation method and the platelet count in our samples ranged between three to six lakhs per cc. All subjects were given single intra-lesional PRP injection and the results were assessed using difference in VAS. In our study we did not use local anaesthetic agent which could bias our study by producing pain relief.

The results of our study matched with the results of the study by Ehab Mohamed Selem Ragab et al on 25 patients with plantar fasciitis, they concluded that average pain at the time of presentation was 9.1 and post autologous PRP injection was 1.6 at end of follow up (10.3 months).[1] Which was statistically significant ($p<0.001$).

In a comparative study by Ertugrul Aksahin et al they concluded that both PRP and corticosteroid treatment is equally effective in treating plantar fasciitis.[2]

The mean pain score at presentation was 8.08. The mean pain scores at subsequent intervals of 1,2,4,6 months after injection were 4.32, 2.60, 1.88 and 2.00 respectively. ($P<0.05$ which is statistically significant). The maximum pain relief was seen at 4th month post PRP injection and the pain relief was sustained till the last follow up.

The limitations of our study were that our study is not a randomized control double-blinded study, and the sample size was small and follow up was of shorter duration. The available data is insufficient to validate the efficacy of PRP in relieving pain in patients with Plantar Fasciitis. Further randomized control studies with large study population and the longer duration of follow up are needed to validate the efficacy of autologous PRP in the management of plantar fasciitis.

CONCLUSION

From our study we have found that Intra-lesional autologous PRP is effective in relieving pain in patients with plantar fasciitis. PRP is biological and can be a safe adjuvant in the treatment of Plantar Fasciitis.

ABSTRACT

Background: The morphology of the proximal femur is a topic of extensive research. The hip joint is one of the most commonly replaced joint. The era of replacement has given rise to various implants that can be used to replace the proximal femur. This present study addresses these issues involving ethnic differences in the geometry of the proximal femur in Indians and its differences between people of various ethnicity.
Methods: The total population that was radiographed was 178 (n=178). There were 78 males and 100 females. The age of the participants were spaced from 25-75 years age groups. The parameters were measured.
Results: The canal flare index in South-Indians was an average of 3.23 with 70% of the study population having normal CFI (3-4.5), 30% of the population having a stove pipe configuration CFI (<3). Majority of the Indian population favour a un-cemented fixation (70%).
Conclusions: In summary all current implants have to be revised on population basis to fit the changing anthropometry of our proximal femur.

Keywords: Femur canal, South Indian population, Canal flare index

INTRODUCTION

The morphology of the proximal femur is a topic of extensive research. The hip joint is one of the most commonly replaced joint. The era of replacement has given rise to various implants that can be used to replace the proximal femur. The integral part of any replacement is to reproduce the biomechanics of the original joint in the prosthetic components in order to achieve good clinical outcome both in terms of patient and implant. Many of the conventional implant systems manufactured by various conglomerate companies are made in correlation with the sizes of the femora of Europeans.[1] The use of these implants in the Indian population, owing to its small size of the femur has been plagued with numerous complications like intra-op splintering of the proximal end of femur. It is also the bane of the Asian-Indian Orthopaedic surgeons to work with such ill-fitting implants.

Most implant systems are usually designed on the basis of European femora, which are believed to be larger than Asian population. The implantation of these prosthesis often results in problems like fractures of the proximal femur or less confirming prosthesis leading to loosening.[2]

This present study addresses these issues involving ethnic differences in the geometry of the proximal femur in Indians and its differences between people of various ethnicity. It also evaluates the adequacy of fit of the conventional femoral stems in Indian population.

The aim and objective of the study was to determine the proximal femur morphology in South Indian population determined with radiographs and from cadaveric dry bones and to determine the differences between anthropometry of South Indian population and other ethnic groups.

METHODS

This is a prospective study consisting of two fundamental parts, involved in assessing the anthropometric dimensions of the proximal femur. In the first part of the study we have evaluated anthropometry of 178 volunteers radiographically. The second part of the assessment was done with cadaveric femora obtained from the Department of Anatomy, PSGIMSR. 50 cadaveric dry femora were obtained and direct measurement of measurable anthropometric data was done. The study was conducted in PSGIMSR Coimbatore, Tamil nadu, India from August 2013 to August 2014.

Inclusion criteria were South Indian population and people of age 25 years and above. Exclusion criteria were no prior pathology in the femur- infection (old/healed/active), congenital anomalies, contractures and deformities around the hip, previous hip surgeries and open epiphysis.

Parameters templated

- Femoral head diameter
- Horizontal offset
- Neck shaft angle
- Endosteal diameter at a level 20 mm above lesser trochanter (D)
- Endosteal diameter at the summit of the lesser trochanter (E)
- Endosteal diameter at a level 20 mm below the lesser trochanter (F)
- Endosteal diameter at the level of the Isthumus (G-10 cm below lesser trochanter)
- Canal flare index.

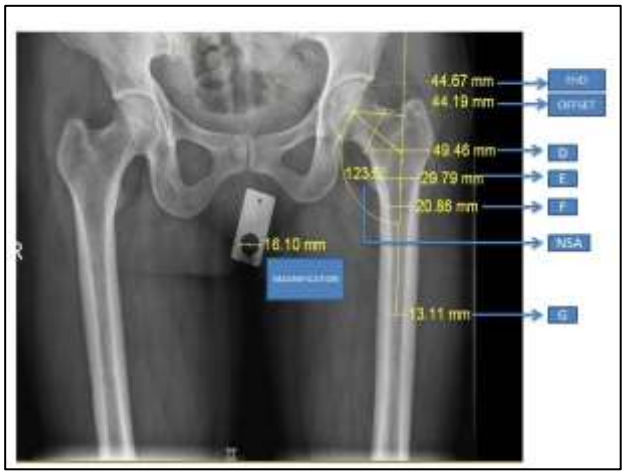

Figure 1: Radiograph templating.

Methodology of templating

Endosteal diameters

The endosteal width is measured at various locations based on reference lines which have been already defined as per Noble P C et al. The apex of the lesser trochanter is taken as the first landmark. The endosteal width at the level of the apex of lesser trochanter (E), endosteal width 20 mm above (D) and below (F) the lesser trochanter and 10 cm below the lesser trochanter (G) is measured. The mid-point of these endosteal width lines are connected to form the axis of the shaft of femur. One more point is taken measuring 10 cm distal to the apex of the lesser trochanter (G) which is considered as the isthumus. Endosteal width at that level is also measured.[3-5]

Femoral head diameter

The femoral head diameter is taken as the largest vertical diameter (superior-inferior) of head perpendicular to the axis of the neck of femur. The neck axis is drawn by drawing neck widths at 2 regions on the neck of femur, preferably in the trans-cervical and sub-capital region. The midpoints of these two lines are joined and extended further to form the axis of the neck. The femoral head diameter is measured perpendicular to this line taking the largest superior-inferior diameter of the femoral head.

Horizontal offset

The horizontal offset is also known as the actual femoral offset. The horizontal offset is measured as the distance between the centre of the femoral head to the axis of the shaft of femur. The x ray is taken in the said protocol mainly to reveal the proper and maximal offset of the femur.[6]

Neck shaft angle

The neck shaft angle is the angle subtended between the shaft axis and the axis of the neck of femur.[3,4,6]

Canal flare index

The ratio between the endosteal diameters 20 mm above the lesser trochanter (D) and at the level of isthumus (G) is called the canal flare index. Based on the values of canal flare index they were grouped in to normal (3-4.7) , champagne flute (high tapering in the proximal segment 4.7-6.5), stove pipe (a straight proximal femur relative to distal).[3]

The diameter of the magnification marker in the radiograph is determined for identification of the radiographic magnification error.

Cadaveric dry femora- study

The second part of the study involved with measuring the endosteal dimensions of cadaveric femur specimens. This was done to find out the true anthropometric parameters

of proximal femur in addition to knowing the fit of available femoral stems, So as to determine mismatch between implant and bone if any.

In our study we have taken 50 cadaveric femora. The cadaveric femora were cut at various positions so as to ascertain the endosteal dimensions at various regions of the cadaveric femur. The femora were cut using a motorized cadaveric cutting saw in the Department of Anatomy- PSGIMSR. The endosteal dimensions were measured using a Vernier calliper, at the regions mentioned below.

Figure 2: Cut sections of dry bones at various reference levels (left to right – D, E, F, G).

Figure 3: Method to measure neck shaft angle of cadaveric dry bone.

RESULTS

The mean femoral head diameter was 47.41 mm with a 95% confidence interval for the mean values, a standard deviation of ±4.5 mm. The mean offset in the study population was found to be 42.75±4.3 mm. The mean CFI was found to be 3.23±0.5.

Table 1: Results of radiographic study.

	Mean	SD	Minimum	Maximum
Age	47	10	25	75
Femoral head diameter	47.41	4.5	35	57
Medullary canal width				
D	43.79	5.2	33	61
E	27.35	4.3	17	43
F	19.92	3.5	12	31
G	13.88	2.8	9	23
Horizontal offset	42.75	4.3	34	53
Canal flare index	3.23	0.5	2	5
Neck shaft angle	126.03	4.6	114	137

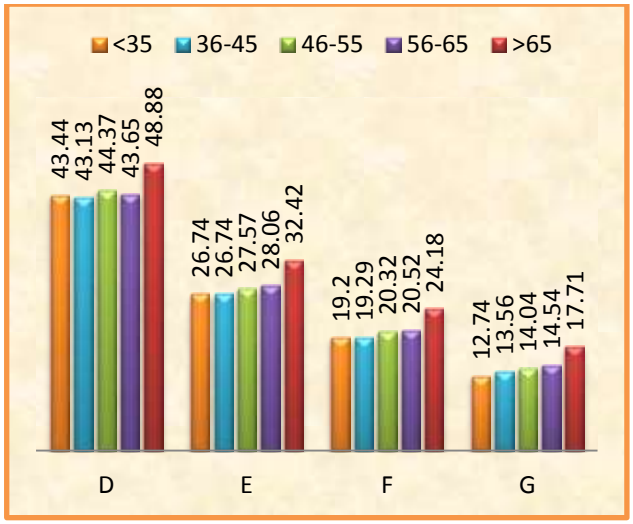

Figure 4: Mean medullary canal width at various levels matched with different age groups.

The above Figure 4 explains the difference in the medullary canal width as the age groups progressed there was a tendency towards increase in the mean width of the endosteal canal diameter.

Table 2: Age wise distribution of canal flare index.

Age group	Stove pipe(<3.0)	Normal (3.0-4.5)	Champagne	Total
<35	4	15	0	19
35-45	21	51	0	72
45-55	14	42	0	56
55-65	12	13	1	26
>65	2	3	0	5
Total	53	124	1	178
%	30%	70%	1%	100%

In the study population 30% had a stove pipe appearance of medullary canal with mean CFI <3. 70 % of the population had normal appearing femora with CFI ranging from 3-4.5 as shown in Table 2.

DISCUSSION

The aim of our study is to evaluate ethnic differences in the anthropometry of proximal femur of South Indians in comparison with other ethnic groups around the world.

The total population that was radiographed was 178 (n=178). There were 78 males and 100 females. The age of the participants were spaced from 25-75 years age groups. The following parameters were measured:

Femoral head diameter

The lowest femoral head diameter measured in our study was 35 and largest femoral head diameter in the study population was 57. The mean femoral head diameter was 47.41 mm with a 95% confidence interval for the mean values, a standard deviation of ±4.5 mm. The most prevalent head size in the given population was estimated in terms of mode for the given range, was found to be 49 mm.

Medullary canal diameters

Medullary canal widths were measured at various locations on the radiographs as described earlier in correlation to the prime seating points of the femoral stem. These levels are the standard reference points to address the changing geometry of the proximal femur. The mean and standard deviations were estimated for each parameter.

Mean canal widths at reference points-

- Endosteal canal width 20 mm above lesser trochanter (D)- 43.79±5.2 mm
- Endosteal canal width at the level of lesser trochanter (E)- 27.35±4.3 mm
- Endosteal canal width 20 mm below the lesser trochanter (F)- 19.92±3.5 mm
- Endosteal canal width at the level of isthumus (G)- 13.88±2.8 mm.

The distribution of endosteal canal widths at various levels were analysed with their age group wise distribution.

As the age groups progressed there was a tendency towards increase in the mean width of the endosteal canal diameter. This was most significant in the >65 years age groups. This was consistent with decreasing trend of canal flare index as age progressed.

Canal flare index

The mean and standard deviation for the same was calculated. The mean CFI was found to be 3.23±0.5. An age wise distribution of the canal flare index.

In the study population 30% had a stove pipe appearance of medullary canal with mean CFI <3.70% of the population had normal appearing femora with CFI ranging from 3-4.5.

There was progressive tendency towards stove pipe appearance of femoral endosteum as age progressed. Most strikingly noted in the >65 years age group with a mean canal flare index of 2.86. The younger age groups predominantly have a more normal type of femur. The distribution was found to be statistically significant in terms of distribution with progressive decline in the endosteal dimension as age progressed, and the femoral endosteum attaining a stove pipe like appearance ($p < 0.05$).

The gender wise distribution of the canal flare index was assessed, mean CFI in males was found to be 3.14±0.4, compared to the mean of 3.29±0.5 in the female pool. There were statistically significant differences in the gender wise distribution of the mean canal flare index ($P < 0.05$).

Horizontal offset

Horizontal offset calculated as the distance between the center of femoral head to the axis of the femoral shaft, which defines the abductor muscle tension was measured in all 178 subjects. The mean offset in the study population was found to be 42.75±4.3 mm.

Differences in anthropometric parameters of Indian femora vs. other ethnic population

The ethnic differences in the anthropometry of the proximal femur was assessed by matching the values of our present study with that of values previously measured in other ethnic populations. For the comparison we have taken the values of proximal femoral anthropometry of the Caucasian population according to the study by Noble P C et al (n-200), the importance of this study was its vitality in bringing up of the dimensions for creation of the various somatotypes for the cemented and un-cemented replacement armamentarium.[4] The study has allowed us to have sufficient arsenal for replacement at the same time allowing the implant to accommodate itself in to bulk of the femora. Anthropometric analysis of a Swiss population based on study by Rubin et al, French population by Massin et al, Malay population by Baharuddin et al, Thai population by Mahasavariya et al.[5,14-16]

Femoral head diameters

The difference in the femoral head diameters across various ethnic groups was assessed.

The present study showed mean femoral head diameters in the South Indian population to be 47.16±4.5 mm. The mean femoral head diameter of Indian population was compared with that of the Malay population 40.81±3.43 mm. The Malay population was found to have smallest femoral head diameters. The mean femoral head diameter of the present study was compared with the Thai population - 43.98±3.47, the Thai population had smaller femoral head dimensions. The mean femoral head diameter of the present study was compared with the Swiss population- 43.40±2.26 mm, the Swiss population had significantly smaller femoral head diameters. The mean femoral head diameters of the South Indian population was compared with the French population, they had lesser mean femoral head diameters- 45.60±4.20 mm compared to Indian population. There was no statistically significant difference in the mean femoral head diameters between Indian and Caucasian femora- 46.1±4.8 mm.

Canal diameters

The population mean endosteal dimensions were measured at four reference levels and assessed between various groups. The mean femoral head diameter at the four reference levels for the South Indian population was endosteal diameter 20 mm above lesser trochanter (D)- 43.79±5.2 mm, endosteal diameter at the level of lesser trochanter (E)- 27.35±4.3 mm, endosteal diameter 20 mm below lesser trochanter (F)- 19.92±3.5 mm Endosteal diameter at the isthumus (G)- 13.8±2.8 mm. There was no statistically significant difference between the endosteal diameters of South Indian and Malay population when matched against present study at the level of D (20 mm above lesser trochanter) and F (20 mm below the lesser trochanter). However at the level of G (isthumal diameter) it was found to be smaller in the Malay population (9.73±1.8 mm). These differences were statistically significant. There is no statistically significant difference in the mean canal diameters at the four reference levels when Indian femora were matched with the Swiss population indicating a close resemblance in terms of endosteal dimensions. There was no statistically significant difference between the endosteal diameters of the South Indian population (present study) and the French population. The endosteal widths of Indian femora was smaller by 2.0 mm in comparison to the Caucasian femora at all 4 reference levels which was statistically significant ($P < 0.05$). Even with a magnification error of 3 mm between present study and Caucasian study the endosteal dimensions are smaller by 2 mm in comparison to Caucasian femora. This suggests that the actual difference is much more.

Offset

The mean offset in the Indian population was 42.75±4.3 mm. The offset values of the South Indian population were compared with the Malay population- 31.50±5 mm. The offset of the Malay population was found to be significantly smaller than the South Indian population. The offset values of the South Indian population were compared with the Japanese population– 30.45±4.26 mm. The offset of the Japanese population was found to be significantly lower than the South Indian population. The offset of the South Indian population was compared with the French population who had a mean offset of 41±6.20 mm. The offset of the French population was close to that of the South Indian population and the difference was not statistically significant. The offset of the South Indian population was compared with the Swiss population who had a mean offset of 47±7.2 mm which was the highest among the ethnic groups in study. The mean offset of the South Indian population was 4.25mm lower than the Swiss population. This probably correlates with the bigger size of the femora among European population. There is no significant difference between the offset of South Indian population and Caucasian population- 43±6.8 mm.

Canal flare index

The mean canal flare index in the Indian population was found to be 3.23.The mean canal flare index of the South Indian population was compared to the Caucasian population which had a canal flare index of 3.8. The difference was statistically significant. The canal flare index of the South Indian population was compared with the French population who had a canal flare index of 3.6. The differences were found to be statistically significant between South Indian and French population, in terms of trending of the canal flare index. This probably suggests a better bone stock in the European population, with the European populations having more Champagne flute configuration of canal flare, therefore will favour more of an un-cemented fixation.

Neck shaft angle

The mean neck shaft angle was found to be 126 degrees in the present study of South Indian population. The verge neck shaft angle of the South Indian population was compared with the Japanese population. The Japanese population had an average valgus femoral angulation with mean neck shaft angle of 137 degrees in comparison to South Indian population.

The neck shaft angle of the South Indian population was compared with the Malay population. The mean neck shaft angle of the Malay population was 130 degrees. There was a slight inclination towards valgus mean femoral angulation in the Malay population when compared with the South Indian population in the present

study. There was no statistically significant difference between the neck shaft angles of present study and Caucasians -125 degrees. Analysis thus indicates more valgus femoral neck shaft angulations Asian population groups.

CONCLUSION

The canal flare index was found to be decreasing with age which is in correlation to the age related decrease in the femoral bone stock. The Asian and Indian femur bone is of much smaller sizes in comparison to European femurs.

Limitations of study

The radiographic study had a mean magnification of 3 mm. There was radiation exposure to normal subjects who have volunteered for the study. The age of the dry bones was not available.

Part II was a retrospective study where we took a data of patients who were operated earlier in our institute and had completed atleast 2 years of follow-up.
□ □□□□□□□□□d□□ □□□□□□□□□□With this study we found that for effective functioning of bipolar prosthesis IPJ movement remains a vital cog in the success of the bipolar prosthesis. In this study we found that there is good amount Inter-prosthetic joint movement of bipolar prosthesis at short – term and mid - term follow-up. The functional outcome is also good when Inter-prosthetic joint movement is more than 25%.

□ □□□ □rd□□Neck of femur fracture, bipolar hemiarthroplasty, inter prosthesis joint

□□□r□d□□□□□□□□

Fracture neck of femur has been recognised since the time of Hippocrates and is a common orthopaedic problem in old age and they have a tremendous impact on both the health care system and society in general [1]. Despite marked improvements in the implant design, surgical technique and patient care, they still remain an unsolved fracture as for as treatment and results are concerned among the orthopaedic fraternity around the world [2]. Fractures of the neck of femur are on increase, which is not unexpected, as the general life expectancy has significantly increased during the few decades. These fractures may double within next 20 years and fracture rate doubles for each decade of life after 5th decade of life [□]. It's has been predicted that by the year of 2050, the number of hip fractures would triple.
This is the commonest fracture in old aged individuals because of osteoporosis and advancing age causing more brittleness of bone. So prolonged immobilization during such fractures in elderly will jeopardise the life span of the patient and further complicates the problem. This forces one to totally abandon complete immobilisation to achieve a bony union, or to resort early ambulatory procedures by surgery.
The blood supply to neck and head of femur is extensive, intricate and complicated. Healing process mainly depends on good blood supply. Non-union, avascular necrosis of femoral head and secondary degenerative arthritis are the principal complications of this fracture. The surgeon may have control over the problem of non-union, whereas he may have none over avascular necrosis and arthritis. This further handicaps the treatment of these fractures as the healing process is always in doubt. It's also a known fact that hip is a weight bearing joint and many performance based functions depend on hip joint. A successful operation at hip joint should provide painless, stable hip with wide range of movements.

Under these circumstances one has to decide whether the prolonged immobilization has to be employed to achieve bony union or quick ambulation by hemi-replacement arthroplasty, to achieve fair degree of function. Since early 1950's prosthetic replacement was introduced for solving the problems of Fracture neck of femur and vitallium intramedullary prosthesis received a hearty welcome, thus preventing Non-union and avascular necrosis. The Austin – Moore and Thompson prostheses have been successful implants in treating fracture neck of femur. Disabling pain and acetabular erosions are frequent complications after the use of Moore prosthesis [□]. So in an attempt to retard the acetabular wear, prolong the life of the implant and delay the need for revision surgery the bipolar prosthesis was developed by James E Bateman in Toronto in 1974, which had the great advantage of second joint, below the acetabulum. It was named bipolar prosthesis, since it had an outer head of metal which articulates with acetabulum and a second inner metallic head which articulates with High Density Poly-Ethylene (HDPE), lining the inner surface of outer head. So hip motion is to occur at 2 interfaces – primarily at the prosthetic interface and secondarily at the metal – cartilage interface, thus minimising the articular wear. This prosthesis was found to be very useful and results were encouraging [□].

But studies attempting to demonstrate the relative movements at the interfaces have yielded conflicting results. It's known that a friction produces particulate debris from the polyethylene liner and this was thought to be the cause of foreign body reaction causing stiffening up of the inter-prosthetic joint and also osteolysis and aseptic loosening of the implant. Recent studies have shown that over a variable period of time the bipolar prosthesis will become unipolar functionally due to stiffening up of the inter-prosthetic joint (IPJ).

This study represents the assessment of the inter-prosthetic joint movement in bipolar prosthesis done for fracture neck of femur at 6months and mid-term follow-up by radiological means. By this study we will be able to assess whether bipolar prosthesis really functions as it's name suggests or vice versa as the literature suggests.

Consist of 2 parts. Part I is a (prospective study) in which Patient's who undergone Bipolar hemiarthroplasty for fracture neck of femur at PSG Hospitals were included in the study after obtaining their consent during the period of December 2011 to June 2013.

Part II was a retrospective study where we took a data of patients who were operated earlier in our institute and had completed atleast 2 years of follow-up.

M □□d □□d □□□ □□□□□

By Convenient sampling method, the patients undergoing bipolar hemiarthroplasty for fracture neck of femur were assessed radiologically for amount of inter-prosthetic joint motion during post-opeartive period.□

□

□□ □□□□□d

- For all patients Life ortho care bipolar prosthesis was used (ISO – 13485 certified company). Implant made of 316 – Stainless steel. Femoral stem length is 150 mm, diameter – 8 mm. Outer head diameter varies from 37 to 53 mm with 2 mm increment. Inner prosthetic femoral head diameter was 26 mm and the lining between outer head and inner head is made of UHMWPE (Ultra High molecular Weight Polyethtylene). Neck shaft angle is 130 degrees. 2 types of prosthesis are available (Fixed only with collar, Modular with or without collar and Extra – long stem also available).
- No funding was received from the Implant Company for the purpose of this study.

□

□r □□□□□□□□□d □□

□r □□□□r □□□□□ □□□□□ □□□

All patients who are undergoing bipolar hemiarthroplasty□for fracture neck of femur are considered for the study after getting a written consent from them. All Patients were adequately worked up before surgery and all patients were taken up for surgery within 72 hours. Certain therapeutic measures such as Deep breathing exercises, Static Quadriceps exercises, ankle pumps were taught to the patient pre-operatively. A detailed history about the mode of injury and type of fracture were noted.

□

□□r □□□□□r □□d □r □□

All surgeries were performed on an elective basis using standard□aseptic precautions, Surgery was performed under spinal or general anaesthesia. Patient was positioned laterally lying on the unaffected side. For all the patient's lateral approach (Hardinge approach) was used in our series.

□

□□□□□□□r □□□□□r □□□□□

Throughout the post-operative period adequate care was taken□ to prevent abduction and external rotation of the limb. All patients received Quads strengthening X's and mechanical DVT prophylaxis during immediate post-operative period. All patient's were started on Full weight bearing ambulation as tolerated by the patient. Once initial pain subsided specific X-rays were done to assess the inter-prosthetic joint (IPJ) and outer bearing movement was assessed during immediate post-op (24 to 48 hours) , at 6 weeks and after 6 months with operated hip in neutral and maximum abducted positions.

□

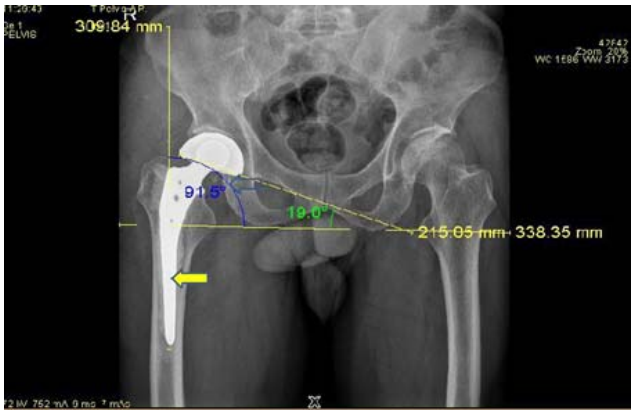
□r □□□□ □□□□□□□:

Two A.P x-rays of pelvis were taken. One with limbs in neutral position and neutral rotation and the other x-ray with affected limb in Maximum abduction are taken.

□

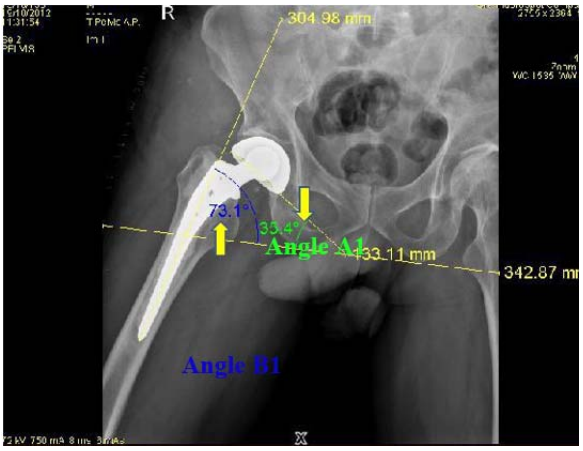
□d □□□□□□□□□□ □□□□□□ □□□

We followed the method of p lain radiographs, as described by Bochner *et al*.



On the X-ray in the neutral position, 3 lines are drawn as follows:

□□□□**1** □a line drawn tangential to the most inferior aspects of the ischial tuberosities which is used as a reference line.



□□□□**2** □drawn along the the inferior margin of the acetabulum

□□□□□□Drawn along the centre of the long axis of femoral stem.

- Angle A was defined as the intersection of the line drawn from the inferior margin of acetabular component and the reference line (line of ischial tuberosities).
- Angle B was formed by the intersection of the ischial reference line with a line drawn along the center of the long axis of the femoral stem.
- The same exercise was repeated on the maximum abduction anteroposterior radiograph also and the angles are marked as A^1 and B^1.

□□□□□□Operated Limb in Maximum Abduction

- Now, B^2 is the difference between angle B and B^1 which represents the total amount of Hip abduction of the operated limb.
- A^2 is the difference between angle A and A^1 which represents the amount of motion taking place between the acetabular component and the acetabulum (Outer bearing interface).
- As we have 2 variables ie. (B2 – total amount of abduction, A2 – motion at the outer bearing interface), the difference between B^2 and A^2 represents the amount of abduction taking place at the inner bearing (Inter-Prosthetic joint movement).
- Thus the total amount of abduction, movement at outer bearing interface and movement at inter-prosthetic joint were calculated and tabulated for each patient at each follow-up.

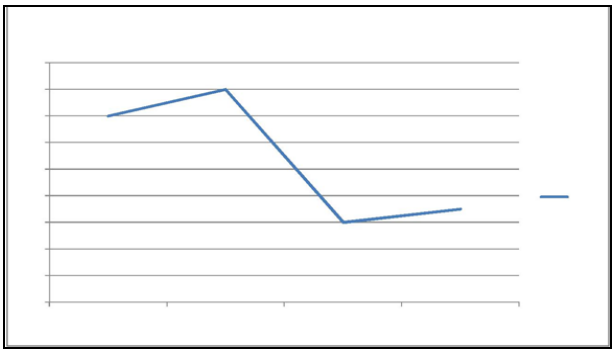
X-ray of pelvis with both hips (Abduction of operated hip) with bipolar prosthesis on right side showing Angle A1 – 43.3 and Angle B1 – 74.4 degrees.
A = 45.1, B = 83.4, A1 = 43.3, B1 = 74.4 (Degrees)
B2= 9 Degrees (Total Abduction)
A2 = 1.8degrees (Motion @ Outer Cup)
B2-A2 = 7.2 Degrees (Inter-Prosthetic Joint Motion)
A2 = 20% (Motion @ Outer Cup)
B2 - A2 = 80% (Inter-Prosthetic Joint Motion).
At the end of 6 months follow-up, in addition to Radiological assessment Functional outcome was also assessed with Oxford hip score.
Part – 2 (Retrospective study):
Patients in this group who had already undergone Bipolar H.A and completed 2 years follow-up were reviewed. The x-rays were taken in the similar fashion as described above. Functional outcome assessment was done using Oxford hip score. The retrospective study helped us to assess IPJ motion at midterm follow-up.

□

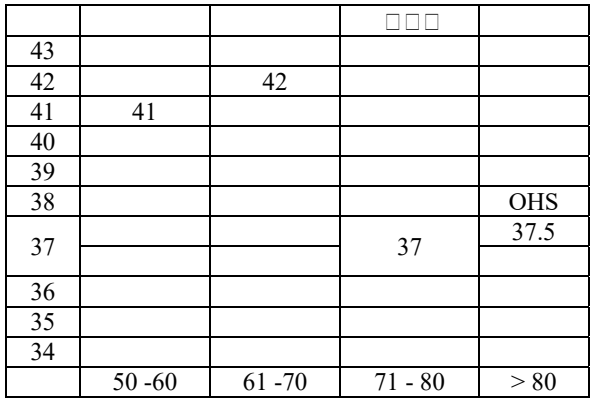
□ □□□**rd**□□ □□□□□□□**r**□□□□ □ □□

- It's useful to assess the outcome after surgical procedures by measuring 'patients' perceptions in adjunction to surgery. OHS assesses pain (6 items) and function (6 items) of the hip in relation to daily activities such as walking, dressing, sleeping etc.12 items with 5 categories of responses. Scores range from 0 to 4 (worst to best).
- Grading :
- 0-19 □ Worst, May indicate severe hip arthritis, requires some form of surgical intervention.
- 20-29 □ Fair, May indicate moderate to severe hip arthritis. Assessment by X-ray
- 30- 39 □ Good, May indicate mild to moderate hip arthritis. Non-surgical treatment, such as exercise, weight loss, and /or anti-inflammatory medication.
- 40-48 Excellent, May indicate satisfactory joint function. May not require any formal treatment.

Table 1: Radiologically Assessed Total Abduction, Outer Cup Motion And Inter – Prosthetic Joint Motion



Follow up	Patient's	Mean B^2 (in degrees)	Mean A^2 (in degrees)	Mean $B^2 - A^2$ (in degrees)	Mean A^2 (in%)	Mean $B^2 - A^2$ (in%)
Immediate						
Post-op	30	18	8	10	45	55
6 weeks	28	23	13	10	57	43
6 months	30	25	18	7	72	28



B^2 – represents Amount of Total abduction, A^2 – represents amount of movement between the outer cup and the acetabulum, $B^2 - A^2$ represents amount of IPJ motion.

Table 2: [illegible]

[illegible]	[illegible]	Mean [illegible]	[illegible]	Mean [illegible]	Mean [illegible]

Table shows comparison between the IPJ motion and OHS in Retrospective Study. Since the sample size is small in retrospective study this data was not compared with the data in the Prospective study. For the current retrospective data the analysis was not statistically significant.

□ □□□□□□□□□□□□

The basic advantage of the Bipolar prosthesis over conventional unipolar prosthesis is movement at the two interfaces ie. Between the prosthetic inner femoral head and polyethylene liner and between acetabulum and the outer head. It was proposed that the complications like acetabular erosions would be delayed or prevented by reducing wear due to sliding motion in the acetabular socket. The high molecular weight polyethylene (HMWPE) articulation also absorbs some of the impact forces during gait. This advantage of Bipolar over unipolar prosthesis has been accepted by many studies□but there have been some reports in the literature that cast doubt on the continuity of inter-prosthetic movement in a bipolar prosthesis over time. Various radiographic studies have been done in which the prosthesis was imaged in various non-weight-bearing and static weight-bearing positions to estimate the fraction of movement that is occurring at the inter-prosthetic joint in a bipolar prosthesis. Phillips[6]□ used radiograph in supine position, first in neutral and then in maximum abduction and adduction.

Verberne used image intensifier to do radiological examination. In this context we undertook the present study of evaluating the IPJ motion radiologically over a period of time at 6 months and at the end of 2 years. We had also tried to co-relate the amount of IPJ movement to Functional outcome to assess whether there's any improvement in the quality of life in patient's with good IPJ motion. We followed the method of plain radiographs, as described by Bochner *et al*. In our series the amount of IPJ movement was 55% during immediate post-op, 43% during 6weeks & 28% at the end of 6 months. The mean Inter – prosthetic joint movement at end of 2 years follow – up was 31% for patients in the retrospective group. So at the end of 6 months 66% of the patients had > 25% of Inter prosthetic joint movement in our prospective study and 80% had > 25% in the retrospective study. However we are not analyzing the same group of patients in the prospective and retrospective study & the sample size of retrospective study is small. This could have probably resulted in higher inter – prosthetic joint movement at the end of 2 years. Drinker and Murray reported that although some inner motion occurred in most implants, it was less than predicted. Philips TW (1987) had done a study on Fluroscopic movement in 100 patients who had undergone Bateman Bipolar arthroplasty. Out of these 100 patients Group I had 76 patients with arthritis of hip and Group II had 24 patients with neck of femur fractures. In 80% of group I patients, the prosthesis retained Bipolar function at the end of 4 years follow-up study as compared to only 25% of group II patients retained the bipolar functioning of the prosthesis□

Verbene G.H.M (1983), did a radiological study of movements of two components in Variokopf prosthesis in 20 patients with fracture neck of femur during Immediate, 1 month and 3 months post-operative period. He observed that the IPJ lost mobility and at 3 months it became almost completely stiff with inter-prosthetic joint motion of only 16.9% being retained.

Bochner RM, in a study 26 patients with Bateman's Prosthesis who were assessed radiologically for inter-prosthetic joint motion, concluded that bipolar function was retained at the end of 4 years and the motion was shared between both the joint interfaces [□]. In their study the inter-prosthetic joint motion at 6 months was 19%. In a study conducted Anil kumar rai, from Banaras hindu university, varanasi, india during the period march 2003 to january 2011 treated with BHU bicentric bipolar prosthesis, showed that in cases of fracture neck of femur, the percentage of total abduction occurring at the interprosthetic joint at 3 months was 33.74% (mean value of all the patients), which fell to 25.66% at 1.5 years and remained stationary till 6 years. So they concluded that some amount of IPJ motion is still preserved at the time of their mid-term follow-up of 6 years. Higher Inter-prosthetic joint motion was observed in the arthritic group as compared to fracture group. This could be explained possibly due to friction phenomenon.

The results of our study regarding the Inter – prosthetic joint movement was comaparable to other studies in literature. Verbene *et al*. showed only 16.9% inter-prosthetic Joint movement at the end of 3 months in 20 patients & Bochner *et al*. showed 19% movement at the end of 6 months in 18 patients. Our study had better inter-prosthetic joint movement of 28% at end 6 months. This result probably could have been due to lower sample size of the above 2 studies.

□

□□□□r □□□□□□□□□□□□□□□□□□□r □□□r □□□□□□□□□□□□□□ □□□□ □□□

1. Condition of the Acetabulum: In patients with normal articular cartilage of acetabulum, the outer cup probably slides more when compared patients with arthritis. This can probably due to friction at which the primary movement occurs in IPJ. Only at the terminal range of movements prosthetic femoral head impinges on the neck leading to movement of the outer cup.
2. The Inner femoral head size used by Verbene *et al* was 32 mm which could have probably decreased the IPJ motion, when compared to Bochner and Philips *et al* where they used 22 mm inner femoral head. In the study done by Philips TW they had suggested that lower the femoral prosthetic head size, then lower will be the friction between the Polyethylene liner & femoral head & decreased stress on outer metal cup, which will result in lower acetabular erosions.
3. In previous studies they had used prosthesis with High density polyethylene which is prone for formation of wear debris over time, which could have possibly played a role in decreasing the IPJ motion. The wear debris formed from UHMWPE is much lower than the HDPE used in those days which could have contributed to better IPJ movement.
4. Since in our study we had used Bipolar prosthesis consisting of UHMWPE liner & optimum size prosthetic Femoral Head, our patients had better inter-prosthetic joint movement when compared with Verberne *et al*. & Bochner *et al*. we also assessed the age of the patient co – relating with Inter –prosthetic joint movement, but we did not find any statistical signifance.

□□□□□□□ □□□□□□□□□□□□□□□□□ □□□□□ □□□ □□□□□□□ □□□**rd** □□ □□□ □□□**r** □□□□**d** □□□□□□□ □□□ □□□□□□□□□□□ □□□□□□□**M** □□□□□

Various criteria were used to assess the functional results following bipolar hemiarthroplasty. How best the patient is returned to the pre-fracture status has been the main criteria. In India our customs demand Squatting and sitting cross leged without difficulty. To achieve this patient should have good range of flexion, abduction, adduction and external roation at the hip and full flexion at the knee. Our final results at 6 months after bipolar hemiarthroplasty in our series were analyzed using Oxford Hip Score. The results were compared with the available western and Indian series where bipolar hemiarthroplasty was done for neck of femur patients.

Hinchey (1976)	225	52.4	20.4	10.7	16.4
Saxena and saraf (1978)[76]	82	46.1	44.8	6.5	2.6
Mukeherjee and Puri (1986)	55	29	49	18	4
Bavadekar and Manelkar (1987)	328	60		30	10
Arvade (1987)	104	70		16	14
Our series (2012 -13)	40	56	32	10	2

His table depicts the percentage of functional results following bipolar arthroplasty done for fracture neck of femur.

The difference between excellent and good results are minimal and therefore they can be gropued together as satisfactory results. In the series above Hinchey had 72.8%, Saxena [76]90.9%, Mukerjee and Puri 78%, Bavedekar 60% satisfactory results were achieved. In out series satisfactory results were achieved in 88% of our cases. Only 2% of the patients had poor results due to moderate /marked pain.

We found that there was no stastistical significance in between the age, sex Vs OHS. However we were able to analyse the relation between the IPJ motion and OHS. We found that there was significant increase in OHS in patients with IPJ motion of more than 25%. So we conclude that more the amount of IPJ motion preserved better will be the functional outcome in patients with bipolar arthroplasty done for femoral neck fractures

□

□

□□□□□□□□□

With this study we found that for effective functioning of bipolar prosthesis IPJ movement remains a vital cog in the success of the bipolar prosthesis. In this study we conclude that: There is good amount Inter-prosthetic joint movement of Bipolar prosthesis at short – term and mid - term follow-up. The functional outcome is also good when Inter-prosthetic joint movement is more than 25%.

□□□ □□□□□□□□□□□□□□□□□□□□**d**□

- In this study the patients in the prospective and retrospective are not the same. And hence the results show a trend rather than being specific.
- Sample size is small
- Long term studies are required

Issues in management of fractures complicated by compartment syndrome

Venkatesh Kumar N, Arvind Kumar SM, Vetri Ganapathi and Sairamakrishnan S

DOI: https://doi.org/10.22271/ortho.2017.v3.i4e.44

Abstract
Introduction: Compartment syndrome has been identified as an acute devastating orthopaedic emergency and early fasciotomy is the only way to prevent any complications This retrospective study proposes to analyse the issues in management of fractures complicated by compartment syndrome occurring pre-operatively and post-operatively.
Aim: To study the issues involved in the rationale for deciding the method of fracture stabilization following fasciotomy. To study the problems, complications and functional outcome of fracture stabilization. To analyze and establish methods to the optimally manage the issues involved.
Materials and Methods: A review of patients admitted in the orthopaedic department at our institution who presented with or developed compartment syndrome and associated with fractures were chosen. Passive stretch pain and serve pain out of proportion were the main clinical indicators considered. Decision to perform fasciotomy was carried out based on the differential P value and were treated with double incision fasciotomy Patients were followed up every month for the first 6 months and then every 6 months. All the patients, who were reviewed, were functionally assessed based on Upper Extremity Functional Index (UEFI) and Lower Extremity Functional Scale (LEFS).
Results: A high suspicion of compartment syndrome must be maintained for all cases. The early diagnosis and treatment within 12 hours is critical to reduce morbidity and prevent any long term sequale. Compartment syndrome causes delay in bone healing. Risk of infection is not increased.

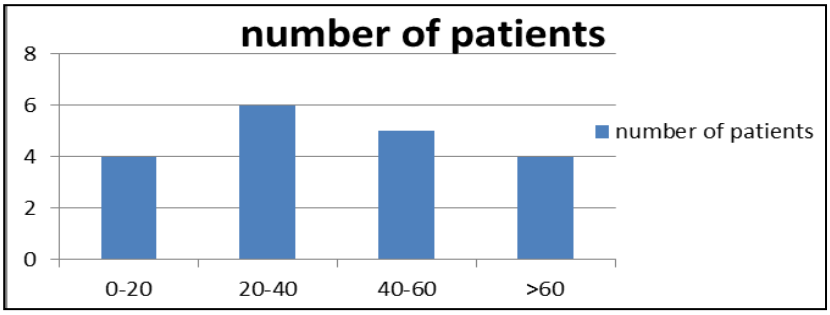
Keywords: compartment syndrome, fracture healing, faciotomy

Introduction
Compartment syndrome has been identified as an acute devastating orthopaedic emergency. Till date, compartment syndrome is one of the major complications in an injured limb. And early fasciotomy is the only way to prevent any complications due to compartment syndrome. Delay in diagnosis had been identified as the only cause of failure of treatment.
This retrospective study proposes to analyse the issues in management of fractures complicated by compartment syndrome occurring pre-operatively and post-operatively.

Aim and Objectives
Aim
To retrospectively study the issues in management of fractures complicated by compartment syndrome occurring pre-operatively and post-operatively.

Objectives
- To study the issues involved in the rationale for deciding the method of fracture stabilization following fasciotomy.
- To study the problems, complications and functional outcome of fracture stabilization.
- To analyze and establish methods to the optimally manage the issues involved.

Materials and Methods
- A review of patients admitted in the orthopaedic department at our institution was carried out. Patients who presented with or developed compartment syndrome and associated with



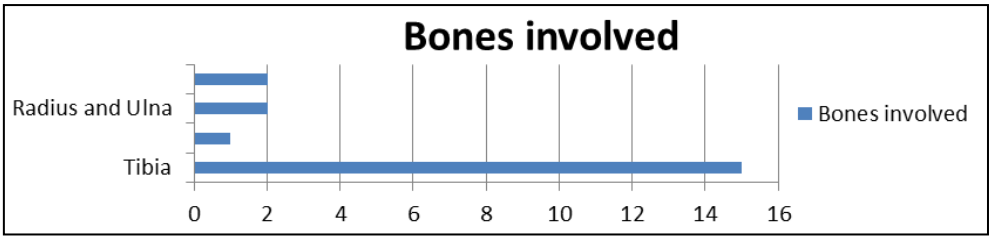
fractures were chosen.

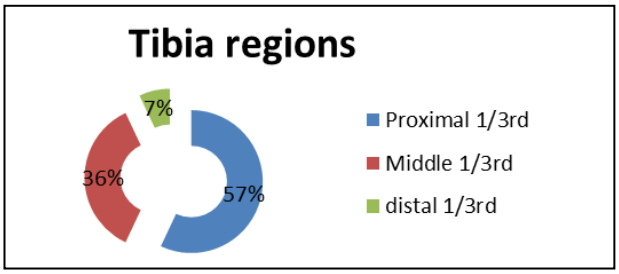
- Compartment syndrome was diagnosed clinically in all the cases, except one. Passive stretch pain and serve pain out of proportion were the main clinical indicators considered. Paraesthesia, paralysis and pulselesness were considered to be supportive of the diagnosis. Comportment pressure was measured in one patient who had a spinal injury. Decision to perform fasciotomy was carried out based on the differential p value. Differential P was calculated by the difference between the patients diastolic pressure and compartment pressure. Fasciotomy is indicated if the value was less than 30mm Hg[24].
- All the patients who had developed compartment syndrome of the leg were treated with double incision fasciotomy, anterolateral and posteromedial. Compartment syndrome of forearm was treated with single volar incision fasciotomy, while that of the thigh also was treated with a single lateral incision.
- The fracture were treated with external, internal or hybrid fixation.
- The fasciotomy wounds were taken up for secondary closure from 4-7 days after fasciotomy with split skin grafting.
- Patients were followed up every month for the first 6 months and then every 6 months. All the patients, who were reviewed, were functionally assessed based on Upper Extremity Functional Index (UEFI) and Lower Extremity Functional Scale (LEFS).
- Painless unprotected weight-bearing and presence of bridging callus on X-ray were together considered as signs of bony union.

Results

There were 21 patients who were diagnosed with compartment syndrome and underwent fasciotomy for the same. But compartment syndrome in 2 of the patients were not associated with fractures and hence excluded from the study.

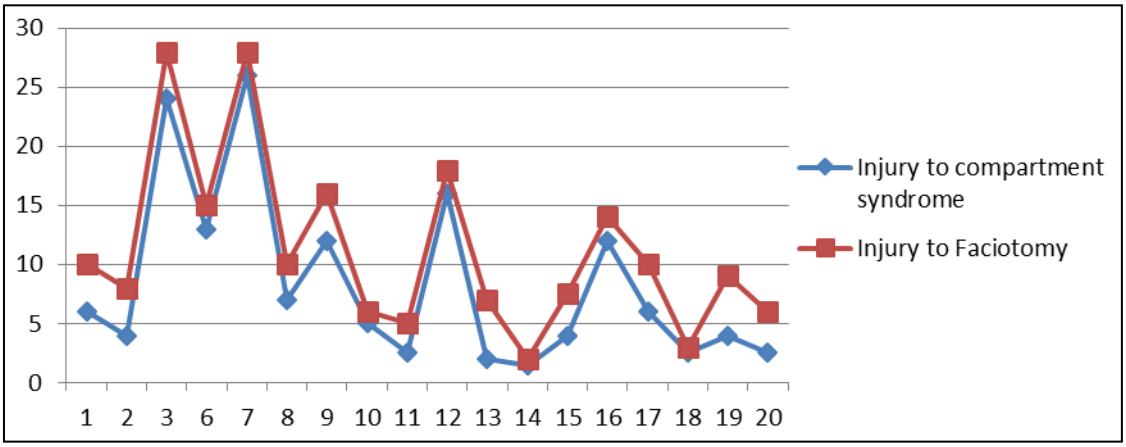
Incidence of compartment syndrome was found to be more common in physiologically young males, especially in the 3rd and 4th decades of life. This is probably due to the comparatively increased muscle mass in younger individuals.





Compartment syndrome is more frequently seen in fractures due to high velocity injuries, mainly in road traffic accidents. (Table 1)

Table 1



Mode of injury	No. of cases
Road Traffic Accident	16
Fall from height	2
Industrial injury	1
Trivial Fall	1

Fifteen of the fractures involved Tibia. Of the fifteen Tibia fractures, three involved the Tibial plateau and one involved a proximal Tibia epiphyseal injury and the rest involved tibioal diaphysis. Compartment syndrome frequently occurs in Tibia compared to all other sites. Occurance in Proximal one third Tibial is the commonest. (Graph 3, 4)

Of the remaining patients, one was a subtrochanteric fracture of the femur. The patient developed compartment syndrome of thigh probably as a consequence of the renal failure he was suffering from. Two were fractures of both bones forearm. One was a fracture around the elbow involving medial epicondyle and olecranon. One patient had additional injuries along with tibial fracture involving the ipsilateral femur and humerus and also compartment syndrome involving the forearm. One patient (Case 21) had sustained a D12 compression fracture with altered neurology of both lower limbs, along with a tibial plateau fracture (internally fixed in an institution outside). When he presented 10 days later, he had the altered neurology and also passive stretch pain with swelling of the affected leg.

The compartment syndromes were diagnosed by clinical monitoring. The delay in development of compartment syndrome following injury was 8.3 hours (1.5 hours to 26 hours, excluding case 21). The average delay in performing the fasciotomy after injury was 11.3 hours (2.5 hours to 28 hours).

There was delay in 2 of the cases (case 3 and 7) presenting to our institution as they received first aid in an outside institution primarily. Case 21, a 10 day old missed post-operative compartment syndrome, was not considered in the time of delay, because it was a case of established and missed compartment syndrome, on presentation from a different hospital. The patient's intra-compartmental pressure of all the compartments of the leg was measured using an electric arterial pressure monitor by an infusion technique. The differential P of the involved leg was found to be 10mm Hg, indicating the need for fasciotomy. Differential P of the other leg was found to be 40mm Hg.

All patients were clinically monitored for compartment syndrome from time of presentation, and also post-operatively. During the study, two distinct groups of patients were identified.

1. Patients who presented with compartment syndrome following a fracture.
2. Patients who developed compartment syndrome after surgical fixation of a fracture (cases 1, 2, 6, 8, 9 and 14)

Table 2: Grouping of patients with compartment syndrome

Compartment Syndrome Following	No. of Patients
Fracture	12
Surgical fixation of fracture (s0	6

Of the 12 patients who developed compartment syndrome after a fracture, 7 cases which were monitored from admission developed compartment syndrome. And they were taken up for fasciotomy with appropriate fixation.

Of the 18 cases considered, 6 of the fractures (cases 1, 2, 6, 8, 9 and 14), 5 tibial diaphyseal fractures and 1 ulna fracture, treated with intramedullary nailing developed compartment syndrome post-operatively. Pre-operatively, four of the fracture limbs were found to be edematous. All the 6 cases were diagnosed with compartment syndrome post-operatively after intramedullary nailing. The delay in establishing the diagnosis of compartment syndrome following intramedullary nailing was 8.5 hours (4 hours to 13.5 hours), caused probably by reduction of the fracture prior to intramedullary fixation. And the average delay in fasciotomy after intramedullary nailing was 11.8 hours (8hours to 16 hours).

Of the fifteen Tibial fractures, 6 were treated with intramedullary nailing (One-Unreamed nail), 4 were treated with Hybrid fixation, 3 were treated with external fixation and the Proximal Tibia epiphyseal injury (case 20) was treated with cancellous screw fixation. One patient with tibial plateau fracture was treated with hybrid fixator primarily. (case 17) the external fixation was converted to internal fixation primarily. (case 17) the external fixation was converted to internal fixation by means of intramedullary nailing after 3 weeks. One patient underwent internal fixation for tibial plateau fracture in an institution elsewhere before presenting to us. The subtrochanteric fracture was treated with Dynamic condylar screw and one of the forearm fractures was treated with K-wire fixation while the other was treated with Ulna square nail. And the elbow fracture was treated with internal fixation. The time lag in diagnosis, delay in fasciotomy and method of fixation of each case has been detailed in the master chart.

Except one, none of the cases had incidence infections or non-union. The patient who developed infection was a case of missed compartment syndrome.

All the patients were reviewed with an average follow-up of 33 months (6 months to 60 months). 2 patients (case 3 and 6) died due to unrelated causes. One patient (case 21) died due to sepsis leading to multi organ failure secondary to a 10 day old missed compartment syndrome.

The average time of healing in upper limb fractures was 11 weeks (9 to 15 weeks) and in lower limb fractures was 17 weeks (12 to 24 weeks). In two tibial fractures, the delay in healing needed bone grafting. Healing was relatively delayed in patients who had undergone fasciotomy 10 hours after the injury or internal fixation compared to those who had gone fasciotomy in less than 10 hours, in case of both upper and lower limb fractures.

3 patients (Case 1, 9 and 16) had neurological insult secondary to acute compartment syndrome. One patient (case 1) had weakness (Power 1/5) of the anterior compartment muscles of the leg at the time of diagnosis of compartment syndrome. He went on to recover partially (Power3/5) over a period of 3 months and then no further. Another patient had weakness (Power 3/5) of extensor hallucis longus at time of diagnosis of compartment syndrome and went on to recover in 3 weeks. One other patient (case 16) had developed severe volksmann ischemic contracture of the forearm due to delay in presentation to the hospital and hence delay in presentation to the hospital and hence delay in fasciotomy. The average in fasciotomy following injury in these cases was 13 hours (10 hours to 16 hours). Though the risk of infection is high, except one, none of our cases had any infection. Severe and extensive muscle necrosis of most of the muscles of the leg was found during fasciotomy of one of the patients (case 21), which ultimately led to sepsis and above knee amputation of the limb.

Two of the cases (case 7 and 9) had no signs of union at the end of 12 weeks both clinically and radiographically. The patients required bone grafting as a secondary procedure at 3 months to induce bony healing. The patient with volksmann ischemic contracture lost functionally of the upper limb, from elbow distally.

The functional outcome is decreased in patients who had undergone fasciotomy after 10 hours. However, younger patients showed better recovery even if they had undergone fasciotomy after 10 hours, compared to older patients.

Table 3

Patient Groups	Average functional outcome
Compartment syndrome after a fracture	85%
Compartment syndrome after fracture fixation	86%

The average functional outcome score of the cases, excluding those lost to follow-up is 68 and percentage of maximal function is 85%. The decrease in functional is 85%. The decrease in functional outcome score was due to the dysfunctional status of the affected limb in case 16. The percentage of maximal function increased to 91% on excluding case 16. The average percentage of maximal function of cases with post-operative compartment syndrome (cases 1, 2, 8, 9) was 86%, ompared to the 85% in cases primarily diagnosed with compartment syndrome (93% on excluding case 16). Mo significant difference was found in the functional outcome of both the group of patients.

Discussion

Compartment syndrome has been extensively studied. But difficulty and delay in diagnosis of the condition is the major problem encountered. The management of fractures associated with compartment syndrome also does not have fixed guidelines.

The study analysis nearly all the issues involved in management of the compartment syndrome and the associated fractures.

The study shows that compartment syndrome commonly occurred in physiologically young males, similar to all other studies [1, 21, 25, 37]. And high velocity injuries were also identified as the major cause of compartment syndrome as in most studies [1, 21, 25, 37]. Compartment syndrome of leg was the most common followed by that of forearm. And tibial fractures were the major cause of compartment syndrome of leg. McQueen et al showed that 36% of compartment syndromes follow tibial diaphyseal fractures.[22] Of all tibial fractures, proximal tibial fractures were most commonly involved. The higher incidence of compartment syndrome in proximal tibial fractures has been attributed to the vulnerable blood supply of the popliteal artery and the posterior tibial artery, due to the vessel bifurcation and enclosing tight osse of ascial canal.

Six of our cases developed compartment syndrome after the associated fracture was treated by surgical stabilization. McQueen et al found an incidence of 5.5% compartment syndrome in fractures treated by reamed nailing compared with 12.2 % in externally fixed fractures [22] The cause of compartment syndrome in post –operative cases has been postulated to be sudden decrease in compartment size following reduction of the fracture prior to intramedullary fixation

All diagnosis of compartment syndrome were made clinically. One patient was diagnosed with compartment syndrome 10 days after internal fixation of a tibial plateau fracture. The compartment syndrome was missed due to the spinal injury sustained by the patient and altered neurology below the thoracic level. All patients with tibial and forearm fractures were monitored clinically, for stretch pain and out of proportion pain, preoperatively from admission and also postoperatively.

Cases at risk of developing compartment syndrome were identified and monitored. Measure of intra-compartmental pressure was done only for patients under nerve blocks, with altered state of consciousness, with spinal cord injury and children who are not able to express themselves. In other patients, intra – compartmental pressure was measured only when clinical signs are inconclusive and to determine the need for fasciotomy. McQueen emphasized in numerous studies that diagnosis of compartment syndrome can be made only by continuous monitoring of the intra –compartmental pressure [4, 21, 22, 23, 24]. Continuous intra-compartmental monitoring is preferred to a single reading. However, Twaddle and Amendola stressed that continuous monitoring of all patients due to the need for equipment and manpower. They advised clinical monitoring to diagnose compartment syndrome and to measure intra compartmental pressure in a specified group of patients as mentioned above. And they observe that the judicious use of monitoring is required to prevent over diagnosing compartment syndrome.

Turen proposed that skeletal stabilization of fractures was needed immediately after fasciotomy to aid in the healing of soft tissues which was also concurred by Twassle and Amandola [36, 37]. Georgidas and Hake et al observed that closed fractures and uncontaminated open fractures, presenting with compartment syndrome, can be treated with primary internal fixation following fasciotomy, as there are low or negligible risks of infection and non-union.[9, 11] And this treatment protocol simplifies the bony and soft tissues cover must be obtained to cover the implant and fracture site.

Twaddle and Amendola observed that the stabilization technique used depends on the location and character of the fracture and the skill of the surgeon, but should minimize operative trauma to a limb that may already have had its

circulation compromised. Therefore, if possible, intramedullary nailing to stabilize the bone (and hence the soft tissues) is recommended. After the osteosynthesis has been completed, soft tissues coverage over the bone should be attempted [37].

All the fractures in our study were stabilized after fasciotomy by external fixation or internal fixation. Following fasciotomy, the fracture was considered to be an open one.

In metaphyseal and metaphyseal–diaphyseal fractures, we used external fixation as the method of choice for primary stabilization, We used external fixation for primary method of stabilization in 9 of the 15 tibial fractures. For juxta–articular fractures, we used external fixators or hybrid fixators. Hybrid fixators with inter fragmentary screw fixation were used in 4 cases of which 2 were tibial plateau fractures. The integrity of the articular surface was maintained by means of the hybrid fixators. The advantages of external fixation are the safety and ease of application, less devitalization of soft tissues and decreased operating time. Difficulties were faced early mobilization of the patient and wound care.

Of the 6 tibial diaphyseal fractures, 5 were treated primarily by means of external fixation. External fixation was used in diaphyseal fractures, when there was delay in fasciotomy and the viability of the muscles were in doubt and in cases without adequate soft tissues cover following fasciotomy. One of the cases treated with external fixator was taken up for intramedullary nailing at the earliest. The intramedullary conversion increased patient compliance. One tibial diaphyseal fracture was primarily treated with unreamed intramedullary nailing. Wound management was found to be easier after the internal fixation and the patient was also mobilizes early. Early mobilization, easy accessibility to the fasciotomy wounds for wound care, considerable decrease in the bulk of the implant and patient compliance are the advantage of intramedullary internal fixation.

Plate osteosynthesis was never considered in any of the tibial fractures, as the risk of devitalizing the already compromised soft tissues and infection were high.

Bony healing was delayed in all cases irrespective of method of stabilization. Time of bony healing did not differ much from that of post-operative compartment syndromes. In both the groups of patients, those who presented with compartment syndrome following an injury and those who developed compartment syndrome after internal fixation, the fracture was considered to be open. Both the groups had delayed bone healing. The average time of bone healing was nearly the same in bothgroups. And the functional outcome of both the groups of patients was nearly the same. Acute complications encountered in our study were neurological insult in three of the patients who underwent delayed fasciotomy of the three, one patient recovered completely, another patient had incomplete recovery, while the third patient had no neurological recovery. Incomplete recovery or total absence of recovery is due to the development of myonecrosis during the compartment syndrome and consecutive fibrosis of the muscles [27, 29].

Delay in diagnosis is primarily due to the delay in presentation to our centre.

Infection of the fasciotomy wounds and fracture site are expected. Fracture site is exposed during fasciotomy and the fasciotomy wound is left open for secondary closure increasing thechaces of infection. In our study, none of the cases developed infection at the fracture site of fasciotomy wound.

All the cases in our study, including the cases that developed compartment syndrome post-operatively, had delayed bone healing. This is probably due to loss of fracture haematoma during fasciotomies. But bone healing was further delayed I patients who underwent fasciotomy after 10 hours compared to those who underwent fasciotomy earlier. Similar results were also observed by Mullet [27]. Court-Brown and McQueen found that complication rates decreased to 4 % from 54 % with early fasciotomy [4].

Functional outcome was decreased I our patients who had undergone fasciotomy after 1 hours. Younger patients showed better functionality. The functional outcome of patients who had post-operative compartment syndrome was no different from those who had presented with compartment syndrome. The functional outcome of any case is determined mainly by the delay in fasciotomy followed by age than any other factor. Mullet et al found that younger patients had better functional outcome. This was attributed due to change in the muscle fiber composition and decreased muscle regeneration due to age [27].

Shortcomings of the study are the limited of number patients, the absence of a control group and also the analysis being done retrospectively. The chance of developing compartment syndrome has decreased considerably due to the early intervention following injury and advancement in monitoring patients early. In spite of these limitations zX, the factors influencing the outcome of the fractures associated with compartment syndrome were identified.

Orthopaedic surgeons must remain vigilant to identify compartment syndromes, both in in- patient and out- patient settings. Future development is likely to center around non-invasive methods of diagnosing acute compartment syndrome is being examined, like near infrared spectroscopy, which measures the amount of oxygenated hemoglobin in muscle tissues transcutaneously.

Conclusion

- A high suspicion of compartment syndrome must be maintained for all cases.
- The early diagnosis and treatment within 12 hours is critical to reduce morbidity and prevent any long term sequale.
- Compartment syndrome causes delay in bone healing.
- Risk of infection is not increased.
- External fixation is the method of choice in metaphyseal and metaphyseal-diaphyseal fractures and fractures without adequate soft tissue cover, when associated with compartment syndrome.
- Hybrid fixators with intra fragmentary screw fixation are used in juxta-articular fractures with communition.
- As bony healing is not compromised in any way, use of intramedulluary fixation is not contraindicated in diaphyseal fractures associated with compartment syndrome.

ABSTRACT

Background: Neck of femur fractures are one of the devastating injuries in the old age. Their incidence is on the rise causing immense stress on the society. One of the most commonly done procedure is bipolar hemiarthroplasty. In our study we have evaluated the acetabular erosion after hemiarthroplasty, in neck of femur fracture patients after a minimum period of 2 years and have tried to correlate it with activity level of the patient. The aim of the study were early detection of acetabular erosion; to assess the functional outcome after minimum of 2 years after hemiarthroplasty by modified UCLA score; to correlate the functional activity level and radiological acetabular erosion.
Methods: This is a retrospective radiological and clinical study. The post hemiarthroplasty plain radiographs, showing AP view of hip joint taken in the Department of Radiodiagnosis, PSGIMS&R will be studied along with activity level assessment. By Convenient sampling method, all the patients undergone cemented bipolar hemiarthroplasty, for fracture neck of femur after minimum of 2 years were assessed both radiologically and clinically. Functional activity level was assessed by Modified UCLA scoring system.
Results: By this study we suggest an easy and effective way of evaluating acetabular erosion and clinical activity. There is significant increase in acetabular erosion as the duration after surgery increases.
Conclusions: By this study we suggest an easy and effective way of evaluating acetabular erosion and clinical activity. There is significant increase in acetabular erosion as the duration after surgery increases. The clinical activity is by and large not significantly altered as the erosion progress at mid-term follow up.

Keywords: Neck of femur fractures, Bipolar hemiarthroplasty, Acetabular erosion

INTRODUCTION

Neck of femur fractures are one of the devastating injuries in the old age. It is well recognized even from the era of Hippocrates. The accurate number of hip fractures worldwide is impossible to determine, but the global incidence in the year 2000 has been estimated at 1.6 million and the projections for the future suggest further increasing numbers. In addition to the suffering of the individual the economic strain on society due to hip fracture is immense.

Management of displaced intracapsular hip fracture in elderly remains controversial. Options include hemiarthroplasty or total hip arthroplasty. Total hip arthroplasty has shown better clinical outcome and lesser reoperative rate, but in the elderly frail population who often suffer from fracture of the neck of the femur, morbidity rates are high.[1]

Hemiarthroplasty is one of the commonest procedures done for neck of femur fractures. It provides pain relief and early mobilization. The Moore and Thompson prostheses have been successful implants in treating

fracture neck of femur. Disabling pain and acetabular erosions are frequent complications after the use of Moore prosthesis.[1] So in an attempt to retard the acetabular wear, prolong the life of the implant and delay the need for revision surgery the bipolar prosthesis was developed by Bateman in Toronto in 1974, which had the advantage of hip motion occurring at 2 interfaces, primarily at the prosthetic interface and secondarily at the metal cartilage interface, thus minimizing the articular wear.

This prosthesis was found to be very useful and results were encouraging. However in long-term studies show that the bipolar prosthesis starts acting as unipolar prosthesis with time and hence leads to some erosion. However not all patients with acetabular erosions were symptomatic.

In our study we have evaluated the acetabular erosion after hemiarthroplasty, in neck of femur fracture patients after a minimum period of 2 years and have tried to correlate it with activity level of the patient.

Aim and objective

1. Early detection of acetabular erosion.
2. To assess the functional outcome after minimum of 2 years after hemiarthroplasty by modified UCLA score.
3. To correlate the functional activity level and radiological acetabular erosion.

METHODS

Source of data

This is a retrospective radiological and clinical study. The post hemiarthroplasty plain radiographs, showing AP view of hip joint taken in the Department of Radiodiagnosis, PSGIMS&R during the period between June 2015 to May 2016 will be studied along with activity level assessment. A total of 22 patients were evaluated.

Mode of data collection

By convenient sampling method, all the patients undergone cemented bipolar hemiarthroplasty, for fracture neck of femur after minimum of 2 years were assessed both radiologically and clinically.

Inclusion criteria

All patients operated for neck of femur fracture with cemented bipolar hemiarthroplasty after a minimum period of 2 years.

Exclusion criteria

Exclusion criteria were surgical site hip Infection; any preexisting pathologies around the hip; previous hip surgeries; post-operative periprosthetic fractures; neurological conditions like CVA, parkinsonism.

X-ray technique

A plain anteroposterior view of the operated hip joint is taken and assessed for acetabular erosion grading (Figure 1) following the technique of SakrMazen, MD, Girard Julien, MD and FakihRiad, MD. Patient positioned in supine, using digital X-ray, cassette tube distance is set to 100 cms and the beam is centered directly over the hip.

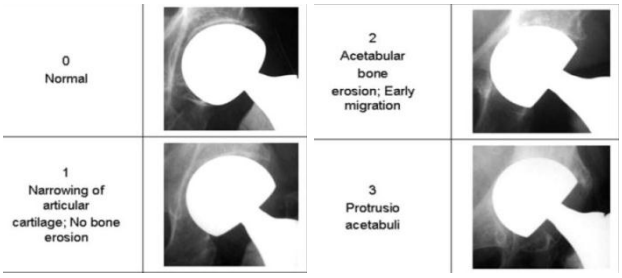

Figure 1: Grades of acetabular erosion.[2]

Activity level assessment[3]

Table 1: Functional activity level was assessed by modified UCLA scoring system.

Modified UCLA scoring system
1. Completely inactive, dependent on other and cannot leave the residence.
2. Mostly inactive or restricted to minimum activities of daily living
3. Sometimes going to social outdoor activities or visiting neighbours.
4. Regularly going to social outdoor activities or visiting neighbours.
5. Sometimes engaging in unlimited house works or shopping.
6. Regularly engaging in unlimited house work or shopping.
7. Regularly using staircase to climb.
8. Lifting or playing with small children.
9. Involving in heavy labour works.

Data analysis

Data collected were entered in Excel Spread sheet and analyzed using STATA statistical software package release 11. We used the two-sided independent-samples t test to compare means across dichotomous variables (i.e. men v. women); the one-way ANOVA test for comparison of means across multilevel variables. Simple calculations like Percentages, Proportions and Mean

values were derived. A type I error of 0.05 was considered in all analyses.

RESULTS

Table 2: Total number of participants according to gender.

Gender	Number of participants
Male	12
Female	10

Table 3: Total number of participants according to age.

Age in decades	Number of participants
60-69	9
70-79	11
80-89	1
90+	1

Total number of patient included in this study was 22. Total number of male patients 12, total number of female patients 10 and mean follow up age was 65 years. Right side hip involved was 11 and left side hip was 11. The mean follow up period was 3.54 years. The mean modified UCLA score was 6.22.

Table 4: Mean Modified UCLA score according to gender.

Gender	N	Modified UCLA score
Men	12	6.08±0.9
Women	10	6.4±0.7

The number of patients in Grades 0 and 1 acetabular erosion was 16 (72.70%) and in Grades 2 and 3 were 6 (27.30%).

Table 5: Mean acetabular erosion grade according to side affected.

Hip side	Number of participants
Left	11
Right	11

Table 6: Distribution of patients according to acetabular erosion grades.

Acetabular erosion grades	No. of patients	
Grade 0 and Grade 1	16	72.70
Grade 2 and Grade 3	6	27.30
Total	22	100%

The mean acetabular erosion when correlated with duration since surgery was statistically significant with p<0.001. Grade 0 & 1 has a mean value of 2.81 years and Grade 2 & 3 has a mean value of 5.75 years. This shows there was increased acetabular erosion as the duration post-surgery increases.

Table 7: Distribution of the study participants based on duration since surgery and grades of acetabular erosion.

Duration since surgery	Number of study participants	Erosion	No.	%
<4 years	18	0 and 1	16	88.9
		2 and 3	2	11.1
4 years	4	0 and 1	0	0
		2 and 3	4	100

Table 8: Mean duration since surgery (in months) according to acetabular erosion grades.

Acetabular erosion Grades	N	Duration since surgery
Grade 0 and Grade 1	16	2.81±0.32
Grade 2 and Grade 3	6	5.75±2.36

P<0.001.

The acetabular erosion grade when correlated with modified UCLA score was not clinically significant with p=0.71. In acetabular erosion Grade 0 and 1 the modified UCLA score was 6.33 and in Grade 2 and 3 the modified UCLA score was 6.18. Since the sample size was small the significance could not be correlated statistically. As the age of the patient increases there was a gradual reduction in activity.

Table 9: Mean Acetabular erosion grades according to duration since surgery (in months).

Duration since surgery	N	Acetabular erosion grades
<4 years	18	0.67±0.69
4 years	4	2.25±0.51

P<0.001

80-89	1	6±0
90+	1	5±0

Table 8 and shows description about Mean acetabular erosion grades according to duration since surgery (in months). This is statistically significant with P-value (<0.001) Erosion increases as the duration increases.

DISCUSSION

Incidence of fracture neck of femur is increasing gradually, probably due to increase in life expectancy of individuals.[4] The ideal treatment is still controversial[5]. Two common procedures done for elderly people are hemiarthroplasty and total hip arthroplasty. Some people advocate primary total hip arthroplasty for neck of femur fracture in elderly. Total hip arthroplasty results in more functional activity level and lesser reoperative rates but has more morbidity.

Hemiarthroplasty is more economical especially in developing countries like India and has lesser morbidity, but has a higher reoperation rate when compared to total hip arthroplasty.

The long term complications of bipolar hemiarthroplasty are acetabular erosion, aseptic loosening and infection.[6] Bipolar prosthesis is thought to have lesser incidence of acetabular erosion than unipolar prosthesis due to reduced movement occurring at acetabular prosthesis interface.

In this study we have tried to assess the acetabular erosion by radiological grading and functional outcome by modified UCLA scoring after a minimum period of 2 years after hemiarthroplasty.

Total numbers of patients assessed in this study were 22 and all underwent cemented bipolar hemiarthroplasty. The mean period of follow up was 42 months (range 2 years - 7 years). Six patients (27.30%) had a moderate to severe acetabular erosion and sixteen patients (72.70%) had minimal or no erosion. The grade of erosion was found to increase with follow up interval. With the follow up period of less than 4 years (18 patients) 16 patients (88.9%) had nil or minimal erosion and 2 patients (11.1%) had moderate to severe erosion. With follow up period of more than 4 years 4 patients had moderate to severe erosion. The mean follow up period in our study was 3.54 years and the significant acetabular erosion noted was 27.3% this could be compared with the study of Mazen et al, they had 33% erosion grade at the follow up period of 3 years.[7]

In this study all the patient's functional activity level were assessed by modified UCLA score, the mean modified UCLA score was found to decrease with increase in the age of the patients. Due to small study group the correlation of the modified UCLA score anti acetabular erosion was not statistically significant. One patient who had the longest period of follow up and maximum grade of acetabular erosion had a good level of functional outcome with modified UCLA score of 7. The pain did not restrict her functional activity.

Philips, London in his study found that the factors that had highest correlation were the level of physical activity and duration of follow up.[8]

Moon et al also found in their study that the progression of acetabular erosion correlated directly with the duration of articulation of the prosthesis within the acetabulum and this degeneration of articular cartilage becomes the cause of migration of bipolar cup, which is the major cause of failure of cemented bipolar arthroplasty. They also found the cause of degeneration to be multifactorial and it is accurately difficult to distinguish and measure the contributory level of each factor. They also found that all acetabular cartilage will show degeneration approximately 7 to 8 years after surgery.[9]

In our study all the 4 patients who had a follow up of more than 7 years had significant acetabular erosion. Hence the choice of total hip arthroplasty or a hemiarthroplasty in a fracture neck of femur may be determined by the life expectancy and the activity of the patient.

CONCLUSION

By this study we suggest an easy and effective way of evaluating acetabular erosion and clinical activity. There is significant increase in acetabular erosion as the duration after surgery increases. The clinical activity is by and large not significantly altered as the erosion progress at mid-term follow up.

Limitations of the study

Small study group, short period of follow up.

Funding: No funding sources
Conflict of interest: None declared
Ethical approval: The study was approved by the institutional ethics committee

A Mechanical Device for the Reduction of Distal Radius Fracture

L. Priya, N.Venkatesh Kumar, M.SanjayBalaji, C.V.Revanth

Abstract: ***Distal radius fracture is one of the most common fractures that occur to a person or a child who undergoes any accidents or has any bone diseases. There are several ways of treating this fracture. It involves relocating the fractured bone by a process called reduction. A novel method of reducing the radial bone using a mechanical device has been proposed where it decreases the number of surgeons, time required to reduce the distal radius fracture and seeks to improve the accuracy of reduction. This paper describes the mechanism of reduction, design considerations and the disease conditions for which the device could be used.***

Keywords: Distal radius fracture; reduction; internal fixation; external fixation; K-wires; Aluminium; C-arm; Fluoroscopy.

I. INTRODUCTION

A distal radius fracture is a common bone fracture of the radial bone in the forearm. Because of its proximity to the wrist joint, this injury is often called a wrist fracture. The fractured hand is immobilised during treatment. Sometimes surgery is needed for complex fractures. Specific types of distal radius fractures include Colles' fracture, Smith's fracture, Barton's fracture and Chauffeur's fracture. As a generic term for distal radius fracture "Colles' fracture" is used to avoid confusion among the names applied to specific patterns of fracture.

The most common cause of this type of fracture is a fall on an outstretched hand. In adults this fracture is the consequence of moderate to severe force such as a fall from a substantial height or a motor vehicle accident. The risk of trauma is raised in patients with Osteoporosis and other metabolic bone diseases[1]-[7].

The distal radius fracture is treated by a procedure called Reduction. Reduction is a surgical procedure to restore the fracture or realigning to the right position by displacing the bone with the application of certain amount of force. Reduction could be classified as open reduction and closed reduction. Closed reduction is a procedure to reduce a broken bone without surgery. It allows a bone to grow back together. When this procedure is done as soon as possible it works well. The fractured area of the patient is first anesthetized with hematoma block, local anaesthesia, sedation or a general anaesthesia. Manipulation are done by placing the arm under traction and unlocking the fragments [8],[9].

Various surgical tools and implants are used in orthopaedic applications. Few such tools are K-wires, internal and external fixators, nails, plates and rods. The K-wires or Kirschner wires or pins are sharpened, smooth stainless-steel pins. They are used to hold the bone fragments at the injury site. In order to keep the reduced bones and soft tissues at a distance from the injured place a surgical treatment called External fixation is done with the use of K-wires and fixators. This treatment provides unimpeded access to the skeletal and soft tissue structures for the initial assessment and also for secondary treatments that are required to fix the bone continuity and a functional soft cover [10]-[15].

Depending on the type of deformity the deformed bone is then reduced with appropriate closed manipulations. A splint or a cast is applied to immobilize and protect the broken bone. A C-arm or any other imaging medical equipment is used tocheck the fracture site and to ensure the reduction was successful.

In Open reduction the fractured fragments are seen directly by dissecting the tissues. And the same procedure done for closed reduction is made.The Fig.2 shows K-wires made of stainless steel. The Fig.1 and Fig.3 shows the X-ray images of a normal hand and a hand with distal radius fracture respectively.The Fig.4 and Fig.5 shows the X-ray images of hand post internal fixation external fixation respectively.

Fig.3 X-ray image of a hand with distal radius fracture

Fig.4 X-ray image of hand post internal fixation

Fig.5 X-ray image of hand post external fixation

Treatment of distal radius fracture using casts is usually successful with healing and return to the normal function as expected. Some residual deformity is common but this often reforms as the child grows. In the elderly, distal radius fractures heal and may result in adequate function after reduction. In younger patients the injury requires greater force and results in more displacement particularly to the articular surface. Unless an accurate reduction of the joint surface is obtained, these patients are very likely to have long term symptoms of pain, arthritis and stiffness.

The surgical tools and implants used for medical applications must be biocompatible and should not induce any ill effects to the patients. High corrosion resistance, durability, lightweight, radiolucent are the most important properties the surgical tools must possess. Materials like titanium alloys, stainless steel alloys and aluminium alloys are the most widely used alloys. Depending upon the degree of severity and cost of treatment different alloys are chosen. Aluminium is a low-cost biocompatible metal and its being used in hospitals widely [16]-[18].

II. MATERIALS

The designed mechanical device for the reduction distal radius fracture was made of 1060 grade aluminium. This alloy has high corrosion resistance, light weight and radiolucent properties that are needed for the surgical procedure. Also, this material can be sterilized as many times as needed. The properties of the material don't change in time. The composition of 1060 grade aluminium is shown in the Table 1.

Straps made of Velcro are wrapped around the palmar region and the radio-ulnar region to keep the hand fixed in position. Except for the small finger, the thumb and the index, middle and ring fingers are wrapped using Chinese finger straps to keep it intact.

The Chinese finger straps are made of nylon material which is used conventionally in surgeries. These straps attached to the fingers are connected to the T shaped screws to provide traction.

Table 1: Material Composition of 1060 grade Aluminium

Metal name	Composition (%)
Aluminium	99.6
Copper	0.05
Iron	0.13
Magnesium	0.03
Manganese	0.03
Silicon	0.03
Titanium	0.03
Vanadium	0.05
Zinc	0.05

III. METHODOLOGY

The hand length and hand width combined constitutes the hand size. The average hand length and width for male are nearly 190mm and 85mm respectively. The average hand length and width for female are nearly 170mm and 75mm respectively. Keeping these values into consideration the Wrist reduction device was made.

A. Design and Implementation of Wrist Reduction Device

The designing and implementation of the Wrist reduction involved several steps. Initially the model of the device was designed using PTC Creo, CAD software. Then a prototype of the model was done using 3D printer. The prototype was made of polylactic acid. The functionalities of the device were tested to know if it suits the required constraints. After few modifications the final Wrist Reduction Device was made using Aluminium alloy.The Fig.6 explains the designing and implementation of Wrist Reduction Device in the form of flowchart. The designed Wrist Reduction Device is shown in the Fig.7. The Wrist Reduction Device is made to produce load by adjusting the center radial adjuster. It can also withstand high loads as much the hand could handle.The dimensions of various components in Wrist Reduction Device are tabulated in Table 2.

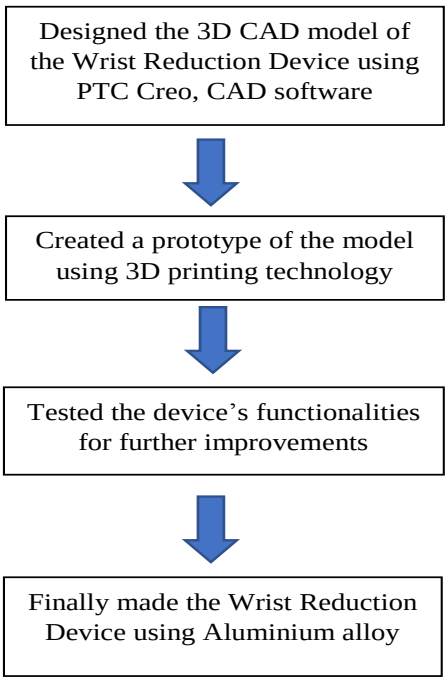

Fig.6 Flowchart of designing and implementation of Wrist Reduction Device

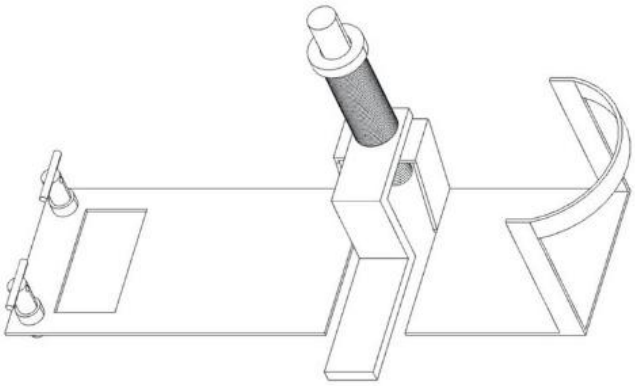

Fig.7 The 3D CAD model of the designed Wrist Reduction Device

Table 2: Dimension of various components

Parameter	Dimension (mm)
Pitch of the external thread	1.5 mm
Pitch of the internal thread	1.0 mm
Thicknesss of the Wrist and Base plates	3.0 mm
Length of the Wrist plate	150 mm
Length of the Base plate	140 mm
Width of the Wrist plate	65 mm
Width of the Base plate	65 mm

B. Mechanism of Reduction by the Mechanical Device

The mechanical Wrist Reduction Device has 2 plates. One for keeping the palmar region and other for placing the radio-ulnar region. These two plates are called Wrist plate and Base plate. These two regions are wrapped using straps or crepe bandages to avoid movements and keep the hand tight to the device.

In the first step, the thumb and the index finger, middle finger and ring finger are inserted into the Chinese finger straps. The fingers are fastened. The Wrist plate has two T shaped screws. After fastening, one nylon rope strapped to the thumb is attached to T shaped screw in front of it. Another nylon rope strapped to the three fingers is attached to T screw in front of it. The two T shaped screws are rotated to provide traction as required. The Wrist plate and Base plate are immovable and kept in horizontal direction while providing traction. The shaft with threads and a small circular nut present in the middle portion is interlocked. It keeps the plates fixed.

In the second step, the shaft is rotated to keep the Wrist plate in the required angle with respect to the shaft. The shaft is again interlocked with the nut. The Base plate and Wrist plate are made immovable again. As a result, ulnar deviation is done.

In the third step, the middle L-shaped part is raised and lowered by rotating the radial adjuster. As a result, the proximal fragments or the broken bone gets elevated. The broken bone gets aligned in the right position.

Either local anesthesia or general anesthesia is given to the patient prior to the reduction procedure. The bones of the hand are drilled to make bores of required dimensions. Then K-wires and fixators are inserted into the bones through the bores to keep the reduced bones in the fixed position. The position of the K-wires is monitored using a C-arm or fluoroscopy to guide it through the bones. After that a plaster of paris cast is made over the hand and the arm is allowed to heal.

This procedure can be done by a single surgeon alone.

The chances of occurrence of fracture due to the usage of the device in older patients and in patients with Osteoporosis are very low since the device itself doesn't produce any force or amplify the applied on it. But it only translates the force applied by the doctor on the wrist. The Fig.8 shows a surgeon operating a C-arm equipment to view the fractured hand while doing Wrist reduction.

Fig.8 A surgeon operating C-arm equipment

C. Mechanism of Reduction by the Conventional Method

In the conventional method, more than two surgeons are required. Anaesthesia is provided to the patient prior to surgery. The patients hand is placed over a radiolucent table. Then traction is provided to the hand by a surgeon while another surgeon holds the radio-ulnar bones. Then ulnar deviation is done by one surgeon. Then one or two surgeons realigns the fractured bone to the original position by the reduction procedure. Then K-wires and fixators are inserted to the bone depending on the severity. These are guided by X-ray based imaging machines like C-arm or fluoroscopy. A C-arm is widely used to guide the K-wires. Then a palter of paris cast is made over the hand to heal.

IV. RESULTS AND DISCUSSIONS

Thus, a low cost mechanical device is a viable inclusion in the orthopaedics for reduction of broken wrist. By using this device, the human effort needed to reduce the broken wrist is reduced. The Front view of the Wrist Reduction Device is shown in Fig.9.The Top view of the Wrist Reduction Device is shown in Fig.10.The Front view of the Wrist Reduction Device with a patient's hand placed in the device is shown in Fig.11.

Fig.9 The front view of the Wrist Reduction Device

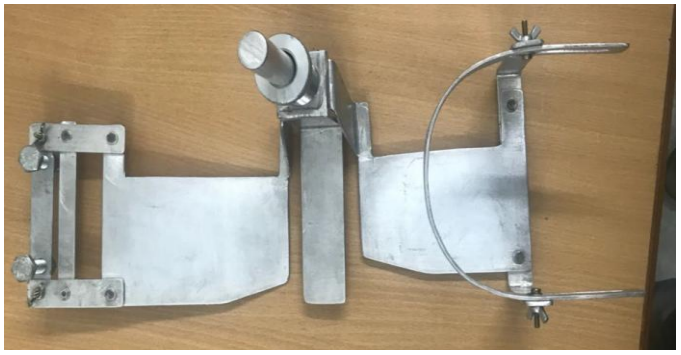

Fig.10 The top view of the Wrist Reduction Device

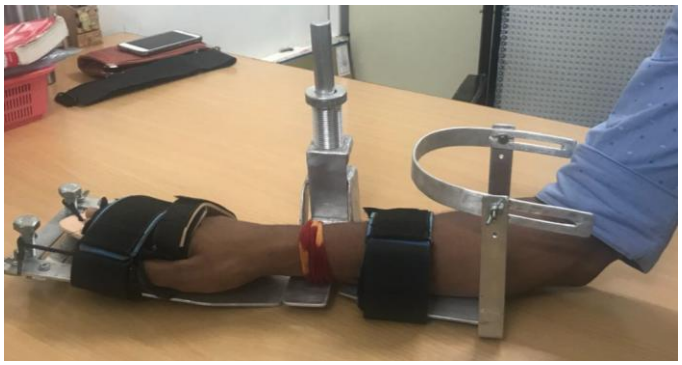

Fig.11 The front view of the patient's hand placed on the Wrist Reduction Device

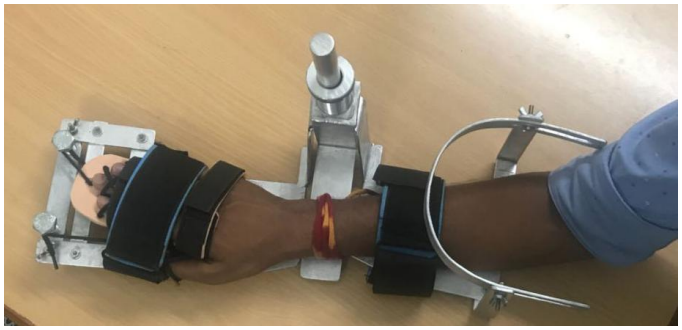

Fig.12 The top view of the patient's hand placed on the Wrist Reduction Device

The Top view of the Wrist Reduction Device with a patient's hand placed in the device is shown in Fig.12 shows the Wrist Reduction Device made of Aluminium. Comparison of conventional method and the mechanical based Wrist Reduction Device is to be done on the following aspects; Time taken for reducing the distal radius fracture, percentage of cases on which successful

reduction is achieved, accuracy of reduction achieved and feedback from doctors is to be used for the purpose of concluding whether the proposed method is better than conventional method. This device could be used for both invasive and non-invasive reduction of fractures bone.

V. READINGS

Department of orthopaedics, PSGIMSR were evaluated and accepted the research study entitled "*Wrist Reduction device*" and Clinical trial is held for a period of six months at PSG Hospitals, Coimbatore.

- **Objectives:** To design a mechanical device to reduce the human effort needed to fix a broken wrist.
- **Background:** medical practice in PSG Institute of Medical Sciences and Research.
- **Participants:** 20 patients- with broken wrist.

This device is operated by the physicians and they have rated the device based on its performance, stability and device longevity. Table 3 shows the rating values evaluated by the medical staffs in the scale of 5.

Table 3:Physician's outcome towards the device

Number of Physicians	Performance	Stability	Longevity
Physicians 1	3.5	4	4.5
Physicians 2	4	5	4.5
Physicians 3	3	3.5	5
Physicians 4	5	4.5	4.5
Physicians 5	4.5	4	5

VI. CONCLUSION

The Wrist Reduction Device can be used as an alternative method to reduce the distal radius fractures which relies upon manual reduction procedures for reducing it. By using the wrist reduction device, the human resource and human effort required to reduce the distal radius fracture can be dramatically reduced and by doing so the time consumed to reduce the most commonly occurring fracture is reduced thus making the medical personal available to treat the patients when they are most needed. An additional axial pull adjustment can be added. The device can be adjusted to fit all lengths of hand. The pitch could be optimised. More clinical trials should be done for improving the device's functionality. The device costs around Rs.5500 (INR). It could be made available in the market and used by many doctors for the reduction procedure. It might decrease the medical expenses of the patient if used.

"Outcome Analysis of Proximal Humerus Fractures Treated by Minimal Internal Fixation".Journal of Evolution of Medical and Dental Sciences 2014; Vol. 3, Issue 20, May 19; Page: 5585-5591, DOI: 10.14260/jemds/2014/2633

ABSTRACT: The aim of the study was to evaluate the functional outcome in patients treated with proximal humeral fracture who were treated with minimally internal fixations like K-wires, osteosutures etc.

KEYWORDS: Proximal humerus fractures, minimal internal fixation, k-wires, osteosutures, osteoporosis, functional outcome.

INTRODUCTION: Treatment of shoulder fractures has been the subject of much controversy and confusion. This is because of the complex nature of injury which makes the treating surgeon difficult to comment about displacement without proper x – rays, associated soft tissue injury (rotator cuff) and such injuries needs meticulous post-op rehabilitation[1].

Accurate definition of the type of fracture, patient compliance problems that limit rehabilitation medical co-morbidities affecting prognosis, and time from injury to treatment are critical factors affecting outcomes of these injuries. Additionally, technical factors in the surgical reconstruction of these fractures require surgical experience that few surgeons have the opportunity to develop[2].

About 2 to 3 % of upper extremity fractures occur in proximal humerus and 3/4th of these fractures occur after 60 years of age and commonly seen in women. More than 85% of proximal humerus fractures are minimally displaced. In the remaining 15% of fractures, only a few are severe fracture dislocations, about which much debate is centered [3, 4].

The aim of the study was to evaluate the functional outcome in patients treated with proximal humeral fracture who were treated with minimally internal fixations like K-wires, osteosutures etc.

MATERIALS AND METHODS: This study was conducted at PSG Institute of Medical Science and Research, Coimbatore. Our study was a retrospective study and involved 21 patients with proximal humerus fractures that were treated by minimal internal fixation. The age of our patients ranged from 21 to 70 years. Fractures were classified according to Neer's classification system. Patients were initially assessed for airway, breathing and circulation. Initial immobilization was done for the affected arm with a sling. Assessment was also done for associated injuries. Routine antero posterior and lateral radiographs were taken and CT-Scan was done if needed.

Inclusion Criteria:

- All two-part to four-part fractures according to Neer's classification[3].
- Those fractures treated by closed reduction and percutaneous pin fixation, osteosutures and cancellous screw fixation.

DOI: 10.14260/jemds/2014/2633

Exclusion Criteria:

- Those fractures treated by conservative methods, plate osteosynthesis and nailing.
- Head splitting fractures.
- Compound fractures.

Operative Technique: General/Regional anesthesia was administered and the patient was placed in dental chair position with a sand bag underneath the scapula.

Parts were prepared and draped and closed reduction with arm abducted to about 70 degrees to 80 degrees was performed with an assistant holding at the elbow and progressive controlled longitudinal fraction, while posterior pressure is applied to humeral shaft to reduce it underneath the humeral head.

The accuracy of reduction was checked under image intensifier and if satisfactory, the same was fixed using either threaded or smooth 'K'- wires. Two 'K' wires were passed through the lateral aspect of humerus shaft just above the deltoid insertion and one through the anterior cortex. If greater tuberosity was displaced, then two more pins were inserted in retrograde for reduction and fixation.

If after closed reduction, the alignment was found not to be in satisfactory position or if the fragments were badly displaced, then open reduction with minimal soft tissue dissection was performed through deltopectoral approach. The fragments were fixed either with osteosutures using non-absorbable materials preferably ethibond, 'K' wires or cancellous screws carefully avoiding anterior humeral circumflex artery.

Post operatively, the arm was immobilized in a sling. Antibiotic coverage was given routinely (3 doses). Immediate post-operative X-Rays were done. Passive and pendulum exercises were started as soon as pain and swelling subsided. Due attention was given to pin tracts. Arm sling was discontinued by the third week and full range of movements was started.

Follow-up radiographs were taken at four weeks to six weeks-time. Pins were removed when radiological evidence of union was seen usually at five weeks (range four to ten weeks). Patients were then reviewed once in a month for initial two months. Then once in every three months for nine months.

FOLLOW UP ASSESSMENT:

POST OPERATIVELY:

- Adequacy of fixation, Re reduction/secondary procedure.
- Joint penetration, Axillary nerve, Pin infection.

FUNCTIONAL ASSESSMENT:

- ROM by goniometer, Neer's scoring

RADIOLOGICAL ASSESSMENT:

- Pin migration, Neck shaft angle, Union of fracture, Metal failure, Myositis, Avascular necrosis

OBSERVATIONS AND ANALYSIS: Out of 21 patients treated, 13 were male and 8 were female, with highest incidence at 4th decade. Right side being the dominant side was more affected, which

DOI: 10.14260/jemds/2014/2633

accounted to 57 % and most of the injuries were due to the two-wheeler accidents.3-part fractures constituted to be the common type.

Common mode of fixation was by using K-wires.

Results are depicted in tabular columns.

DISCUSSION: The shoulder is the link of the thorax to the upper extremity. The function of the upper extremity is to provide mobility and power that allows a range of function, from powerful explosive movements seen in athlete actions (e.g., throwing a baseball 100 mph) to very accurate fine movements (e.g., placing the arm in a position to perform microscopic surgery).

Daily independence requires the ability to position the hand within the range of an imaginary sphere and to provide access to both sides of the alimentary system. Disorders of the shoulder, in addition to limiting function, also can produce pain, which can affect the ability to sleep comfortably and the ability to easily obtain gainful employment. Therefore, fractures that involve the proximal humerus (that portion involved with the glenohumeral articulation) can be devastating to quality of life. These fractures also can cost society a significant loss of productivity from otherwise viable members in the workforce.[2]

In this era of biological osteosynthesis, the concept of biological fixation offers many advantages in managing not only complex and high energy fractures but also in Juxta articular fractures as well as in fractures of non- weight bearing bones. In regard to proximal humerus fractures, this concept can be applied by means of closed reduction and percutaneous pinning or a minimal open reduction and internal fixation using Osteosutures or cancellous screws.

Although accurate anatomic reduction cannot be achieved at times, a good functional outcome can be attained which is mandatory for our activities of daily living. The advantages of such fractures being stabilized by minimal techniques are, minimal fixation modes but maintaining the cuff integrity, minimal scar, maximum anatomical restoration, better enhancement of fracture healing, early post-operative rehabilitation and easy implant removal.

Literature review[5-25] has shown that in managing the fractures of proximal humerus, although various options like closed reduction and percutaneous pin fixation, open reduction and internal fixation or Humeral head replacement are available, closed reduction and percutaneous pinning should be reserved for physiologically young and motivated individual with two part fractures and also in minimally displaced three part fractures.

In our study, 85.7% of the patients had a good functional outcome, which is comparable or even better with that of the literature. The average age of our patient was 56 range being 20 years to 80 years, which is little older when compared to most of the studies where patients had a mean age of 43 years but this has not influenced the outcome. The most common fracture pattern in our study was three part which accounted for 57.1%.

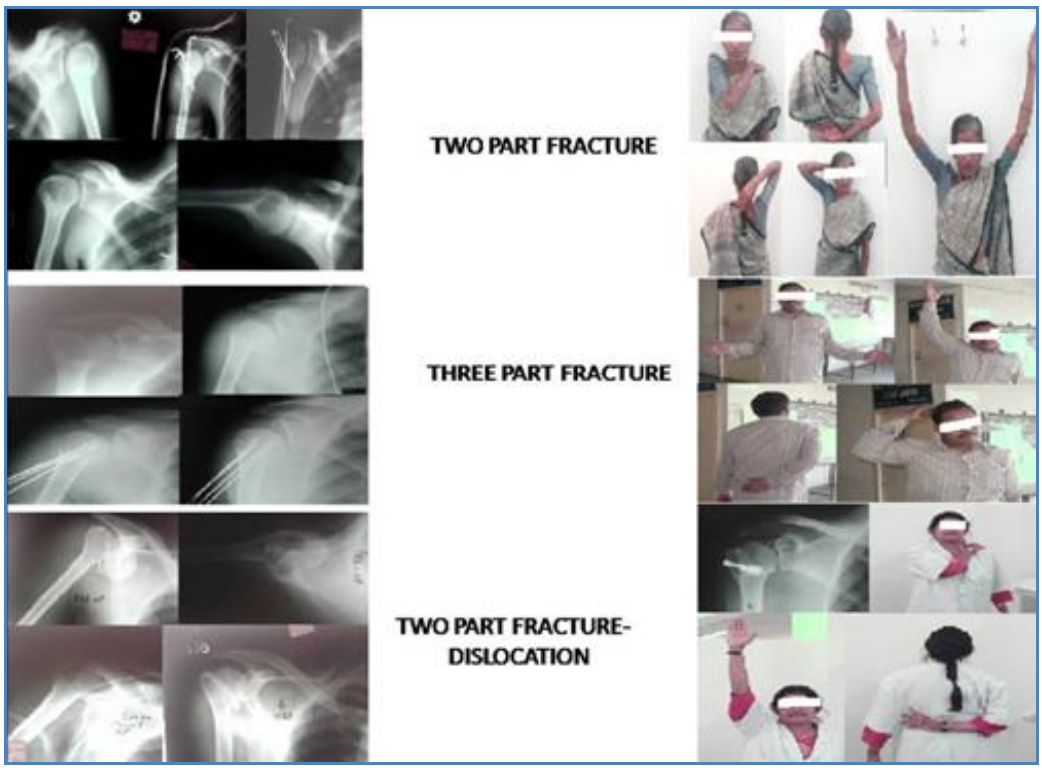
This is little contrary to that of literature where in all studies two part fractures were predominant. The common mode of fixation that was used in our study was by using closed reduction and percutaneous pin fixation with K – wires in 17 patients, which accounted for 81%. Of the remaining 4 patients, open reduction with minimal soft tissue handling was done and the fractures were fixed by Osteosutures and cancellous screws in 2 patients each. The functional outcomes of these 4 patients were good and comparable to that of Percutaneous pinning of fractures.

DOI: 10.14260/jemds/2014/2633

This may have been due to the fact, that all these 4 patients had 2 part fractures (but displaced widely) which normally has a better outcome. But fallacy is that number of patients treated with this technique is small. So statistically they are not significant. Sex distribution, side of injury and mode of injury did not have any influence on the results.

The average time of pin removal in our study was 4 weeks and the time of union being 8 weeks range (4 weeks to 10 weeks). In a study conducted by Chow et al the average time of union was 10 weeks. In another study by Hans Jaberg et al (JBJS 1992) the union rate was between 6 weeks to 8 weeks almost similar to our study. In respect to complications, one patient had superficial pin tract infection and one had minimal pin loosening which subsequently was managed by antibiotics. We did not encounter any other complications like pin breakage, pin migration, joint infection or avascular necrosis of Humeral head.

The functional outcome that was evaluated according to Neer's criteria showed 85.7% good to excellent results in our study, which in chow et al study was 84%.However this may be attributed to the occurrence of these fractures in comparatively younger middle age group of patients in our study, whose compliance for physiotherapy and ability for motivation is better whereas in most of the study these fractures are seen to occur in older age groups.



CONCLUSIONS: 2 part proximal humerus fractures yields 100% excellent/good functional outcome when treated with closed reduction and percutaneous fixation.19% fair/poor results in 3 part fractures were due to improper patient selection. Functional outcome is poor in patients > 60 years and this should be considered in patient selection along with communition and bone quality. There is always mild restriction (100) of abduction and forward flexion movement in 3 part fractures without significantly affecting functional outcome. Though technically demanding, with indirect reduction and adequate fixation, the results are good (83%).

[1]Associate Professor, Department of Orthopaedics, PSG Institute of Medical Sciences and Research, Coimbatore, Tamil Nadu, India, [2]Professor, Department of Orthopaedics, PSG Institute of Medical Sciences and Research, Coimbatore, Tamil Nadu, India, [3]Post-graduate Student, Department of Orthopaedics, PSG Institute of Medical Sciences and Research, Coimbatore, Tamil Nadu, India

Abstract

Introduction: Heeled footwear has been in use by women for centuries and has now become an integral part of the wardrobe not only in the west but also in India. Recent research suggests that up to one third of women suffer from permanent problems as a result of their prolonged wearing of heels. One in 10 women wear it at least for 3 days a week, and a recent survey found that one-third of them had permanent problems.

Purpose: Whether the high heel wear is the actual cause of back pain is not yet clear. Literatures vary in their results regarding the same. Hence, the present study was done to assess this cause and effect.

Methods: The study was conducted at the orthopedic outpatient department of a tertiary care hospital, from July 2014 to December 2014.100 female patients who were using heeled shoes and who volunteered to participate in the study were included. The heel height was measured using measuring tape and were classified into three groups (<2.5 cm, 2.5-5 cm, >5 cm). A Proforma with a questionnaire was given to all the participants and their response were noted.

Results: Out of the 100 female volunteers, who participated in the study, 44 had complaints of heel pain regardless of the heel height, 56 had back pain, and many had both heel pain and back pain complaints, based on the questionnaire evaluation. We were further able to distinguish both heel pain and back pain, based on the heel height worn, duration of wear (in years) and duration worn/day.

Conclusion: There was a positive correlation between duration of wear and height of footwear with regards to both heel and back pain. However, a definitive cause and effect could not be established because of smaller sample size.

Key words: Back pain, Heel pain, Shoes, Statistical analysis, Women

INTRODUCTION

Walking is the most common form of human locomotion from a motor control perspective, human bipedalism makes the task of walking extremely complex. One condition known to compound the difficulty of walking is the use of heeled shoes, which alters the natural position of the foot-ankle complex.[1] This thereby produces a chain of reaction effects that travels up to the lumbar vertebrae. High-heeled footwear is defined as the footwear having a heel that is higher than the toe. Throughout the history, this footwear is considered as a symbol of sexuality, class and gender. When the foot slants forward, a much greater weight is transferred to the ball of the foot and toes, which increases the likelihood of damage to the underlying soft tissues that supports the foot. When the wearer tips the foot forward, this in turn puts pressure on the lower back and hence causes back pain. This particular study on post-adolescent volunteers was aimed to study the correlation between heeled footwear and heel and back pain.

MATERIALS AND METHODS

The present study was conducted on 100 female patients who attended orthopedic outpatient department at institution during the period from July 2014 to December

Corresponding Author: Dr. N Venkatesh Kumar, Department of Orthopaedics, PSG Hospitals, Peelamedu, Coimbatore -641 004, Tamil Nadu, India. Phone: +91-9842241304. E-mail: drven@rediffmail.com

2014. Patients were drafted into the study based on inclusion criteria which included:

a. Age >15 years and <55 years
b. Without any foot and spine deformities. Patients were explained about the study and only those who volunteered and gave their consent were included in this study. The procedures followed were in accordance with the ethical standards.

The evaluation was based on questionnaire which was given to all the participating volunteers and heel height was measured with the help of inch tape as illustrated in Figures 1-3. Appropriate information collected in the questionnaire was entered in data collecting sheet for the purpose of statistical analysis.

Patients were categorized based on their age group (18-25, 25-45, 45-55), occupation (student, staff, housewife), heel height (normal [<2.5 cm], low heel [2.5-5 cm] and high heel [>5 cm]), duration of wear in years (0-5 and 5-10 years) and in hours/day (0-5 and 5-10), type of sole (leather, wooden, rubber, plastic). The data collected were statistically analyzed by Chi-square test.

Observation

A total of 100 female patients were included in the study after obtaining their informed consent. There were 63 students, 28 staff, 9 housewives who participated as volunteers. There were 12 people wearing heels with height 2.5-5 cm, 4 people wearing heels with height >5 cm and 74 people wearing heels with height 0-2.5 cm. In our study, 67 people were using soft sole type and 33 people were wearing hard sole type. There were 36 people wearing heeled footwear for more than 5 years, and 54 people were using heeled footwear for 0-5 years. 15 people were wearing heeled footwear for 0-5 h/day and 85 people were wearing heeled footwear for more than 5 h a day. Regardless of heel height worn, the duration of footwear had a significant influence on heel and back pain (Table1) and similarly prolonged wear in a day had a significant influence on heel pain (Table 2).

Figure 1: Heel height being measured

Figure 2: Method of measuring heel height using measuring tape

Figure 3: Volunteers who participated in the study

DISCUSSION

Heeled footwear has been in use by women for centuries but not all individuals wearing heels suffer from clinical problems. In ancient Egypt, wearing shoes may have served to set apart lower classes from the nobility as normal people walked around bare foot while the rich wore flat leather shoes. Moreover in ancient times, height would vary so that the higher the soles, higher the social status.

Research suggests that long-term heel use can both "compromise muscle efficiency and increase the risk of injuries." Heeled shoes slant the foot forward and down while bending the toes up, more the feet is forced into this position, more it may cause the gastrocnemius muscle to shorten.

Table 1: Relationship between heel height with back and heel pain (duration of wear in years)

Heel height	Heel pain			Back pain		
	0-5 years	>5 years	Significance	0-5 years	>5 years	Significance
0-2.5 cm (74[n])	14[n]	28[n]	0.017*	32[n]	-	0.016*

Heel height	Heel pain			Back pain		
	0-5 h	>5 h	Significance	0-5 h	>5 h	Significance
0-2.5 cm	6	36	0.053*	4	28	0.456
2.5-5 cm	3	6		3	-	
>5 cm	-	2		1	1	

*As analyzed by Chi-square test

When walking in high heeled shoes, a significant reduction in ankle plantar flexor muscle movement occurs, whereas increased work is performed by the hip flexor muscle during transition from stance to swing phase. Reduced effectiveness of ankle plantar flexors during late stance results in a compensatory enhanced hip flexor pull off. Large muscle movements and increased work at hip and knee occur while wearing high heels.[2]

Wearing high heels is thought to increase an individual's likelihood of experiencing a lateral Ankle sprain. The flexed and inverted posture of the plantar while wearing high heels may increase an individual's risk of experiencing a lateral ankle sprain.[3]

Foster *et al.*,[3] found signs of increase in ankle sprains in patients wearing high heels for a prolonged duration. Esenyel *et al.*,[2] described changes in the biomechanics of walking like increase in plantar flexion in people using high heels. In the particular study, we werenot able to assess the changes in biomechanics of foot while wearing high heels as it is a purely observational study.

There is also a definitive change in subtalar joint axis while walking on a high heeled shoe in comparison to a normal shoe, hence wearing of high heel may cause foot and heel pain.[4]

High heeled shoes cause an increase in the lordotic curve of the lumbar spine.[5] Increased ankle plantar flexion causes a kinetic chain of compensation up the lower extremity that ends with hypertonic psoas muscle, producing a lumbar hyperlordosis. A hyperlordotic lumbar spine in turn will lead to back pain.

Brent *et al.*,[9] found alteration in biomechanics of the lumbar spine. In prolonged high heels wear, chain of events around the ankle were observed, like increased ankle plantar flexion which in turn led to an increase in a lordotic curve.[6]

Eisenhardt *et al.*,[5] measured pressure distribution under foot for bare feet versus heel height and found increase in distribution related to heel height. Opila-Correia *et al.*,[7] studied the kinematics of high heeled walking and found that high heeled walking was associated with increased knee flexion in the stance phase. Kerrigan *et al.*,[6] used biomechanical gait analysis and inverse dynamics to evaluate joint loadings during high heel walking and found that even moderate high heels would contribute to osteoarthritis of the knee.[8]

Electromyography analysis of the lower limb muscles in high heel users and regular footwear users showed significantly increased leg muscle activity.[9]

Based on the observations from our study done on 100 volunteers wearing heels who came to the orthopedic outpatient department for other problems, prolonged duration of wear in years/hours of wear per day resulted in heel pain that significantly affected their daily activities. Furthermore from this study, it was observed that prolonged wear of heels in due course, also resulted in back pain which again was found to be directly proportional to duration of wear in years.[10]

Even though we have derived certain conclusive results from the study, it does have few pitfalls, for instance its an observational study and results obtained were purely based on statistical analysis of the questionnaire reports. Most of the studies done on heeled footwear considered heel height more than 9 cm as high heel, whereas in our study low heel is considered <2.5 cm while heels between 2.5 and 5 cm are considered moderate and more than which is considered as high heels. Moreover, we couldnot have a definite discrimination of the type of sole worn and no changes in the final outcome with respect to the sole type worn.[11,12]

The present study did prove it right that prolonged heels wear resulted in heel pain and back pain, but concrete justification couldn't be provided as the study was done on a small group of 100 volunteers.

CONCLUSION

This study was done with an intention to break the myth or confirm the reality that high heels footwear causes heel pain and back pain. We did succeed in obtaining a stastically significant correlation between the duration of heels wear in both hours/day and a number of year worn with heel and back pain. The pitfall of this study being the minimal sample size, and it was done as an observational study based on a questionnaire evaluation.

Abstract. Bones that provide the structural support of the body, are composed of many inorganic compounds and organic materials that all together can be used to determine the mineral density of the bone. The bone mineral density (BMD) is an index measure that is widely used as an indicator of the health of the bone. A densitometry study from dual X-ray absorptiometry (DEXA) system is a popularly used method to assess BMD. BMD values vary depending on race, age, gender and other health conditions. As DEXA is quite an expensive method and requires frequent calibration process to work properly, in this paper, we explore the possibility of developing an affordable and reliable system depending on single X-ray absorptiometry with the use of supervised learning methods. The methodology based on inference is tested on a data set consisting of spine and pelvis X-ray images of patients of varying ages between 10 and 90 years of PSG Hospitals, Coimbatore, India and the results proved to be an indicator of density of the bone.

Keywords: BMD · Classification · Supervised learning · Support vector machines · Generalized boosted regression model · Extreme gradient boosting model

1 Introduction

Bones are dynamic connective tissue that constitute the endoskeleton of vertebrates. They support and protect many organs of the body, store minerals, produce red and white blood cells. Bones have complex internal and external structure, come in different shapes, hard and strong in nature but lightweight and serve multiple functions. Bones together with muscles, ligaments and joints help in movement of various body parts. Bone is made up of bone matrix. It is composed primarily of inorganic hydroxyapatite and organic collagen. Bone is formed by the process of mineralization and calcification of this matrix around entrapped cells. Remodelling is the process of resorption followed by replacement with little change in shape and occurs throughout a person's life which tends to

phase down with advancement of age. The purpose of remodelling is to regulate and maintain calcium homeostasis, repair micro-damaged bones and to shape the skeleton during growth.

Bone mineral density (BMD) is a measure of the amount of hydroxyapatite (Hap) and mineral salts per unit area in the bone that is used as an indicator of the bone's health. The mineral content in a bone sample is evaluated by direct evaluation through the atomic absorption spectroscopy and inductively coupled plasma method or by indirect method, which consists of single or dual X-ray diffraction and computer tomography to obtain the bone mineral density. The indirect method of measurement is painless, non-invasive and involves low radiation exposure over the spine or hip region. By using direct methods, it is possible to obtain quantitative information regarding the bone mineral components, whereas in indirect methods, the information is closely related to the optical absorption of the bone tissues. Nowadays, BMD is measured by dual-energy X-ray absorptiometry (DEXA). The DEXA system uses double X-ray intensities in order to obtain two images, one of which is taken at high energy, whereas the second one is taken at low energy. The difference between the two is normally used to calculate the BMD by means of a calibration function of the system itself. WHO defines BMD to be 2.5 standard deviations (SD) or more below the peak bone mass as a normal T score (above −1 SD); between −1 and −2.5 SD defined as mildly reduced bone mineral density and below −2.5 SD as osteoporosis.

The average density of the bone is around 1000 to 1200 mg/cm^2. The density varies with age, race and gender. Bone density tests measure two conditions, osteopenia and osteoporosis. BMD would be greater than or equal to 833 mg/cm^2 for normal people. Osteopenia is a condition where BMD is lower than normal, like between 648 mg/cm^2 and 833 mg/cm^2 [2]. With further bone loss, osteopenia leads to Osteoporosis, a disease of the bones, where BMD is still reduced (less than 648 mg/cm^2), bone micro-architecture deteriorates and the amount and variety of proteins in bone are altered. Poor bone density relates to higher probability of fracture. Bones become weak and can break from a minor fall or even from simple actions like sneezing and twisting. People over the age of 50, people with smoking habits, drinking habits, long term use of steroid drugs, Vitamin D deficiency and women with early menopause are more susceptible for having less bone density. Women are more susceptible to get Osteoporosis due to the reasons: (1) Women tend to have thinner, smaller bones than men (2) Estrogen, a hormone that protects bones, decreases sharply when women reach menopause, which can cause bone loss. Fractures are the most dangerous aspect of osteoporosis. Acute and chronic pain is often attributed to fractures from osteoporosis and can lead to further disability and early morbidity and functional impairment. In essence, the daily activities of a person become a painful ordeal and overall quality of life declines. Reduced bone mass is therefore a useful predictor of increased fracture risk. Normal and Osteoporotic conditions of a bone are shown in Fig. 1.

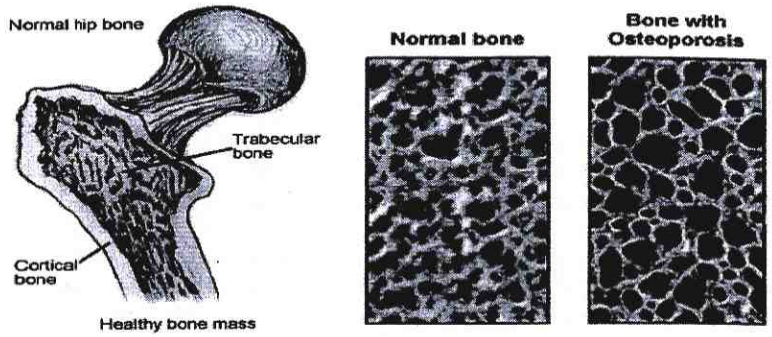

Fig. 1. Normal bone image: a. Trabecular bone b. Micro-architecture of normal and Osteoporosis affected bone

DEXA is the most widely used and most thoroughly studied bone density measurement technology. But it is quite an expensive method in developing countries like India. Moreover BMD values calculated depend on race, age and other conditions and not a constant for all people throughout the world. Hence, this paper explores the possibility of developing an affordable and reliable system to study bone mineral density using X-rays which is a very basic and conventional screening morality.

Section 2 discusses the related work. Section 3 discusses the proposed methodology used in this paper. Section 4 elaborates on image enhancement, feature extraction and bone mineral assessment using different classification methods. Section 5 reports on the experiments conducted and the results obtained. Finally, Sect. 6 concludes the work.

2 Related Work

DEXA is recognized as the acceptable method to measure BMD. DEXA scans can have errors between 5 and 8% due to calibration, positioning and other factors. X-rays are more cheaper and many researchers have shown that there exists relationship between plain radiographic patterns and three-dimensional trabecular architecture.

Luo et al. [12] have shown that the plain radiograph contains architectural information directly related to the underlying 3D structure based on the study of human calcaneal trabecular bone. Veenland [19] has assessed the suitability of different texture analysis methods for use in radiographs and also to select texture features that are able to quantify the changes in the radiographic trabecular pattern occurring in osteoporosis. Chappard et al. [3] showed that texture analysis by Euclidean and fractal methods provided significant differences in the two bones of a rat model submitted for disuse induced by Clostridium botulinum Toxin and found that such analysis on radiographs appears able to detect architectural differences in the trabecular architecture even when bone loss has not

reached a value sufficient enough to induce changes appreciable by DEXA. Again, Chappard et al. [4] have shown that the trabecular characteristics were found to be highly correlated with texture parameters describing the X-ray image and suggested that the texture analysis of X-ray films might be a suitable approach to investigate the disorganization of bone in osteoporosis. X-ray films constitute a 2D projection of the trabecular architecture, the resulting image is texture and this may be an indicator of disease etiology.

Guggenbuhl et al. [9] in their study found a good correlation between texture analysis of X-ray radiographs and 3-D bone microarchitecture assessed by micro-CT of human iliac bone. Jimenez-Mendoza and Espinosa-Arbelaez [11] have determined the parameter equation that defines the ratio of the pixels in radiographs and BMD and demonstrated the methodology on Wistar rats' femur bones on a calibrated system.

All this suggest that the study of bone mineral health by direct means is tedious and harmful to the human body and so an indirect measure by the DEXA is an accepted methodology. With the technology yet to reach the common masses being hindered by cost and the BMD values available are only for the white race, the study of BMD using X-ray images is a boon for the developing nations like India.

3 Proposed Methodology for Indication of Bone Mineral Density

Researchers have investigated the relationship between bone health and bone X-ray images through various experiments. This study is based on the concept of transitive inference. Suppose R is a relation on set A. Relation R is transitive if $\forall x, y, z \in A, ((xRy) \bigwedge (yRz)) \Rightarrow (xRz)$. A transitive relation between premises is said to occur when the conclusion a R c (read as 'a related to c') follows logically from the premise relations a R b and b R c(a related to b and b related to c). Humans are capable of making transitive inferences and do so routinely. Transitive inference is a form of deductive reasoning. This work is based on the transitive inference: If bone mineral density is related to the DEXA scan of the person, and the DEXA scan can be related to the single X-ray scan, then bone mineral density can be related to the single X-ray scan.

We propose the following methodology: (1) In preprocessing, image filters and H-domes image slicing is applied to enhance contrast in X-ray images, (2) Textural features, statistical features and fractal dimension are computed in feature extraction and (3) three supervised algorithms namely, support vector machines, generalized boosted regression model and extreme gradient boosting are applied to classify patients to have bone mineral density to be high (Normal), or Abnormal (medium and low). The three classification algorithms are also applied to discriminate between Normal, Medium (osteopenia condition) and Low (osteoporosis condition). The three algorithms are applied on female patients alone to infer if distinction is more apparent in females.

Raw X-ray images possess low frequency noise due to X-ray diffusion in soft tissues and high frequency noise due to X-ray acquisition and Imaging characteristics. Chappard et al. [3,4] have applied a median filter to eliminate low frequency noise and a "top hat" filter to eliminate high frequency noise to increase the contrast of the bony structures within the image. Guggenbuhl et al. [9] binarized the images by applying automatic thresholding based on the histogram frequency distribution of grey levels. Abidi et al. [1] applied a series of common enhancement algorithms like linear regression, gamma intensity adjustment, logarithmic intensity adjustment, histogram equalization, edge and morphological operations etc. on X-ray images of luggage scenes and compared the results; They also proposed a new method to determine the optimal number of clusters or thresholds when segmenting X-ray images consisting of low density threat weapons. They used image hashing via intensity slicing such that objects of different intensity values are more visible. Intensity slicing can be done by equal interval image slicing, cumulative image slicing and H-domes image slicing. In this paper, we propose to use median filter to eliminate low frequency noise and "top hat" filter to eliminate high frequency noise and H-domes image slicing for intensity slicing of image hashing for the bone X-ray images.

Materka and Strzlecki [13] have discussed that image texture is a rich source of visual information and that feature extraction, texture discrimination, texture classification and shape reconstruction are the major issues in texture analysis; Results from the feature extraction stage are used for texture discrimination, texture classification or object shape determination. Also, to be noted is that analysis of fractal dimension can additionally enrich diagnostic knowledge about bone microarchitecture. Chappard et al. [3,4], Guggenbuhl et al. [9] have used run-length distribution, "skyscraper" fractal analysis, "blanket" fractal analysis and statistical analysis in their experiments to establish the correlation between texture analysis and bone mineral content, between texture analysis and histomorphometry and between texture analysis and bone micro-CT, respectively. In this paper, we propose to use the texture features, run-length distribution, fractal dimension, and statistical parameters as features. Normally, bone density accumulates during childhood and reaches a peak by around 25 years of age. Bone density is then maintained for about 10 years. After the age of 35, both men and women will normally lose 0.3–0.5% of their bone density per year as part of the aging process. Also women are more susceptible to low bone density. Hence, age and gender are also added into the feature set.

Learning methods can be classified into supervised, unsupervised and reinforcement. Supervised learning methods (or Classifiers) exhibit good mapping capabilities between the input patterns and their associated outputs(classes). They learn by examples, can predict new outcomes from past trends and can process information in parallel at high speed and in a distributed manner. Data are partitioned into training and test sets. Classifiers are continuously made to learn the instances in the training set to map to their classes, upto an allowed tolerance and this is the training phase. In the testing phase, the test data are input to verify the class of the instances by the stabilized weights in the training

phase. Cross-validation is to split the training set into training set and validation set. A k-fold cross-validation partitions the training set into k sets. For each model complexity, the learner learns k times, each time using one of the sets as the validation set and the other sets as the training set. It selects the model that has the smallest average error on the validation set.

The features so extracted are applied to three classification algorithms Support Vector Machines (SVM), Generalized Boosted Regression Model (GBM) and Extreme Gradient Boosting (XGB). A 10-fold cross-validation was applied to all the algorithms. Support vector machines (SVM) [18] are supervised learning models with associated learning algorithms that analyze data for classification and regression. Boosting refers to a general and provably effective method of producing a very accurate prediction rule by combining rough and moderately inaccurate rules. It has good generalization properties and seems not to overfit in practice. The most straight forward generalization to a multiclass case, called AdaBoost is adequate when the weak learner is strong enough to achieve reasonable high accuracy [20]. Boosting has a sound theoretical base and also has the advantage that the extra computation time that it requires is known in advance. Moreover, in some applications where the dataset is large, the improvement is dramatic, due to the reduction of classification errors and well worth the computational cost [16]. The family of boosting methods is based on a different, constructive strategy of ensemble information. To establish a connection with the statistical framework, a gradient-descent based formulation of boosting methods was derived by Freund and Schapire [6] and Friedman et al. [7,8]. This formulation of boosting methods and the corresponding models were called the gradient boosting machines. This framework also provided the essential justifications of the model hyper parameters. The ensemble models are a useful practical tool for different predictive tasks, as they can consistently provide higher accuracy results compared to conventional single strong machine learning models [14]. Xgboost is an efficient and scalable implementation of gradient boosting framework [5].

This paper proposes to use the above set of algorithms in R [17] for the classification of bone mineral density and glean sufficient knowledge in order to deduce the transitive inference.

4 Classification of Bone Mineral Density in X-Ray Images

The raw X-ray images are impregnant with noise due to diffusion in soft tissues and acquisition and imaging characteristics. So a variety of preprocessing techniques need to be applied to each X-ray image before features are extracted. Extraction of essential features is a necessary step in a supervised learning process so as to differentiate the classes appropriately. The X-ray bone image undergoes preprocessing, feature extraction and classification phases.

4.1 Preprocessing of X-Ray Images

The raw X-ray image is subjected to Weiner filter to reduce noise. The background effects are removed by top hat and bottom hat filters which also have the benefit of adding a significant degree of smoothing to the spectrum. H-domes image slicing is further applied to remove small grains and this slicing method was chosen over equal interval image slicing and cumulative image slicing based on the peak signal to noise ratio (PSNR) on a subset of 25 bone images. The PSNR value is a quantitative measure that is used to compare filter performance between original and the reconstructed image. Figure 2a represents a sample original pelvis image of a patient and 2b represents the enhanced image.

Fig. 2. Pelvis X-ray image: a. original b. H-domes enhanced

4.2 Feature Extraction

Feature extraction is a process by which the X-ray image is broken down into components of essential information that are more useful for describing its structure. The histogram h(i) contains the first order statistical information about the image, i = $0, 1, .. G-1$ where G is the total number of intensity levels in the image. h(i) contains the number of pixels in the whole image, which has this intensity. The approximate probability density of occurrence of the intensity levels is given by

$$p(i) = h(i)/M * N \tag{1}$$

where the size of the image is M × N. First-order statistical properties or central moments are derived from it to characterize the texture. The mean takes the average level of intensity and is defined as

$$mean = \mu = \Sigma_{i=o}^{G-1}(i * p(i)) \tag{2}$$

The variance describes the variation of intensity around the mean and is defined as

$$variance = \sigma^2 = \Sigma_{i=o}^{G-1}(i-\mu)^2 * p(i)) \tag{3}$$

Energy is defined as

$$Energy(E) = \Sigma_{i=o}^{G-1}(p(i))^2 \tag{4}$$

Entropy is a measure of histogram uniformity and is defined as

$$Entropy(H) = -\Sigma_{i=o}^{G-1}(p(i) * log_2(p(i)) \tag{5}$$

These first order measures cannot completely describe texture. The second order histogram is defined as the gray level co-occurrence matrix (GLCM) (joint probability distributions of pair of pixels) [10]. Contrast (or inertia) returns a measure of the intensity contrast between a pixel and its neighbor over the whole image and is defined as

$$Contrast = \Sigma_{i=o}^{G-1}\Sigma_{i=o}^{G-1}(i-j)^2 * p(i,j) \tag{6}$$

Correlation returns a measure of how correlated a pixel is to its neighbor over the whole image and is defined as

$$Correlation = \frac{\Sigma_{i=o}^{G-1}\Sigma_{i=o}^{G-1}(i-\mu_i)(j-\mu_j)p(i,j)}{\sigma_i\sigma_j} \tag{7}$$

where μ_i, μ_j, σ_i and σ_j denote the mean and standard deviations of the row and column sums of the matrix. Energy is calculated from GLCM as

$$Energy = \Sigma_{i=o}^{G-1}\Sigma_{i=o}^{G-1}p(i,j)^2 \tag{8}$$

Homogeneity returns a value that measures the closeness of the distribution of elements in the GLCM to the GLCM diagonal and is defined as

$$Homogeneity = \Sigma_{i=o}^{G-1}\Sigma_{i=o}^{G-1}\frac{p(i,j)}{1+(i-j)^2} \tag{9}$$

A feature vector is created for each X-ray image based on global qualities like average gray level, average contrast, smoothness, moments, uniformity and

entropy (Eqs. 1 to 5), gray level run length statistics like Short Run Emphasis (SRE), Gray Level Run Emphasis (GRE), Gray Level Non-uniformity (GLN), Run Percentage (RP), Run length non-uniformity (RLN), and fractal dimension, gray level co-occurrence matrix (GLCM) characteristics like contrast, correlation, energy and homogeneity (Eqs. 6 to 9). Age and gender are also added into the feature vector. Algorithm I in Table 1 states the procedure for feature extraction.

4.3 Classification

R [17] is a language and environment for statistical computing and graphics. It is a GNU project developed at Bell laboratories by John Chambers and colleagues. R provides a wide variety of statistical (linear and nonlinear modelling, classical statistical tests, time-series analysis, classification, clustering) and graphical techniques, and is highly extensible. R is designed around a true computer language and it allows users to add additional functionality by defining new functions. As specified above the supervised learning algorithms used in this paper are SVM, GBM and XGB. The results are tabulated in Table 2 for a 2 class problem. The ROC curves are specified in Figs. 3, 4 and 5 for SVM, GBM abd XGB respectively.

Table 2. Results for normal/abnormal classification (all patients)

Classifier	Accuracy %	Sensitivity	Specivicity	AUC
SVM	82.00	0.92	0.68	0.85
GBM	82.00	0.90	0.68	0.88
XGB	89.00	0.92	0.65	0.88

5 Results and Discussion

PSG Hospitals is a 810 bedded, tertiary care hospital with qualified and experienced faculty and state of the art infrastructure, affiliated to PSG Institute of Medical Sciences & Research, Coimbatore, India [15]. The hospital houses various specialties like Medicine, Surgery, Obstetrics & Gynecology, Paediatrics, Orthopaedics, Radiology and Emergency Medicine. The hospital has been recognized for implementation of various social welfare schemes and is an internationally acclaimed centre to conduct various clinical trials.

Experiments are conducted on 311 pelvis and 160 spine images of the patients screened over a three month period at PSG Hospitals. The X-ray images are 760×580 pixels in size. The age of the patients varied between 10 and 90 and the average age was 46.37. There are 253 males and 218 females. Three experienced doctors identified the class attribute seperately based on the X-ray image and the

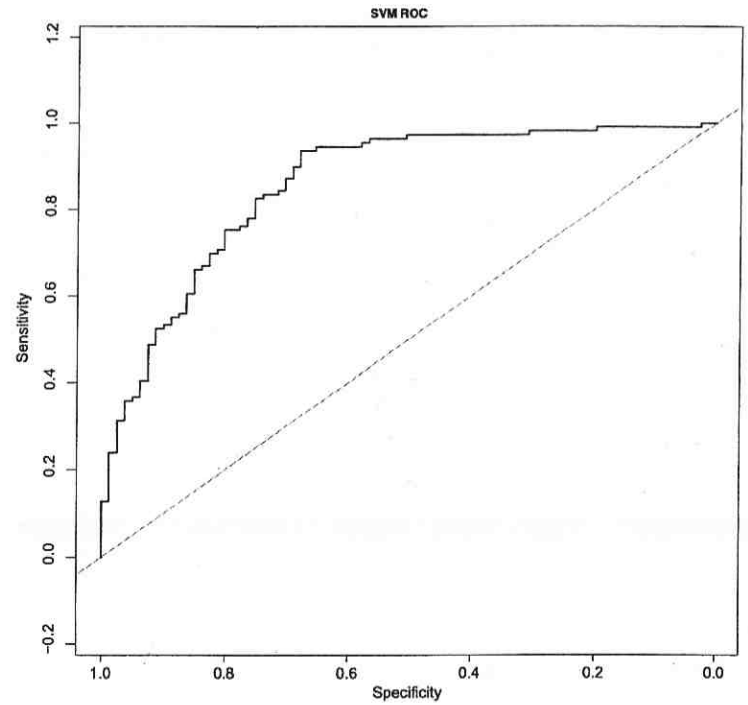

Fig. 3. ROC curve for SVM

class type (Normal/Osteopenia/Osteoporosis) was decided based on the majority voting by them. There was 25% of tie in the class attribute in such a process and lower the class attribute was decided with high density being normal, Osteopenia being medium and Osteoporosis being low.

After the images were pre-processed for enhancement, global, local statistical features, GLCM features, fractal dimension were extracted, age and gender were added and a total of 19 features are finally decided. The feature values are normalized. The 471 images are divided into training and testing at a 60:40 ratio at random and a 10-fold cross validation is used. For comparison purposes, the same set of data are classified by SVM, GBM and XGB. The results are tabulated in Table 2 for the two class problem (Normal/Abnormal) and in Table 3 for a three class problem (Normal/Osteopenia/Osteoporosis). It can be seen that the methodology identifies between normal and abnormal with an accuracy of 89% but when it is to distinguish between osteopenia and osteoporosis away from normal, the accuracy has reduced to 62%. Since, women were more susceptible to low bone density, the methodology was applied only to X-rays of female patients and found to have 82% accuracy. The results are tabulated in Table 4.

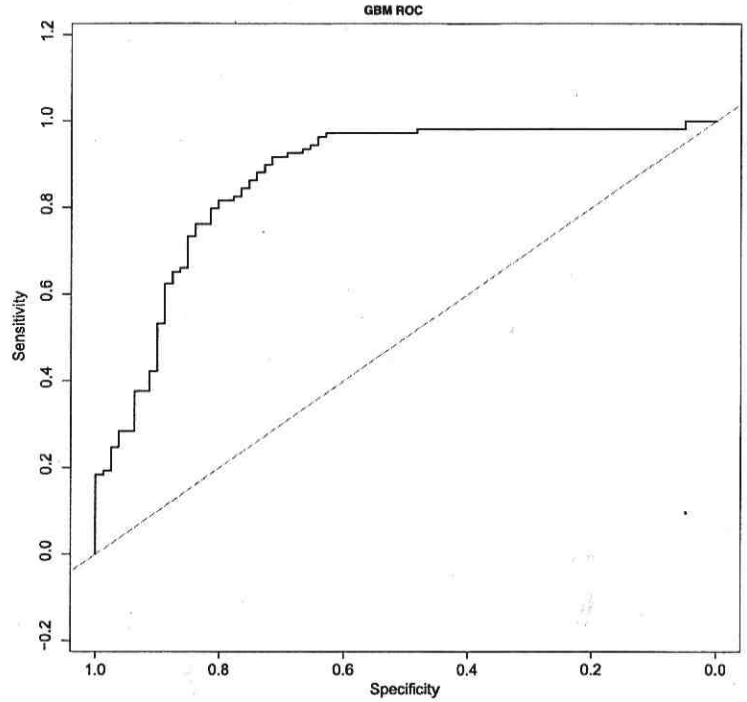

Fig. 4. ROC curve for GBM

Table 3. Results for normal/osteopenia/osteoporosis (all patients)

Classifier	Accuracy %	Sensitivity	Specivicity	AUC
SVM	57.00	0.55	0.78	0.55
GBM	62.00	0.60	0.82	0.55
XGB	59.00	0.55	0.76	0.57

Table 4. Results for normal/abnormal classification (only females)

Classifier	Accuracy %	Sensitivity	Specivicity	AUC
SVM	74.00	0.80	0.61	0.83
GBM	62.00	0.87	0.10	0.51
XGB	82.00	0.95	0.57	0.86

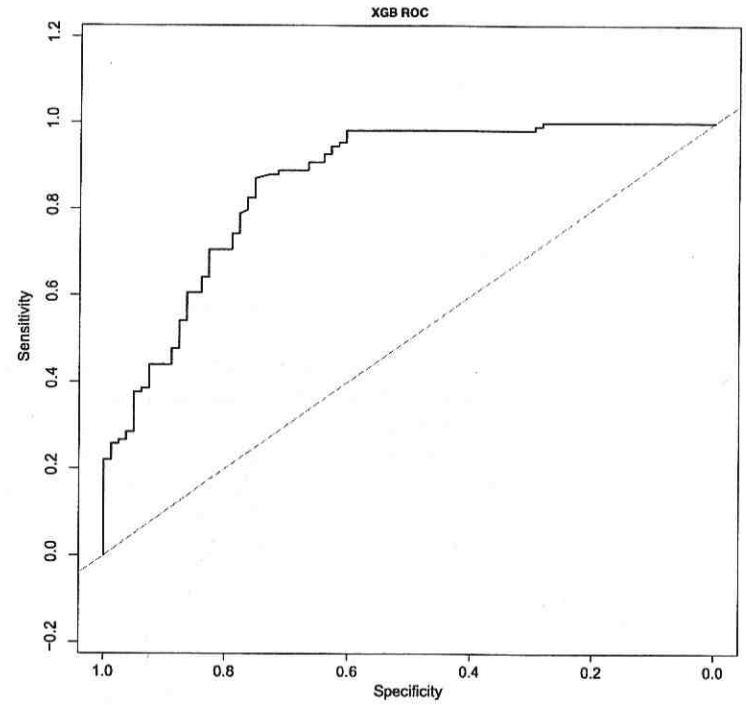

Fig. 5. ROC curve for XGB

6 Conclusion

The methodology described in this paper has extended the idea and relationship established by various researchers between bone mineral health and X-ray radiography images. DEXA equipment from different manufacturers might not give identical results, because of differences in calibration and bone edge detection algorithms. Moreover, the BMD values specified by WHO is based on white women [2] and as a result, the BMD values calculated for other countries or on other race for the same age cannot have this as the reference.

The proposed system is based on the strong correlation between the X-ray images and their underlying microarchitecture and the health of the bones. The system weighs on the transitive dependency and explores through inferential component, the bone mineral density by classification methods. The proposed system could identify abnormality with an accuracy of 89% for all patients and with an accuracy of 82% for only females, though the accuracy reduced to 62% for the three class problem. The proposed system is cheaper, portable, versatile and dependable to study changes in the density of minerals in X-ray images of bones. It is meant to be a guidance to the doctors to prescribe further medication

if required. Similar to DEXA, it is a non-contact and non-invasive method. As more radiography images are added to the data set, the classification algorithms would be able to learn the characteristics of the images pertaining to a particular demography, age and race and able to classify much better. Additional features or a better image enhancement algorithm on the X-ray images may indeed be the future scope of work.

Functional outcome of Tibial condyle fractures treated by minimally invasive plate osteosynthesis

Dr. N Venkatesh Kumar, Dr. Arvind Kumar SM, Dr. Udayamoorthy S and Dr. Sanjeev S

DOI: http://dx.doi.org/10.22271/ortho.2017.v3.i1l.113

Abstract
Introduction: Tibial plateau fractures with intra-articular extension are very difficult to manage. Age, skin conditions, compartment syndrome and osteoporosis further increase the obstacles in the healing process.
Complex biomechanics of its weight bearing position and complex ligamentous stability and articular congruency are the main reason why these fractures are of concern to surgeon.
In our study we have evaluated the functional outcome of locking plate fixation of tibial condyle fractures using minimally invasive technique, a minimum period of 6 months after plate fixation by Rasmussen score and Knee society score.
Materials and Methods: Tibial plateau fractures treated by minimally invasive plate osteosynthesis using locking compression plate from January 2010 to January 2015 were taken into the study. All the patients who had completed the inclusion criteria were called for assessment of functional outcome of knee using Rasmussen score and knee society score.
Results and Discussion: In our study, we were able to get away with unilateral plating for type V and type VI fractures without any late complications like loss of reduction and malalignment.
Choice of the procedure/implant should be based on the fracture pattern, bone quality and intraoperative reduction.
Conclusion: Treatment of intraarticular tibial plateau fractures is still unsolved.
Our results in minimally invasive percutaneous plate osteosynthesis (MIPPO) technique is in par with the literature.

Keywords: Tibial fracture, Schatzker, osteosynthesis, implants

Introduction
The knee joint is complex and most commonly injured joint now because of increased motor vehicle accidents and sports related injuries. As it is a superficial joint, it is more exposed to external forces and gets easily injured. Tibial plateau fractures with intra-articular extension are very difficult to manage. Age, skin conditions, compartment syndrome and osteoporosis further increase the obstacles in the healing process.
Complex biomechanics of its weight bearing position and complex ligamentous stability and articular congruency are the main reason why these fractures are of concern to surgeon. The ideal treatment of high-energy tibial plateau fractures is controversial. Open reduction and stable internal fixation helps in maintaining the articular surface and restoration of the mechanical alignment which allows early mobilization of knee. But, techniques of open reduction and internal fixation compromise the soft tissues and the rate of wound infection is relatively high.
Various other methods of treatment like hybrid fixation and now plate fixation using minimally invasive technique have been suggested. Each method has its own advantage and disadvantages.The development of locking implants has allowed the use of minimally invasive technique for unilateral plating [37-39] with improvement in handling the soft tissue [40-43].
There are lot of studies which assess the general outcome of these fractures but there are only few studies which assess the functional outcome of these fractures which is more important to the patient. In our study we have evaluated the functional outcome of locking plate fixation of tibial condyle fractures using minimally invasive technique, a minimum period of 6 months after plate fixation by Rasmussen score and Knee society score.

Materials and methods

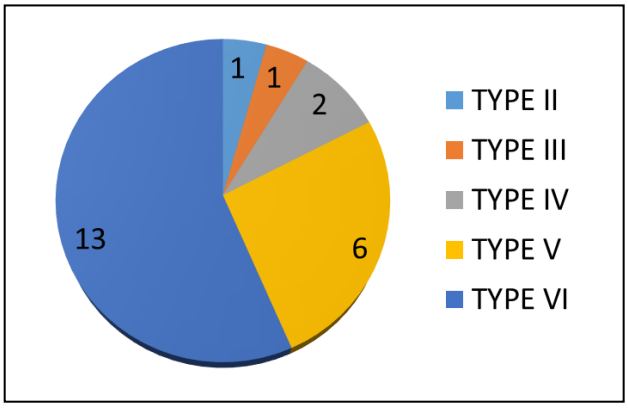
Tibial plateau fractures treated by minimally invasive plate osteosynthesis using locking compression plate from January 2010 to January 2015 were taken into the study.

Inclusion criteria

Age group: 18 years to 60 years all tibial condyle fracture treated by minimally invasive plate osteosynthesis.

Exclusion criteria

1) Skeletally immature patients,
2) Neurovascular injuries,
3) Concomitant lowerlimb fractures like patella, femur, ankle and pelvic fractures.
4) Open fractures



Methodology

This was both retrospective as well as a prospective study. For the retrospective study in-patients and out-patient records of the study population were collected from the medical records department and OT register. Age, gender of the patients, mode of injury, side of involvement, Associated injuries and medical comorbidities were documented. The Neurovascular status of the affected leg, compartment syndrome and any blisters or open wounds was noted. All Tibial condyles fractures were graded preoperatively using Schatzker classification. Patients were followed up postoperatively after a minimum period of six months after surgery. All the patients who had completed the inclusion criteria were called for assessment of functional outcome of knee using Rasmussen score and knee society score.

Results

n our study, 13 patients belonged to type VI, 6 patients belonged to type V, 2 patients belonged to type IV, 1 patient belonged to type III and type II respectively.

Total Number of Patients

Thirteen patients had right tibial plateau fractures and remaining ten patients had left tibial plateau fractures. Only fractures which were treated with MIPPO technique were taken for the study. RTA was the mode of injury in all the cases. In our study type VI Schatzker fractures was the commonest type. Functional assessment was assessed by Rasmussen score (subjective score) and knee society score (objective score). Average follow up period was 22.08 months.

Mean Follow Up

SL.NO	TYPE	AVERAGE FOLLOW UP (MONTHS)
1.	I	-
2.	II	17 (6-17)
3	III	18 (6-18)
4.	IV	32.5 (6-47)
5.	V	19.8 (6-27)
6.	VI	23.1 (6-53)

In type VI Schatzker there were thirteen patients of whom seven patients were treated by lateral plating and six patients were treated by medial plating. Mean Rasmussen score of type VI fractures was found to be 25.6, average knee society score was found to be 93.2 and mean range of knee flexion was found to be 118.8 degrees. All the patients were started on partial weight bearing from 8 weeks and full weight bearing by 12 weeks.

Average Scores by Knee Society and Rasmussen Score

Sl. No	Type	Knee Society Score	Rasmussen Score
1	1	-	-
2	2	98	27
3	3	96	29
4	4	94	26.4
5	5	81.3	22.8
6	6	93.2	25.6

Six patients belonged to type V Schatzker group. Mean follow up was 19.8 months (6-27). Lateral plating was done for 2 patients and medial plating was done for 4 patients. Average Rasmussen score was 22.8, mean knee society score was 81.3 and average range of knee flexion was found to be 118.3 degrees. Only one patient had flexion contracture of 10 degrees. All the patients were started on partial weight bearing at 8 weeks and full weight bearing was started at 12th week. Postoperatively there were no wound infections.

In type IV Schatzker fractures there were two patients. Mean follow up was found to be 32.5 months (6-47). All patients were treated by medial plating. Average range of flexion was found to be 122.5 degrees. Mean Rasmussen score was found to be 26.5. Mean knee society score was found to be 94. There was no wound infection and weight bearing was started at 12th week. In our study only one patient belonged to type III Schatzker fracture. Follow up was done at 18 months (6-18). He was treated by lateral plating and had Rasmussen score of 29. Range of flexion was found to be 120 degrees. Knee society score was found to be 96. No complications were noted.

In type II Schatzker there was only one case which met the criteria. Lateral plating was done. Follow up was done at 17 months (6-17). Rasmussen score was found to be 27, knee society score was 98 and range of knee motion was 125 degrees. No complications were noted. No bone grafts used in our study.

Discussion

Intraarticular tibial plateau fractures are complex fractures accounting for about 1.2% of all fractures. They affect knee function and stability which results in considerable morbidity. These fractures are caused by high velocity injuries and often associated with severe comminution and soft-tissue damage. The goals of treatment are to restore joint congruity, limb alignment and early mobilisation of joint. Stable internal plate fixation without damaging the soft-tissue envelope is very difficult to achieve, only fair results are seen in 20% to 50% in these fractures. Outcome after tibial plateau fracture fixation depends mainly on knee range of motion and strength of the quadriceps. Knee stiffness is more clinically relevant than instability in these fractures.

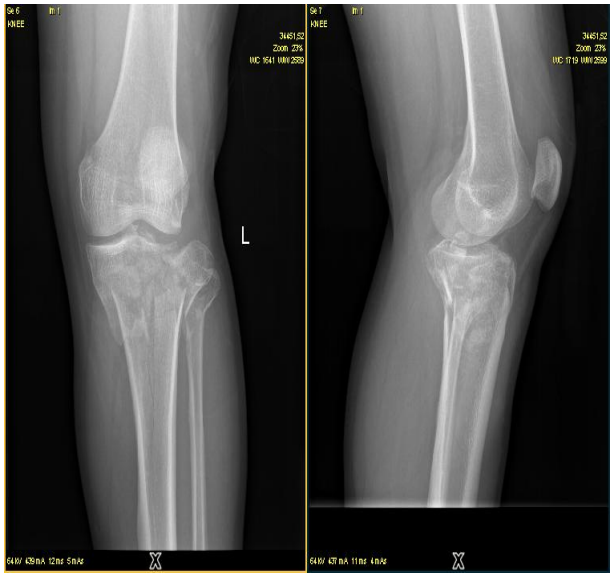
Open reduction and internal fixation (ORIF) with plates and screws enables direct fracture visualisation, reduction, and fixation, but there is high risk of soft tissue injury, stiffness and deep infection. The hybrid external fixator avoids soft tissue problems, but risks non-union, pin tract infections and poor patient compliance.

The concept of preserving the blood supply and atraumatic surgical technique led to the development of biological fixation techniques. Using this technique, soft tissue damage is reduced and shows higher union rate.

The development of locking implants has allowed the use of minimally invasive technique for unilateral plating [37-39] with improvement in handling the soft tissue [41-43].

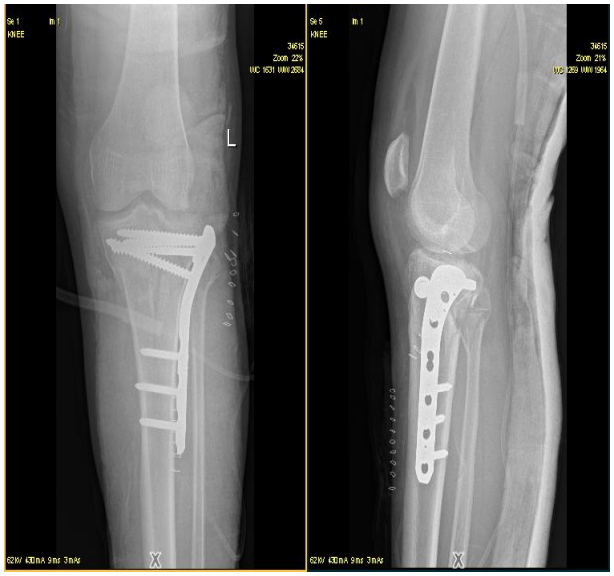
Laterally placed locking plates provide better stability in the presence of complex proximal 1/3rd tibia fracture with metaphyseal comminution and serves as an alternative to medial plate or external fixator for additional support of the medial column when a non-locking plate is used for bicondylar fractures. This plate allows fixation through single incision which avoids wound dehiscence, infection and prolonged immobilisation associated with extensile approaches.

MIPPO enables indirect fracture reduction and percutaneous sub muscular implant placement. Favourable outcome is not due to MIPPO but due to less extensive dissection of soft-tissue envelope and devitalisation of fracture fragments.



The aim of our study was to evaluate the functional outcome of tibial condyle fractures treated by minimally invasive percutaneous plate osteosynthesis. There is no universal scoring system for assessing the functional outcome for these fractures. Literature shows multiple scoring system like Rasmussen, knee society score and oxford knee score. In our study, we have evaluated the patients using Rasmussen score which is subjective score and knee society score which is an objective score. All these fractures were treated by a single plate either medial or lateral (11 lateral and 12 medial). In case of type V and type VI fractures, if needed the opposite condyle was fixed with percutaneous cancellous screws.

Mechanism of injury was road traffic accident for all these patients. The fractures were classified by Schatzker's classification. 13 patients belonged to type VI, 6 patients belonged to type V, 2 patients belonged to type IV, 1 patient belonged to type III and type II respectively. Even though, according to literature type II fractures were the most common, only one patient with type II fracture was included in our study as all other type II & type I fractures in the study period were fixed only by percutaneous screws hence excluded from the study. Type VI fracture with 13 patients (56.5%) were the most common in our study, next was type V (26.08) with 6 patients. Average followup period was 22 months (6-53). Hasnain Raza *et al*, in their study of assessing the functional outcome of tibial condyle fractures of 41 patients by minimally invasive plate osteosynthesis by Rasmussen functional score found excellent results in 18 patients, good in 19 patients and 4 patients had unacceptable results. The mean Rasmussen score was found to be 25.3 and range of knee flexion was 118 degrees. In our study mean Rasmussen score was found to be 26.1 and average range of knee flexion was found to be 120.9 degrees. Of which ten patients had excellent and good results each. Only 3 patients had fair results. This is comparable to the study done by Hasnain Raza. Mohammad Ali Tahririan, Seyyed Hamid Mousavitadi, and Mohsen Derakhshan [13] in their clinical study comparing the functional outcomes of tibial plateau fractures treated with nonlocking and locking plate fixation by knee society score, found a score of 80.2 for locking plate and 72.5 for non-locking plate. Average range of knee flexion was found to be 122.3 degrees for locking plate and 115.7 degrees for non-locking plate. In our study, locking plate was used for all the cases. Average knee society score was found to be 92.5 and average knee flexion was found to be 120.9 degrees. So, functional outcome in our study was marginally better than the locking plate group in that study and significantly better than the non-locking group. This shows the superiority of the locking plate in view of stable fixation and early range of motion when compared to non-locking plate. Chang-Wug Oh *et al* [18] in their study on double plating of (twenty three) type V and type VI proximal tibial fractures using minimally invasive percutaneous osteosynthesis found Eighteen patients with excellent, three patients with good and two patients with fair results. Average Rasmussen score was found to be 26 and average knee range of motion was found to be 123 degrees. In our study, nineteen patients belonged to type V and VI fractures. Average Rasmussen score of these type V and type VI fractures were found to be 24.2. Average range of flexion achieved by type V and type VI was found to be 118.5 degrees. Seven patients had excellent, ten patients with good and two patients had poor results. In their study of ten patients Kye-Youl Cho *et al* [5], used a single midline longitudinal incision and dual plating for the treatment of type V and type VI schatzker fractures. Their mean knee society score for the study group was 85 and the mean range of motion was 125 degrees. They had only one case with delayed wound healing as postoperative complication. In our study, average knee society score was found to be 87.25. One patient had 10 degrees of valgus malalignment in type VI fracture and one patient had flexion contracture of 5-10 degrees. But the functional outcome was not significantly altered when compared with others.



Dual plate gives better biomechanical strength and rigid construct thereby better control of both columns thus avoiding late collapse. There were no major wound problems in any of these studies. Weight bearing was started only at 8-12 weeks which was similar to our study. In our study, we were able to get away with unilateral plating for type V and type VI fractures without any late complications like loss of reduction and malalignment.

Choice of the procedure/implant should be based on the fracture pattern, bone quality and intraoperative reduction.

CASE 1:
Preop Xray

Immediate Postop Xray

After 6 Months

Clinical Picture

Conclusion

Treatment of intraarticular tibial plateau fractures is still unsolved. Our results in minimally invasive percutaneous plate osteosynthesis (MIPPO) technique is in par with the literature. There is no significant difference in the functional outcome between single plating in our study and dual plating of other studies at midterm followup. Choice of the procedure/implant should be based on the fracture pattern, bone quality and intraoperative fracture reduction.

The Charcot foot: Is it a commonly overlooked entity in diabetic population

Prasanna Chandiralingam and Vijay Baba N

DOI: https://doi.org/10.22271/ortho.2020.v6.i1q.1993

Abstract
Charcot Osteoarthropathy of the foot and ankle is one of a complication of diabetic neuropathy. The identification and diagnosis of these cases pose a challenging task to the general care physicians. Equally a challenging condition to treat, Charcot foot management can pose significant difficulties unless the treatment is initiated in early stages. The present study aimed at finding out the prevalence rate of Charcot foot among the diabetic patients presenting to a tertiary care centre.
We had a prevalence rate of 0.01% for Charcot foot among the study population. We could identify that the diagnosis was made late in all our cases and it was difficult to differentiate between infection and Charcot foot. The prevalence rate doubled to 0.02% when we take into account the cases with no clear cut evidence of infection.
Charcot foot is a debilitating complication of diabetes mellitus. Though not a common one we encounter, this complication needs an early diagnosis for prompt treatment. Hence any diabetic foot complications may be ideally referred for specialist opinion at the earliest.

Keywords: Charcot foot, diabetes mellitus, debilitating, early referral

Introduction
Charcot foot is a type of arthropathy due to peripheral neuropathy. It is named after Jean-Martin Charcot, who first recognised that peripheral neuropathy could lead to neuropathic joints [1]. Apart from diabetes mellitus, Charcot foot may present as a complication of various other peripheral neuropathic conditions like Neurosyphilis, syringomyelia, leprosy, poliomyelitis, and/or congenital neuropathy [2]. The Charcot foot disease, though an uncommon entity of diabetes it is a serious and potentially limb threatening complication.
The prevalence rate of Charcot foot in diabetes is not clearly known, but now it is appreciated that it is not as infrequent as it was generally thought[2]. Often it may be easily overlooked by the general practioners, especially in its earlier stages leading to underestimation of its frequency [2, 3]. In the present study we evaluated the prevalence rate of this complication among the diabetic population presenting to a tertiary care hospital.

Materials and Methods
The aim of this study was to determine the prevalence of Charcot foot among the patients presenting to the diabetic clinic of a tertiary care centre. All the patients who presented to the clinic from January 2018 to June 2019 were retrospectively analysed. The diabetic clinic of the hospital was managed by the general medicine department. Hence all the diabetic patients presenting to the hospital were initially managed by the general physicians.
The necessary data were collected with the help of out-patient register and in-patient case records. The total number of patients who were referred to the diabetic foot clinic, managed by the general surgery department for expert management of complications was noted down. The reasons for referral, if any mentioned in the register were also noted. The number of patients referred from the foot clinic to the orthopaedic department for the management of bone related complications was noted.

The patient details who were admitted for the management of foot complications as in-patients were taken from the case records.

Results and Discussion

A total of 2750 cases were enrolled in the diabetic clinic during the study period. 2175 of them were male and the remaining 575 female patients. The average age was 58 years (42 – 86 years). No specific data was available with regard to the types (type I or II) of diabetes. Neither the data regarding the duration of the disease were available.

365 cases were referred to the diabetic foot clinic for management of complications. Pain was the predominant reason for referral in 250 of the cases. The other reasons for the referral were swelling in the foot and leg in 65 cases and ulcerations in the foot and ankle region in 50 cases. A majority of these 365 cases were managed as out-patients with 88 of them being admitted for the management of severe complications. 37 of them were admitted for the management of diabetic foot ulcer. The remaining 51 cases were diagnosed as cellulitis and were admitted for intravenous antibiotics and further appropriate management.

An orthopaedic referral was given for 35 of the ulcer case after the X- rays taken had shown bone abnormalities. The referrals were given with the suspicion of osteomyelitis, but were proven to be a case of Charcot foot after the orthopaedic referral. This resulted in a prevalence rate of 0.01 percent (35/2750) of Charcot foot in the present study.

Charcot Osteoarthropathy is a degenerative, progressive and a relatively painless arthropathy of single or multiple joints caused by underlying neuropathy, with peripheral joints most commonly affected. The commonest cause of Charcot disease nowadays is diabetes mellitus. It presents as an erythematous, warm, swollen foot and ankle, thereby making it difficult to distinguish from infection clinically [4].

In the present study, when we evaluated the case records of the admitted patients diagnosed as cellulitis there was no conclusive evidence of cellulitis in more than half of the cases. 27 of the 51 cases were having an erythematous, warm and swollen foot, which were managed as cellulitis. These cases could probably represent an earlier stage of Charcot foot.

Eichenholtz [5] has defined 3 stages of Charcot arthropathy based on the natural history of the condition. (Table 1)

Table 1: The modified Eichenholtz [5] classification.

Stage	Radiographic findings	Clinical findings
0 (prodromal)	**Normal radiographs**	**Erythema, warmth, swelling**
I (development)	Osteopenia, fragmentation, joint subluxation or dislocation.	Erythema, warmth, swelling, ligamentous laxity.
II (coalescence)	Absorption of debris, sclerosis, fusion of larger fragments.	Decreased erythema, warmth and swelling.
III (reconstruction)	Consolidation of deformity, joint arthrosis, fibrous ankyloses, smoothening and rounding of fragments	Absence of erythema, warmth and swelling with stable joint +/- fixed deformity.

Note: Stages I – III were originally described by Eichenholtz, and stage 0 was later added by Shibata *et al*. [6], since the clinical signs in Charcot foot were found to precede the radiological changes.

Accordingly if the 27 cases diagnosed as cellulitis were countes as stage 1 Charcot foot, it would bring the total number of cases as 62. Then the prevalence of Charcot arthropathy would double to 0.02% (62/2750). Literature estimates of Charcot Arthropathy prevalence ranges from 0.08% in the general diabetic population to 13% in high-risk diabetic patients [7].

An anatomical classification depending on the pattern of involvement of Charcot foot was proposed by Brodsky *et al*. [8]. (Table 2)

Table 2: The anatomical classification of Charcot foot (Brodsky).

Type	Lesion location	Joints involved
1	Midfoot	Naviculocuneiform, tarsometatarsal.
2	Hind foot	Subtalar, calcaneocuboid, talonavicular.
3A	Ankle	Tibiotalar.
3B	Calcaneus	Tuberosity fracture.

In our study the majority (10) of the cases were of type 3A (Fig. 1) and the remaining (6) were of type 1 (Fig. 2). Charcot foot is most common in people with type 1 diabetes in their 5th and 6th decade of life but can also occur in younger patients with type 2 diabetes mellitus as well [9]. In our study the average age at presentation was 58 years. The patients could not be categorised into type 1 or 2 as the details were not available. None of our patients had bilateral involvement, whereas Charcot foot can be bilateral in about 25% of cases [10]. Usually the duration of diabetes is more than 12 years [11] and men are commonly affected as compared to women.

Fig 1: a, b: Clinical picture of a diabetic foot ulcer over the ball of great toe. c,d: X-rays the same patient reveal severe destruction of 1st MTP joint, suggestive of Charcot arthropathy.

Fig 2: note the grossly deformed ankle joint (a), with ulceration over the lateral malleolus (b), and a gross destruction of the ankle in X-rays (c).

Conclusion

The diagnosis of Charcot foot in its initial stages is still a challenging task for the general physicians. The best treatment for the Charcot foot however has to be initiated in its early phase for better outcomes. Though uncommon, Charcot foot is a debilitating complication of diabetes especially at later stages. Hence all diabetic patients with foot and ankle complications may be referred earlier to the concerned specialist for appropriate management.

High Heels Footwear Causes Heel Pain and Back Pain: Myth or Reality?

N Venkatesh Kumar[1], **Chandralingam Prasanna**[1], **V Shyam Sundar**[2], **Aakaash Venkatesan**[3]

[1]Associate Professor, Department of Orthopaedics, PSG Institute of Medical Sciences and Research, Coimbatore, Tamil Nadu, India, [2]Professor, Department of Orthopaedics, PSG Institute of Medical Sciences and Research, Coimbatore, Tamil Nadu, India, [3]Post-graduate Student, Department of Orthopaedics, PSG Institute of Medical Sciences and Research, Coimbatore, Tamil Nadu, India

Abstract

Introduction: Heeled footwear has been in use by women for centuries and has now become an integral part of the wardrobe not only in the west but also in India. Recent research suggests that up to one third of women suffer from permanent problems as a result of their prolonged wearing of heels. One in 10 women wear it at least for 3 days a week, and a recent survey found that one-third of them had permanent problems.

Purpose: Whether the high heel wear is the actual cause of back pain is not yet clear. Literatures vary in their results regarding the same. Hence, the present study was done to assess this cause and effect.

Methods: The study was conducted at the orthopedic outpatient department of a tertiary care hospital, from July 2014 to December 2014.100 female patients who were using heeled shoes and who volunteered to participate in the study were included. The heel height was measured using measuring tape and were classified into three groups (<2.5 cm, 2.5-5 cm, >5 cm). A Proforma with a questionnaire was given to all the participants and their response were noted.

Results: Out of the 100 female volunteers, who participated in the study, 44 had complaints of heel pain regardless of the heel height, 56 had back pain, and many had both heel pain and back pain complaints, based on the questionnaire evaluation. We were further able to distinguish both heel pain and back pain, based on the heel height worn, duration of wear (in years) and duration worn/day.

Conclusion: There was a positive correlation between duration of wear and height of footwear with regards to both heel and back pain. However, a definitive cause and effect could not be established because of smaller sample size.

Key words: Back pain, Heel pain, Shoes, Statistical analysis, Women

INTRODUCTION

Walking is the most common form of human locomotion from a motor control perspective, human bipedalism makes the task of walking extremely complex. One condition known to compound the difficulty of walking is the use of heeled shoes, which alters the natural position of the foot-ankle complex.[1] This thereby produces a chain of reaction effects that travels up to the lumbar vertebrae. High-heeled footwear is defined as the footwear having a heel that is higher than the toe. Throughout the history, this footwear is considered as a symbol of sexuality, class and gender. When the foot slants forward, a much greater weight is transferred to the ball of the foot and toes, which increases the likelihood of damage to the underlying soft tissues that supports the foot. When the wearer tips the foot forward, this in turn puts pressure on the lower back and hence causes back pain. This particular study on post-adolescent volunteers was aimed to study the correlation between heeled footwear and heel and back pain.

MATERIALS AND METHODS

The present study was conducted on 100 female patients who attended orthopedic outpatient department at institution during the period from July 2014 to December

Corresponding Author: Dr. N Venkatesh Kumar, Department of Orthopaedics, PSG Hospitals, Peelamedu, Coimbatore -641 004, Tamil Nadu, India. Phone: +91-9842241304. E-mail: drven@rediffmail.com

2014. Patients were drafted into the study based on inclusion criteria which included:

a. Age >15 years and <55 years
b. Without any foot and spine deformities. Patients were explained about the study and only those who volunteered and gave their consent were included in this study. The procedures followed were in accordance with the ethical standards.

The evaluation was based on questionnaire which was given to all the participating volunteers and heel height was measured with the help of inch tape as illustrated in Figures 1-3. Appropriate information collected in the questionnaire was entered in data collecting sheet for the purpose of statistical analysis.

Patients were categorized based on their age group (18-25, 25-45, 45-55), occupation (student, staff, housewife), heel height (normal [<2.5 cm], low heel [2.5-5 cm] and high heel [>5 cm]), duration of wear in years (0-5 and 5-10 years) and in hours/day (0-5 and 5-10), type of sole (leather, wooden, rubber, plastic). The data collected were statistically analyzed by Chi-square test.

Observation

A total of 100 female patients were included in the study after obtaining their informed consent. There were 63 students, 28 staff, 9 housewives who participated as volunteers. There were 12 people wearing heels with height 2.5-5 cm, 4 people wearing heels with height >5 cm and 74 people wearing heels with height 0-2.5 cm. In our study, 67 people were using soft sole type and 33 people were wearing hard sole type. There were 36 people wearing heeled footwear for more than 5 years, and 54 people were using heeled footwear for 0-5 years. 15 people were wearing heeled footwear for 0-5 h/day and 85 people were wearing heeled footwear for more than 5 h a day. Regardless of heel height worn, the duration of footwear had a significant influence on heel and back pain (Table1) and similarly prolonged wear in a day had a significant influence on heel pain (Table 2).

DISCUSSION

Heeled footwear has been in use by women for centuries but not all individuals wearing heels suffer from clinical problems. In ancient Egypt, wearing shoes may have served to set apart lower classes from the nobility as normal people walked around bare foot while the rich wore flat leather shoes. Moreover in ancient times, height would vary so that the higher the soles, higher the social status.

Research suggests that long-term heel use can both "compromise muscle efficiency and increase the risk of injuries." Heeled shoes slant the foot forward and down while bending the toes up, more the feet is forced into this position, more it may cause the gastrocnemius muscle to shorten.

Table 1: Relationship between heel height with back and heel pain (duration of wear in years)

Heel height	Heel pain			Back pain		
	0-5 years	>5 years	Significance	0-5 years	>5 years	Significance
0-2.5 cm (74[n])	14[n]	28[n]	0.017*	32[n]	-	0.016*
2.5-5 cm (12[n])	3[n]	6[n]		3[n]	Nil	
>5 cm (4[n])	1[n]	1[n]		1[n]	1[n]	

[n]Number of patients, *As analyzed by Chi-square test

Table 2: Relationship between heel height with back and heel pain (duration of wear in hours)

Heel height	Heel pain			Back pain

2.5-5 cm	3	6		3	-	
>5 cm	-	2		1	1	

*As analyzed by Chi-square test

When walking in high heeled shoes, a significant reduction in ankle plantar flexor muscle movement occurs, whereas increased work is performed by the hip flexor muscle during transition from stance to swing phase. Reduced effectiveness of ankle plantar flexors during late stance results in a compensatory enhanced hip flexor pull off. Large muscle movements and increased work at hip and knee occur while wearing high heels.[2]

Wearing high heels is thought to increase an individual's likelihood of experiencing a lateral Ankle sprain. The flexed and inverted posture of the plantar while wearing high heels may increase an individual's risk of experiencing a lateral ankle sprain.[3]

Foster *et al.*,[3] found signs of increase in ankle sprains in patients wearing high heels for a prolonged duration. Esenyel *et al.*,[2] described changes in the biomechanics of walking like increase in plantar flexion in people using high heels. In the particular study, we werenot able to assess the changes in biomechanics of foot while wearing high heels as it is a purely observational study.

There is also a definitive change in subtalar joint axis while walking on a high heeled shoe in comparison to a normal shoe, hence wearing of high heel may cause foot and heel pain.[4]

High heeled shoes cause an increase in the lordotic curve of the lumbar spine.[5] Increased ankle plantar flexion causes a kinetic chain of compensation up the lower extremity that ends with hypertonic psoas muscle, producing a lumbar hyperlordosis. A hyperlordotic lumbar spine in turn will lead to back pain.

Brent *et al.*,[9] found alteration in biomechanics of the lumbar spine. In prolonged high heels wear, chain of events around the ankle were observed, like increased ankle plantar flexion which in turn led to an increase in a lordotic curve.[6]

Eisenhardt *et al.*,[5] measured pressure distribution under foot for bare feet versus heel height and found increase in distribution related to heel height. Opila-Correia *et al.*,[7] studied the kinematics of high heeled walking and found that high heeled walking was associated with increased knee flexion in the stance phase. Kerrigan *et al.*,[6] used biomechanical gait analysis and inverse dynamics to evaluate joint loadings during high heel walking and found that even moderate high heels would contribute to osteoarthritis of the knee.[8]

Electromyography analysis of the lower limb muscles in high heel users and regular footwear users showed significantly increased leg muscle activity.[9]

Based on the observations from our study done on 100 volunteers wearing heels who came to the orthopedic outpatient department for other problems, prolonged duration of wear in years/hours of wear per day resulted in heel pain that significantly affected their daily activities. Furthermore from this study, it was observed that prolonged wear of heels in due course, also resulted in back pain which again was found to be directly proportional to duration of wear in years.[10]

Even though we have derived certain conclusive results from the study, it does have few pitfalls, for instance its an observational study and results obtained were purely based on statistical analysis of the questionnaire reports. Most of the studies done on heeled footwear considered heel height more than 9 cm as high heel, whereas in our study low heel is considered <2.5 cm while heels between 2.5 and 5 cm are considered moderate and more than which is considered as high heels. Moreover, we couldnot have a definite discrimination of the type of sole worn and no changes in the final outcome with respect to the sole type worn.[11,12]

The present study did prove it right that prolonged heels wear resulted in heel pain and back pain, but concrete justification couldn't be provided as the study was done on a small group of 100 volunteers.

CONCLUSION

This study was done with an intention to break the myth or confirm the reality that high heels footwear causes heel pain and back pain. We did succeed in obtaining a stastically significant correlation between the duration of heels wear in both hours/day and a number of year worn with heel and back pain. The pitfall of this study being the minimal sample size, and it was done as an observational study based on a questionnaire evaluation.

Low back pain in pregnancy: Prevalence among south Indian population

Prasanna Chandiralingam and Sri Divya K

DOI: https://doi.org/10.22271/ortho.2020.v6.i1m.1953

Abstract
Females during pregnancy commonly encounter back pain at some point of time. Unfortunately, this symptom is quiet carried away and often neglected by the health care providers. Low back pain in pregnancy can have a significant impact both psychologically and physiologically as well. In the present study we intended to find out the prevalence rate for this symptom among the South Indian population by formulating a questionnaire proforma.
There was a 27.82 % prevalence rate for low back pain in our study. Though we did not differentiate the back pain as lumbar pain and pelvic girdle pain, quiet a majority of the patients (40%) were facing mild to moderate disabilities because of the pain. The mean duration at the onset of the symptoms was 26 weeks of pregnancy. The mean age of the patients with low back pain was 26 years.
Identification of the back pain symptoms during pregnancy is needed so as to assess and provide proper management to such patients.

Keywords: Low back pain, pregnancy, prevalence, disability

Introduction
Low back pain (LBP) is a commonly encountered symptom from pregnant females. Studies have estimated that LBP is prevalent in about 50 % of females at some point of time during pregnancy [1, 2]. Although it is confined to the pelvic area and not so harmful to the females or their foetuses, it is quiet a disabling symptom [3, 4]. LBP is said to cause moderate disability and about 10 % of patients will take off time from work [5, 6]. Back pain in pregnancy is due to various factors, such as mechanical, hormonal and others [1, 2, 7-9].
In the present study we tried to figure out the prevalence of LBP among the south Indian population, attending a primary health care.

Materials and Methods
The aim of this study was to determine the prevalence of LBP among the pregnant females. The study was conducted at a government primary health centre, Southern India, from January 2018 to December 2018. A proforma (fig.1) was created and data collected accordingly among all patients attending the antenatal clinic. A total of 488 patients data were collected during this period.
All the patients who were attending the antenatal clinic for the first time at the time of registration of their pregnancy were included in the study. Those patients who were in their subsequent visits at the time of initiation of this study were excluded because of the chances of error in calculations, as majority of the patients were not able to recollect an episode of LBP at their previous visits.
Apart from the patient's demographic profile, the first leading question was 'whether you have any type of back pain?' If the answer was 'No', further data's were skipped and if the answer was 'yes', the proforma was completed. The patients were subsequently followed-up until the time of delivery and if the patient had a symptom of LBP at any point of time, the proforma was completed at that time.
Patients who had LBP prior to the present pregnancy were excluded from the study. Similarly patients who had pre-existing organic pathology (intervertebral disc prolapse, spondylolisthesis, etc.,) that may contribute to LBP and patients who had a recent history of trauma to the back were also excluded from the study.

Results and Discussion

Data was collected for a total of 478 patients during the study period. 16 patients had a pre-existing history of back pain prior to the present pregnancy. The LBP was either a pain during menstruation or an on and off back pain of undiagnosed causes. All of these 16 cases were excluded from the study. One patient with complaint of LBP at 8 weeks of pregnancy had a history of trivial fall prior to the presentation and hence was excluded from the study. Another patient who was a multiparous woman in her third pregnancy had spondylolisthesis at L5-S1 level. Though she had no complaints of LBP during the previous two pregnancies, she was also excluded from the study. Hence a total of 460 patient's data was used to analyse the results.

A total of 128 patients were having LBP out of the 460 cases. That worked out a prevalence rate of 27.82 %. This prevalence was quiet low as compared to other studies from African [10] and Western [11] population who had prevalence of more than 50 %. LBP prevalence among Nepalese women was 34 % in a study [12] and was bit closer to that of our study. LBP in pregnancy has been predominantly classified [13, 14] into 2 types: lumbar pain (LP) and pelvic girdle pain (PGP) or posterior pelvic pain (PPP). LP is defined as pain between the twelfth rib and the gluteal fold, while PGP is defined as pain experienced between the sacroiliac joint and the gluteal fold, or in the pubic symphysis [15]. We in the present study did not differentiate between the two types and all patients were classified to be suffering from LBP.

About 40 % of our patients (52/128) who had LBP were facing mild to moderate amount of disabilities. The natures of disabilities were mainly in the form of handling the first child and in doing household chores like fetching water. Though there was some sort of disability only 2 out of these 52 cases had severe enough pain so as to have consulted a specialist for treatment. These 2 were working women and they never took any leave from their work for the LBP. In a study by Wang *et al* [5]. their disability rate was around 60 %.

Of the 460 patients in our study, a majority of them (320) were housewives and the remaining 140 were working women. 92 of them were doing constructional or household works in other homes and 48 were office going. 104 cases among the housewives had LBP, whereas 24 among the working group had LBP. The results are summarised in the table 1.

Table 1: Prevalence of LBP with regard to occupation

Patients		Number	With complaints of LBP (No.)	Prevalance (%)
Total cases		460		
Housewives		320	104	32.5
Working women	Manual work	92	22	23.91
	Office work	48	2	4.16

A total of 184 cases were in their first pregnancy, out of which 32 of them complained of LBP (17.39 %). The remaining 276 cases were either 2nd or 3rd time pregnant. 92 of them had LBP (34.78%). This trend was similar to literature which states that the prevalence of LBP increases with parity [16].

There was one case of twin pregnancy and 3 cases of polyhydramnios, but none of the 4 patients had LBP. The mean age of the patients with LBP was 26 years. The mean duration at the onset of symptoms was 26 weeks (8 to 34 weeks) towards the later part of second trimester. The mean duration at onset of pain was 24 weeks in Nepalese women [12].

LBP typically tends to begin as early as 18 weeks of pregnancy and may persist in the postpartum period for as long as 15 months [17, 18]. We in our study did not study the pattern of LBP and patients were not followed up in the postpartum period.

LBP in pregnancy is often regarded as harmless and quiet commonly ignored by the health care professionals [19]. But they have been reported to have some serious negative psychological effects in various studies [19-21]. Therefore a lack of awareness of this predominant complaint from pregnant women can lead to poor management of such cases. The commonly reported risk factors for pregnancy related back pain are high strenuous workload, frequent or prolonged torso flexion, previous history of LBP, previous history of any trauma to the pelvis [15, 22, 23], body mass index (BMI), and parity. Though, in the present study we did not try to find out the risk factors or their causal relationship. We just tried to make out the magnitude of the problem.

The prevalence rates are influenced by the perception of pain among the various group of population. Also we did not consider the various risk factors involved like BMI. A

detailed questioner involving all the risk factors and other indicators of pain like the visual analog scale (VAS) would have been a good indicator of actual prevalence. The socio-economic status of the patient was also not included in the present study, which was another drawback of the study.

Conclusion

'Back pain' as a complaint from a pregnant woman is often regarded as harmless and a common complaint. But the high prevalence of this complaint and the implications it have in a pregnant females necessitates a proper diagnosis and management.

An absolute indication of Manipulation under Anesthesia (MUA) for frozen shoulder is not extracted from literature. Though advanced medical sciences now have an option for arthroscopic release of soft tissue of shoulder, the results are variable in literature and recurrence recorded in literature varies up 30 to 40 percent. We adopted a non invasive approach for 40 cases of frozen shoulder. A functional outcome of patients treated with MUA and intra-articular injection with Methylprednisolone with Lignocaine (MP) was evaluated. Patients with frozen shoulder including those with diabetes were analyzed clinically, radio logically and SPADI score prior and post procedure done. The percentage of recovery noted. We noticed favorable and positive outcome in 67% despite strictly restricting our follow up for 3 months. A reminder here is the natural course of history which is generally self limiting and varies from 16 to 24 months. In view of possible recovery time, range of motions would further improve with recovery from pain. More than 4 studies were comparable, in this study we found external and internal rotation of shoulder joint not fully recovering, but reaching a range of motion for activities of daily living. Our results were comparable to other studies and conclude that MUA with injection of steroid speeds up recovery in range of movements and provides relief of pain.

Peri Arthritescpulaheumarale was the term used by Duplay in 1872. For painful shoulder with restriction of movements. Over the years aeitipathogenesis evolved with newer terms. 1934 Codman coined the condition Frozen shoulder, and Neviaser 1945 coined the term Adhesive Capsulitis [1]. And other surgeons brought light and charted theoretically the stages of frozen shoulder currently also known as Adhesive Capsulitis. The incidence varies from 2-4% and in some general population 3-7% [1, 2, 3].

Clinically diagnosed as Adhesive Capsulitis, this is a condition where spontaneous adhesion of ligaments, capsule and fibrosis occurs. There are two claims, one suggest synovial inflammation and other a condition similar to Dupuytren's Contracture [2, 4, 11]. Contractures along the long head of Biceps, Infraspinatus, and Supraspinatus.

Treatment varies from NSAIDs, moist heat, physical therapy, oral steroids,

IA Injections, hydro dilation, nerve blocks, Manipulation, open and arthroscopic soft tissue release. Literature supports more incidences in Diabetic patients, females, non dominant hand with bilateral involvement in 12-16% in same individual [1, 2, 3, 4]. Our study was to do noninvasive therapy that is Manipulation under Anaesthesia (MUA) with intra articular injection of 80 mg of Methylprednisolone with 1ml of Lignocaine; which is economical, needs no highly skilled expertise and can be done with standard aseptic procedure even in a District hospital.

To determine the outcome of patients, after we assessed patients for pain, disability and Range of Movements (ROM). The study prospectively recorded the functional outcome of treatment after MUA. We analyzed 40 consecutive patients and outcomes were assessed clinically by SPADI Score.

The Shoulder Pain and Disability Index is the sum total of pain scale and Disability scale and total score is divided by 130 and multiplied by 100 to calculate percentage. Pain is measured by 0-10 with 5 questions. Disability is assessed by 8 questions, score 0-10. Where 0 means no pain and 10 means worst unbearable pain.

Activities of daily living were checked were 0 means no difficulty and 10 means severe difficulty. Higher scales on the subscale will indicate greater pain and disability. Prospective study of 40 patients was conducted in tertiary care Institution of Medical sciences. The study was between May 2019 and May 2020. 40 consecutive patients with painful loss of shoulder movements with limitations in their activities of daily living.

2.1 we included all patients, who have painful and stiff shoulders, with restricted active and passive motion, with normal glenohumeral joint radiologically.

2.2 Any calcific tendinitis, arthritis, traumatic conditions or any other surgeries around the shoulder.

Our study included 40 patients including those with diabetes. All patients gave detail history and evaluation of pain scale and disability done using SPADI score. Clinical Examination and their record of shoulder movements and strength of muscle power were recorded. Only a single X ray in Anteroposterior (AP) view was taken. No patient underwent ultrasound or MRI.

40 patients were hospitalized, and physiotherapy started and all patients were educated for self-mobilization of shoulder. With strict emphasis on avoiding shrugging.

Wall climbing exercise, Pendulum, and other exercises were taught to the patients.

All patients underwent MUA within 5 days and at the same sitting injection 80 mg of Methylprednisolone (MP) mixed with 1 ml of Xyclocaine given anteriorly into gleno humeral joint.

Patient was supine, scapula fixed and pressed with thoracic cage and border of scapula. With help of an assistant. Holding the short lever arm gradual abduction, external rotation adduction and lastly internally rotation movement were done sequentially until audible click was heard.

We had no prior knowledge of pathological thickness of Corocohumeral ligaments, thickness of the capsule, and extent of pathological contractures. Irrespective of the duration we treated all patients with a standard protocol, so intervention rate could be accessed based on outcome at end of 3 months. Out of 40 patients, there were 18 male and 22 females. Out of

40 patients 27 patients were diabetic. 19 patients had right shoulder involvement and 21 left.

The average duration of symptoms like pain and disability was 2.5 months; least duration was 1 month and maximum 7 months. 31 patients after MUA and Inj MP of 80 mg underwent physiotherapy which was supervised for 1 week. 9 patients did not attend supervised physiotherapy at the hospital.

All patients underwent clinical examination at time of MUA, immediately after MUA, after 1st month, 2th month and 3rd month. SPADI score was calculated before procedure immediately after procedure and for each month. The percentage of recovery calculated to merely reflect functional outcome.

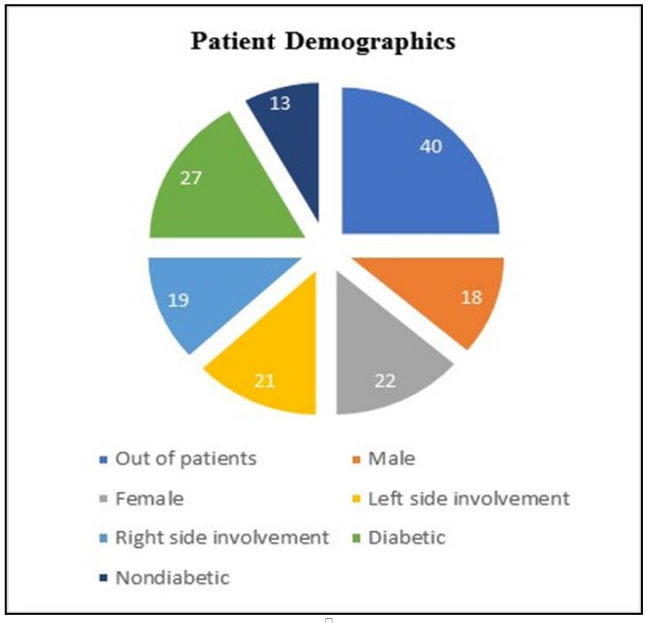

Table 1: Patient Demographics

Male	18
Female	22
Left side involvement	21
Right side involvement	19
Diabetic	27
Nondiabetic	13

Our work sheet tabulated the results in our study with average range of shoulder motions as follows: Abduction 60*, External Rotation (ER) 31°, Internal Rotation 30 (IR), and Flexion 66* at first examination.

We had one patient 55/F who had stiffness and pain who did not respond to treatment, not diabetic, her duration of symptoms was only for 3 months and was of left side. Our hypothesis that it would be like pathogenesis like Duptruyen Contracture in this particular case [4]. Immediately after MUA and injection MP Abduction (Abd) improved to 109.5 EXT rotation (ER) 59.6 Internal rotation (IR) 51° and flexion (FI) 106*

Table 2: Range of motion of shoulder at 3 months

1st month	Abd 125.2°	ER 65.25°	IR 56.5°	FL 123°
2nd month	Abd 132.7°	ER 67.5°	IR 60.2°	FL 130°
3rd month	Abd 135°	ER 68.2°	IR 61°	FL 134°

In our study by using SPADI score for pain and disability we calculated prior to SPADI, Post MUA, and at end of 3 months. In span of 3 months post MUA with injection the range of movements doubled.

The percentage of recovery calculated and averages taken, Preop SPADI Score was

70.7 and Post op 21.45 and the percentage of 67.1%. The predominant range of motions of external and internal rotations were quite resistant to MUA and the underlying pathology of shoulder rotators, their anatomy and pathological changes around them, probably is resistant to MUA.

Statistical Analysis with paired groups were done with comparison before and after MUA of shoulder.

Statistical Analysis paired test of Range of Movements

Abd	Pair 1 Before	VAR00001	110.7692	39	28.50527	7.332	0.000

Discussion

The Frozen shoulder is a condition where in, there is slowly progressive loss of movements of shoulder both active and passive, associated with pain and restriction of activities of daily living. The Natural History of Adhesive Capsulitis is that it is self-limiting. Recovery can take from 24-26 months [1, 2, 3, 4].

However Literature quotes various Surgeons who currently contradict this statement [6], several authors claim pain and loss of range of movements with disability of shoulder. Treatment varies from simple NSAID with moist heat, physiotherapy, oral steroids, intrarticular injections with steroid, hydrodialation, nerve blocks, manipulation, open surgical release and arthroscopic release. Contractures in shoulder may be responsible for ineffectiveness of any treatment. We don't know whether synovial inflammation is the cause or 'Duptruyens type' of capsule of shoulder.

We compared our results with Heidi Vastamaki, and Marti Vasatamaki' study [7].

In their study prior to MUA, Abduction was 75° (ABD), Eternal Rotation 21° (ER), Internal Rotation level of buttock (IR), and Flexion 99° (FL), in our result prior to MUA Abduction was 60°, External was 31°, IR 30° and FL 66°.

End of 8.8 months Vastamaki's study [7] showed in their patients Abduction 167°,

ER 51°, IR level L5 and Flexion 156°. In Our study we obtained at 3rd month on follow up ABD 135°, ER 68°, IR 61° and FI 134°.

Comparing with Thomas[8] et al ABD was 62°, ER 17° IR 17°, FI 165° (pre MUA)

Post MUA at one year follow up was ABD 168°, ER 65°, IR 65°, FL 169°. In our study

ABD 135°, ER 68°, IR 61° and FI 134° at end of 3rd month.

Studies by various authors showed good recovery but they assumed that elderly patients have restricted movements, we stand to contradict to their statements that 90% improvement in pain and range of movements.

Jenkins *et al.*, in their retrospectively had analyzed that 36% had unsatisfactory outcomes [8], in our study it was 33%. The natural history claimed to be self-limiting, can take prolonged duration of time between 14-32 months. Adhesive capsulitis of shoulder with pain and disability would require medication and pose risk of drug induced Nephropathy.

Though optimal time suggested by Vastamaki, and Vajonen is between 6-9 months for MUA, clinical outcome was questionable by many authors. Dodenoff, Levy, Wilson and Copeland in one series, and Janada and Hawins [9] proved that pain and disability can be reduced after MUA. This shortens the time interval of patients to resume work, disease itself cannot be evaluated merely on duration of months and prevailing changes for staging purpose cannot be guessed. Clinical importance of outcome can be questioned and hence its variable. To achieve necessary functional activities there has to be range of motion which is free.

1. Early Recovery

Hence irrespective of duration of symptoms all patients were hospitalized and for 5 days physiotherapy given and then taken up for MUA and Injection MP 80 mg with 1ml of 2% Xyclocaine into the joint.

To enable eating approximately 60-100 of abduction, horizontal abduction about

40-70 degrees. Rotations about lessor range. For reaching perineum 40-60 of abduction and 90 of Internal rotation. Similarly, for combing hair, tucking shirt, or putting on pants, etc.

A range of movements which are not full and free but can able patients do activities of daily living which are pain free [8, 9, 17].

Pain and Disability prior to MUA on Average score was 70.7 (SPADI) after MUA at 12 weeks the score was 21.45. Post SPADI score of 21.45 denotes some residual pain and disability, but with useful functional outcome.

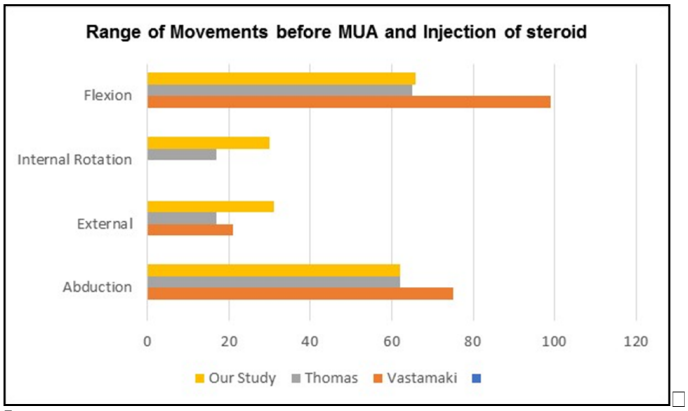
There was no complication in our cases. Grant *et al.* [10] compared MUA with arthroscopically done surgical release and reported that there was not much difference [10]. Arthroscopically done release has risks like chondrolysis due to thermal heat, risk of infection, risk of accidental axillary nerve damage. Open Release with manipulation offers no advantage on the contrary it reduces the speed of recovery. Also risk of infection introduced into the joint.

Rotator Cuff was analysed by Atoun et al with ultrasound before and after MUA and found cuff undamaged [12].

Sasanuma *et al.* [13] found no rotator cuff tears on MRI after Manipulation.

2. Cuff Tear Arthropathy

In a Retrospective study of 51 patients' frozen shoulders done by Wang *et al.* [14] after MUA reported 89% of cases had good results. In our series 67% had good results.



The difference of 22% in the outcome was because all patients were followed up to 3 months strictly. Whereas Wang followed up to 1 year. In their study patients were immediately mobilized, in our study all patients were given rest post of period for 24 hours, to enable them recover from pain.

Another probable cause is 9 patients dropping out of supervised physiotherapy at OPD for 5 days. One patient had

absolutely no recovery, few others had a slow start, our follow up was limited strictly till 12 weeks. We assume out of 22% of cases if given more time recovery rate would improve.

** follow up 1yr or more.

ROM after MUA and Injection of steroid

The study shows functional outcomes is improved after MUA and after Intra articular Inj of MP. Recovery of External rotation and Internal Rotation takes a longer time and their range of movements is again dependent on retraction of capsule and narrowing of clear space around ligaments. Non reversible pathological changes like fibrosis and capsular thickening with adhesions of glenohumeral ligaments.

Farrell *et al.* [15] their study of 19 shoulders after MUA, followed up for 7 years. They obtained Abduction 155°, External Rotation 76°, Internal Rotation 73° and Flexion 159°.

In our study we obtained 135° of abduction, 68° of External Rotation, 61° of Internal Rotation and 134° of Flexion at 3rd month which is beneficial to be patient.

Our study follows up limited up to 3 months. It is evident by MUA and inj of steroid the pain and stiffness improves, the shoulder recovers functional range of movements. However the limitations of this study: 40 patients and follow up to 3 months. No control group of patients, Non divided into 2 groups that is diabetic and non diabetic. Standard and same protocol of treatment followed. No 2 different methods of treatment. Our prospective study included both diabetic and non diabetic patients.

Manipulation of shoulder with injection of Steroid is a good method of treatment.

It's cost effective and speeds up recovery from pain and disability. It can be done safely as a day care procedure, and even in district Hospital. MUA carries little risk, without any need for expert technical skill. Majority of patients are happy for the range of movements recovered.

It is unnecessary to wait and observe for prolonged time or do prolonged follow up. Recurrence rate is low compared to arthroscopic surgical release and is subject to further trials and comparative studies.

Here by thank the librarian Mr. J. Mahendran of PSG Institute of Medical Science and Research.

I acknowledge the help from Dr. Vibaha, intern for helping in calculating averages on excel sheet and also Dr. Anil Mathew, Professor of Community Medicine, PSG, for his statistical analysis and advice.

Analysis of surgical management of proximal humeral fractures

Vijay Baba N and Prasanna C

DOI: https://doi.org/10.22271/ortho.2020.v6.i4d.2341

Abstract
Aim: To assess the outcome of fractures of proximal humerus managed surgically.
Materials and Methods: This prospective clinical study is an analysis of 22 cases of surgically managed proximal humeral fractures, undertaken at the Department of Orthopaedics & Traumatology, Govt. General Hospital, Chennai. Standard anteroposterior radiographs of the affected shoulder were taken in all patients and most of them were further evaluated with Neer's three view trauma series. CT scan was done in patients with complex fracture dislocations, to delineate the fracture pattern and the direction of dislocation. The indications for surgery were displacement more than 1cm and angulation > 45^0. Patients not satisfying these criteria were treated conservatively and not included in this study. All the patients were operated by the standard anterior deltopectoral approach. All the patients were followed up monthly for the first 3 months and later every 3 months. During follow-up patients were clinically evaluated for pain, function and rotation. Radiological evidence of fracture union was observed by serial x-rays.
Result: Majority of the injured patients were males (72%). Mean age of the study population was 36.75 years. RTA was the most common mode of injury (36.3%). There were no bilateral fractures; all were right handed persons and the dominant arm was involved in 16 (72.7%) patients. Early complications were encountered in 6 (25%) patients and late complications were encountered in 8 (30%) patients
Conclusion: This study concluded that functional outcome of two part fractures is better than three part and four part fractures and the results are better with fractures than with fracture dislocations.

Keywords: proximal humerus, fracture, management, surgery

Introduction
Fractures of the proximal humerus are challenging to diagnose and treat. They are not uncommon, accounting for 4% to 5% of all fractures [1, 2]. Emphasis is placed on complete and accurate diagnosis and formulation of safe and simple techniques for restoration of stability, fracture healing, cuff integrity, motion and function.
Diagnosis has been facilitated with adoption of three-right angled trauma series [3-5] supplemented with CT or MRI. With more standard use of four-segment classification system for fracture and fracture dislocation [6-8] a protocol for management and comparison of long term outcome of similar injuries had been made possible.
There have been improvements in fixation techniques during open reduction and in the understanding of the role of prosthetic replacement [9-12] to maximise anatomic restoration while minimising immobilisation time during which stiffness develops.
With the advent of improved fixation techniques the elderly no longer need be denied effective surgical treatment, especially at a time in life, when the shoulders are often needed for ambulation with canes and crutches. Maintenance of good shoulder function may make a good difference for their independent life style. Hence the present prospective clinical study was conducted to assess the outcome of fractures of proximal humerus managed surgically.

Materials and Methods
This prospective clinical study is an analysis of 22 cases of surgically managed proximal humeral fractures, undertaken at the Department of Orthopaedics & Traumatology, Govt. General Hospital, Chennai.

Methodology

Standard anteroposterior radiographs of the affected shoulder were taken in all patients and most of them were further evaluated with Neer's three view trauma series which involves the AP view in the plane of scapula, lateral view in the plane of scapula and axillary lateral view. CT scan was done in patients with complex fracture dislocations, to delineate the fracture pattern and the direction of dislocation.

The indications for surgery were displacement more than 1cm and angulation > 45^0. Patients not satisfying these criteria were treated conservatively and not included in this study. All the patients were operated by the standard anterior deltopectoral approach.

Surgical procedure (Figure 1.1)

Under general anaesthesia, patients were positioned supine on the operating table. A sand bag was wedged under the medial border of scapula to push the affected shoulder forward while allowing the arm to fall backward, thus opening up the front of the joint. Elevation of the head end of the table considerably reduced the bleeding. An incision was made from the coracoid and carried distally in the line of deltopectoral groove to the deltoid insertion. The internervous plane was dissected between deltoid, which is supplied by axillary nerve and pectoralis major which is supplied by pectoral nerves. In most cases, cephalic vein was preserved with either the deltoid or pectoralis major. In some it was ligated. The deltoid was partially erased from the clavicle for better exposure and retracted laterally and superiorly. The long head of biceps found under the insertion of pectoralis major was used as a guide to the interval between greater and lesser tuberosities. It also helped expose the rotator interval between the anterior part of supraspinatus and superior edge of subscapsularis. With the arm abducted 70-90 degrees the tuberosities, humeral head were exposed. Fracture fragments were reduced with bone holding forceps and reduction confirmed with image intensifier. Implants were selected according to the geometry of the fracture.

Cancellous screw fixation

For cancellous screw fixation the displaced greater tuberosity fragment was reduced with bone holding forceps and drill holes made with 3.2mm dill bit and 6.5mm cancellous screws inserted after tapping the near cortex.

Buttress plating

For AO "T" buttress plating, the fracture fragments were reduced. 'T' plate was placed on the lateral aspect and stabilised with cancellous screws for the tuberosity fragments and cortical screws for the shaft.

Tension band wiring

For Tension band wiring, 'k' wires were passed from the greater tuberosity into the shaft. The `k' wires were cut close to the tuberosity and bent. Drill-hole was made in the shaft and a 18G SS wire passed in the form of 'figure of 8' from the `k' wires to the drill hole, stabilising the fracture fragments.

Minimal Fixation with 'k' wire

For minimal fixation with `k' wires, the `k' wires were passed from the shaft to the head of humerus and another `k' wire from the greater tuberosity to the medial cortex of humeral shaft.

Hemiarthroplasty

For hemiarthroplasty the standard anterior deltopectoral incision was extended down to expose the shaft. Subscapsularis was retracted medially with lesser tuberosity to expose the interior of joint. The articular head fragment was removed and the joint cleared of blood clots and bone debris. The intra articular portion of biceps was identified as it attaches to the supraglenoid tubercle of scapula. If it were not injured, it was preserved by retracting it laterally. The stem diameter and length required in the proximal 12 to 15cm of the medullary canal were estimated. Once the stem size and neck length were determined the prosthesis was inserted by hand in 35-40 degrees of retroversion. The amount of retroversion was determined by flexing the elbow to 90 degrees and palpating the epicondyles. Suture passed through tuberosities or tendon bone junction was passed through holes in the neck of prosthesis. Anatomic reduction of tuberosities was done beneath the collar or head of prosthesis and sutures tightened.

Polymethyl methacrylate cement was used to secure the prosthesis in bone, if fixation was not adequately stable.

Fracture dislocation

In irreducible fracture dislocations and head splitting fractures the coracoid was predrilled and osteotomised and retracted with the tendon. Arm was externally rotated and blunt instrument passed between subscapsularis and capsule and stay sutures applied. It was divided one inch from its insertion and retracted. Capsule was incised longitudinally to open the joint and reduce the articular fragment.

In all patients, the rotator interval between anterior edge of supraspinatus and superior edge of subscapsularis was closed with multiple interrupted sutures. The deltoid was reattached to the clavicle and wound irrigated and closed over suction drain.

Post-Op Care and Rehabilitation

Prophylactic antibiotics which were started before surgery were continued for 48 and 72 hours postoperatively.

In a few ice packs were used to decrease the swelling. Passive elbow flexion and extension were started by 24 to 48 hours.

Sutures were removed by 10th postoperative day.

Phase I: Exercises consisting of pendulum exercises were encouraged from the first week. Gentle passive forward flexion and internal and external rotation were started by third or fourth week.

Phase II: Exercises consisting of active range of motion exercises and resistive exercises were started by 4 to 6 weeks.

Phase III: Exercises consisting of advanced stretching and strengthening exercises were started by 3 months. Light weight lifting was started after 3 months.

Follow-up

All the patients were followed up monthly for the first 3 months and later every 3 months. During follow-up patients were clinically evaluated for pain, function and rotation. Radiological evidence of fracture union was observed by serial x-rays. (Figure 1.2)

Statistical Analysis

The recorded data was compiled and entered in a spreadsheet computer program (Microsoft Excel 2010) and then exported to data editor page of SPSS version 19 (SPSS Inc., Chicago, Illinois, USA). Descriptive statistics included computation of percentages.

Results

Discussion

In this study, we have analyzed 22 cases of surgically managed proximal humeral fractures in our hospital. There was male preponderance in our study 16 (72%) which was the same as the study by Flatow *et al.* [13] In a study conducted by Hawkins *et al.* [14] involving 15 patients of proximal humeral fracture, there was female preponderance. This is thought to be a result of advanced osteoporosis.

In our study the average age of the patients was 36.75 years which was much lower than reports by Hawkins *et al.* [14] and Flatow *et al.* [13] and Cornell *et al.* [15]

RTA was the most common mode of injury in our study, probably because majority of the patients were in the younger age group (average 36.75). In a study by Flatow *et al.* [13] fall on the arm was the predominant mode of injury probably reflecting the increase in average age of the patients (53 mean) in their study.

In our study, unusual mode of injury like seizures was present in two patients and electrocution in two patients. There was a predominance of two part fracture in our study (50%) of which greater tuberosity fractures were the most common. Associated dislocations were present in 45% of the patients. With reduction of glenohumeral dislocation if tuberosity fragment remained displaced >1cm or angulated > 45 degrees, ORIF was done. Repair in such patients restored the dynamic stability by reattachment of the muscles of the rotator cuff. Flatow *et al.* [13] in a series of 12 patients reported 50% excellent results and 50% good results in patients treated by ORIF for two part greater tuberosity fracture.

Closed treatment of three part fracture is associated with moderate pain, poor motion and disability. ORIF was associated with good to excellent results in more than 80% of patients in a report by Hawkins *et al.* [14] and recommend operative treatment for healthy active individuals who have a three part fracture of the proximal humerus. Cornell *et al.* [15] reported good results in 10 of 13 patients treated with screw-tension band technique for 3 part fracture. Prosthetic replacement for 3 part fracture has been used by several authors but we have not done prosthetic replacement for three part fracture in our study.

In the treatment of four part fracture and fracture dislocations, less than 10% good or excellent results are obtained with either closed or open reduction or internal fixation. Isolated reports of revascularisation of humeral head following open reduction and internal fixation indicate satisfactory healing. Neer and Rockwood have reported nearly 90% excellent results with an improved technique utilizing long deltopectoral approach and better rehabilitation. [16] This has become the preferred technique of most surgeons and we have also used the same technique. From the data presented in this study, we have demonstrated that majority of the patients had no pain or only mild pain (80%) which is comparable to the study conducted by Hawkins *et al.*15 and Flatow *et al.* [13]

The average active elevation in our study in two part fractures was 149 degrees and average external rotation was 62.5 degrees which are comparable to the study by Flatow *et al.* [13] in a study of 12 patients of two part fractures treated surgically.

The average elevation in our study with three part fracture was 112.85 degrees and external rotation was 45 degrees which are also comparable to the study by Hawkins *et al.* [14] of 15 cases of 3 part proximal humerus fractures treated surgically.

We also have seen few complications in our study. Malunion of greater tuberosity fragment in a patient with 3 part fracture treated with buttress plating resulted in restriction of abduction and impingement. Another patient had malunion of

surgical neck, but had excellent functional result reflecting the fact that radiological outcome may not imply functional outcome.

Heterotopic ossification occurred in one patient with 2 part fracture dislocation, probably because the patient had received native treatment in the form of many attempted reductions and massage. Several authors have reported an incidence of upto 10% of heterotopic ossification in proximal humeral fractures. There were no non-unions or radiographic evidence of avascular necrosis or deep infection in our study.

Finally a prolonged, closely monitored and well defined program of rehabilitation was necessary to obtain the best functional results. We have followed the three phase rehabilitation protocol of Hughes and Neer [17] in all our patients and this has provided good results. For some patients this had taken as long as a year to achieve nearly full range of motion and function.

Conclusion

The present study concluded that: functional outcome of two part fractures is better than three part and four part fractures; the results are better with fractures than with fracture dislocations; in severely comminuted fractures, where anatomy cannot be restored without extensive soft tissue dissection, fixation with 'k' wires and screws gave better functional results and results are best when operative method results in stable fixation that allows early passive mobilization.

ABSTRACT: Stress fractures are common overuse injuries. The pathogenesis is multifactorial and usually involves repetitive sub-maximal stresses. Stress fractures have been frequently reported among young military recruits and in sports persons, but to our knowledge they have not been studied among the paramilitary trainees. The present study was carried out at the Central Industrial Security Force training center at Arakkonam, Tamilnadu from March 2010 to May 2012 to find the incidence of stress fractures among fresh trainees. All patients presenting with symptoms suggestive of stress fractures were evaluated. A total of 5 cases out of a total of 2000 trainees (0.25 %) were confirmed as stress fractures based on clinical and radiological findings.
KEYWORDS: Stress fractures, Paramilitary Trainees.

INTRODUCTION: A stress fracture is the response of bone to repeated stress, none of which by itself is sufficient to cause a fracture. Stress fractures represent one of the most common and potentially serious injuries.[1-3] Stress fractures occur among persons with normal bones and no acute injury who are undergoing physical activity to which they are unaccustomed.[4-6] The underlying pathophysiology is believed to relate to repetitive mechanical loading of bone secondary to physical activity that stimulates an incomplete remodeling response.[7-9]

Stress fractures are traditionally been described in military recruits, but are also seen in sports persons. However they are known to occur in anyone being exposed to a level of physical stress or activity to which he or she is not adapted.[10] A literature search revealed that stress fractures are extensively studied in army recruits and sports persons, but not in paramilitary personnel. Even though the amount of training varies between military and paramilitary trainees, they are also exposed to a high level of physical training to which they are unaccustomed. Hence the present study was initiated with an aim to find out the incidence of stress fractures among the paramilitary trainees

MATERIALS AND METHODS: The study was conducted among the paramilitary trainees at central industrial security forces (CISF) training centre, Arakkonam, Tamilnadu, India. The study period was from March 2010 to May 2012 (27 Months). Approximately 2, 000 trainees were trained at the centre during the study period. All the trainees were males and were in the age group of 21 – 25 years. Fresh trainees from the training centre who reported to our institute with symptoms suggestive of stress fractures were evaluated clinically and radiologically.

Clinical evaluation included a thorough history regarding the activities involved and interpretation of point tenderness at specific regions. All the trainees were particularly enquired about the habit of smoking and alcohol intake. Radiography included antero- posterior and lateral X-ray projections of the involved anatomical region.

DOI: 10.14260/jemds/2014/2174

The training schedule included various forms of physical activities such as drill, short distance sprinting, long distance running, high – jump, obstacles, work- up and firing. All cases diagnosed as stress fractures were given splinting in the form of Plaster of Paris (POP) slab, except for one case of fibula stress fracture. All were refrained from physical activities and were kept on non-weight bearing mobilization with the help of a quadruple walker support for a period of 6 weeks. The patient with fibula fracture was put on a crepe bandage and was advised non-weight bearing. The POP slab was removed at 6 weeks and patients assessed clinically for point tenderness at the fracture site. Activities were gradually increased over a period of 4 weeks.

OBSERVATIONS: A total of five cases were diagnosed as stress fractures based on the clinico-radiological evaluation. The mean age was 23 years (range 22- 25). The fracture distribution was as follows: tibia- 3 cases, femur and fibula- one case each. The stress fracture in the tibia was located in the lower one third in two cases and upper one third region in one case. The femoral stress fracture was at the junction of middle and distal one third. The fibula fracture was located in the mid- shaft region.

All the cases presented with the symptom of pain in the involved extremity. The pain was localized to the fracture site. The patient with femoral stress fracture also had a limp at presentation. The mean duration at presentation was 3 weeks. Pain was typically aggravated with physical activities and progressively worsened with continuation of activities. The pain was relieved with rest in all the cases. None of the trainees were smokers or alcoholics. Radiologically a faint fracture line (lucency) was visible in the case of fibular stress fracture (Fig. 1). Three cases showed heaped up callus at the site of stress fracture without clearly showing a fracture line. Periosteal reaction in the form of sclerosis was seen in one case. Table1 summarizes the observations of this study.

DISCUSSION: Stress fractures are common injuries that begin with repetitive and excessive stress on the bone. This leads to the acceleration of normal bone remodeling, the production of micro-fractures (caused by insufficient time for the bone to repair), the creation of a bone stress injury (i.e., stress reaction), and eventually, a stress fracture.[11, 12] Persons who participate in repetitive, high intensity training, such as athletes and military recruits, are at increased risk of developing stress fractures. Stress fractures, classically been described in military recruits and in sports persons, hence, studied and reported extensively in such populations.

The Central Industrial Security Force (CISF) came into existence in 1969, to guard the industrial establishment and protect them from crime. CISF is just a unique organization in paramilitary forces for India, which works for sea ways, airways and some of the major installations in India. A rapidly grown organization over the past four decades, the trainees receive a highly demanding physical training at the training centers. Therefore, they are equally prone for stress injuries. To the best of our knowledge no studies of stress fractures in paramilitary persons have been reported in literature so far. Hence, the present study was initiated.

We found an incidence of stress fractures as 0.25 per cent in the present study, which was similar to the incidence reported by Das and Goel in trained soldiers.[13] We calculated the incidence taking into account the total number of trainees (5) who had stress fractures to the total number of trainees (2, 000) trained at the centre during the study period. Various studies of stress fractures in

military recruits have found an incidence ranging from less than 2 per cent[14] to an unusually high incidence of 31 per cent.[15]

Several risk factors have been identified for stress fractures. Persons who participate in repetitive, high-intensity training such as athletes and military recruits [16-19], recreational runners who average more than 25 miles per week[17, 20] are at increased risk of stress fractures. Poor nutrition and lifestyle habits may increase the risk of stress fracture. One study found lower 25-hydroxyvitamin D levels in Finnish male military recruits with stress fractures.[21] With the rising need for well-trained paramilitary forces in the country, we believe, they are equally prone for stress fractures as other persons.

In a study of 330 stress fractures in Indian recruit at a military training centre, it was found that; tibia is the commonest bone involved mostly in its upper third.[22] We also found the tibia as the commonest bone involved, but the lower third involvement was more (2 cases) as compared to the upper third (1 case).

Plain radiography should be the first imaging modality considered because of its availability and low cost.[23] Plain radiography is usually negative initially but is more likely to become positive over time.[24] The value of computed tomography (CT) is limited because of lower sensitivity and higher radiation exposure than other imaging modalities.[25] Magnetic resonance imaging (MRI) is superior for early detection of stress injury. However, MRI may also identify reactive bone remodeling (interpreted as early stress injuries) and, therefore, should be clinically correlated for stress fracture.[26, 27]

With plain radiography, a faint lucency may be seen at first, although stress fractures are usually identified by subsequent indirect findings: periosteal thickening or sclerosis, cortical changes with initial decreased density (“gray cortex”), and, more commonly, later callus formation, or endosteal thickening and sclerosis.[18, 24] We were able to identify the stress fracture in plain radiography on all 5 cases probably because, they presented to us at a mean period of 3 weeks. Callus was well seen in majority of our cases (Fig. 2).

Management in all the cases is essentially rest, support to the involved part and abstinence from the strenuous physical activity that caused the stress fracture.

Functional and radiological outcome of lateral approach for hemiarthroplasty for hip

Dr. Dhiyanesh K and Dr. Reguvaran

DOI: https://doi.org/10.22271/ortho.2019.v5.i1d.38

Abstract
With increasing geriatric population, more number of femoral neck and trochanteric fractures are noted. Surgery being the gold standard for early mobilisation, less evidence exists on surgical approach. The aim of this study was to assess the functional and radiological outcome of lateral approach in patients of more than 55 years of age. 30 patients above 55 years of age with an acute fracture of the femoral neck, who underwent hemiarthroplasty through lateral approach, in the Department of Orthopaedics, MGMC&RI, SBV university were followed up for 6 months and their functional and radiological outcomes assessed. The patients were of a mean age of 69.2. The mean Harris hip score was 77.5. There was no incidence of prosthetic dislocation, infection. Complications like Limb length discrepancy, myositis ossificans were noted. Abductor lurch were present which recovered with regular physiotherapy and ambulation. The use of Lateral approach to the hip in hemiarthroplasty showed excellent outcomes and no dislocation rates and hence the preferred approach for hemiarthroplasty.

Keywords: Harding's approach, hemiarthroplasty, neck of femur fracture

1. Introduction
Proximal femur fractures including intra and extra capsular fractures are expected to increase in incidence with increasing average life expectancy of individuals throughout the world. These fractures constitute the higher quotient in all osteoporotic fractures that occur in elderly age group [1] It has been proved time and again that proximal fractures pose a great morbidity and mortality to the patient and economic burden to the society.
Conservative management of intracapsular fractures (neck of femur fracture, femoral head fractures) is associated with higher mortality in the first 30 days post trauma [2]. The surgical options available in 50 and below age group involve closed or open reduction and internal fixation. The options in elderly include hemi arthroplasty (monopolar or bipolar) or total hip replacement based on patient profiles, patients economic condition, personal preferences and training of the surgeon. Complications of anaesthesia and surgery far outweigh the complications of restricted mobility associated with non operative management, except in a very few who are unfit for surgery. The goal of this operation is to provide a stable, pain-free, mobile joint and making the patient mobile and non-dependent [3].

Fig 1: Intracapsular neck of femur fracture

Fig 2: Austin moore prosthesis in situ

Numerous new approaches to the hip have been described since the 1990s; most of the approaches are based on older approaches and are modified for a specific surgical procedure. Mainly two surgical approaches are performed while treating the fracture neck of femur with hemiarthroplasty. Posterior Approach is associated with an increased dislocation rate and revision rate due to dysfunction of the posterior soft tissue structures [4]. The lateral approach is associated with limping of the patient post surgery due to the damage to the abductor muscles [5].

McFarland and Osborne described a lateral approach to the hip that preserves the integrity of the gluteus medius muscle. They noted that gluteus medius and vastus lateralis muscles can be regarded as being in direct functional continuity through the thick periosteum covering the greater trochanter and can be erased as a single unit from posterior to trochanter. Harding described a useful modification of the McFarland and Osborne direct lateral approach by reflecting the anterior half of this bundle. [6] This approach can be easily made with the patient in supine position.

Frndak *et al*. modified the Harding's direct lateral approach by placing the abductor split more anterior, directly over femoral head and neck must not extend more than 2 cm above the lateral lip of the acetabulum to avoid damage to the gluteal neurovascular bundle [7]. This offers exposure of the femoral head and neck requires less retraction. McLauchlin described a direct lateral approach to the hip through the gluteus medius used for many years by Hay at the Stracathro Hospital. Omega incision was described by I.D. Learmonth, wherin a omega shaped incision is made in the Gluteus medius and vatus lateralis, retracting the gluteus medius, minimus along with few bone shingles from the aponeurotic junction of the greater trochanter [8] So we have decided to study a short term follow up of functional outcome hemiarthroplasty done for neck of femur fractures through lateral approach using hardinge's approach.

2. Materials

The study was conducted in MGMC&RI over a period of one and a half years following the ethical committee's approval.Thirty consecutive patients with fracture neck of femur admitted in the department of Orthopaedics through casualty/OPD who required Hemiarthroplasty were selected for the study.

3. Methodology

Patient with a suspected neck of femur was admitted in the casualty ward, he/she was clinically examined and analgesics were given to relieve pain. Traction was maintained during radiological examination to minimize the pain and the diagnosis was confirmed. X-ray of pelvis with both hip joints-anterior-posterior view, X-ray of involved side hip with femur full length-AP and lateral view were taken. This was followed by routine work up for surgery. Patients were detailed regarding the purpose of the study and surgery, all consents obtained. Garden's Classification of Fracture Neck of Femur. Skin traction was applied for the affected limb to reduce the pain. Pre-operative training was given on -Deep breathing exercises, Static quadriceps and calf muscle pumping exercises, strengthening exercises to upper limbs. We used Austin moore's prosthesis /bipolar prosthesis based on canal diameter and social background of the patient.

Lateral (Harding) approach under combined spinal +Epidural /spinal anaesthesia, patient was put in a lateral position with the affected hip facing upwards. After painting and draping the affected lower limb and hip a lazy J- incision centring over greater trochanter is made.

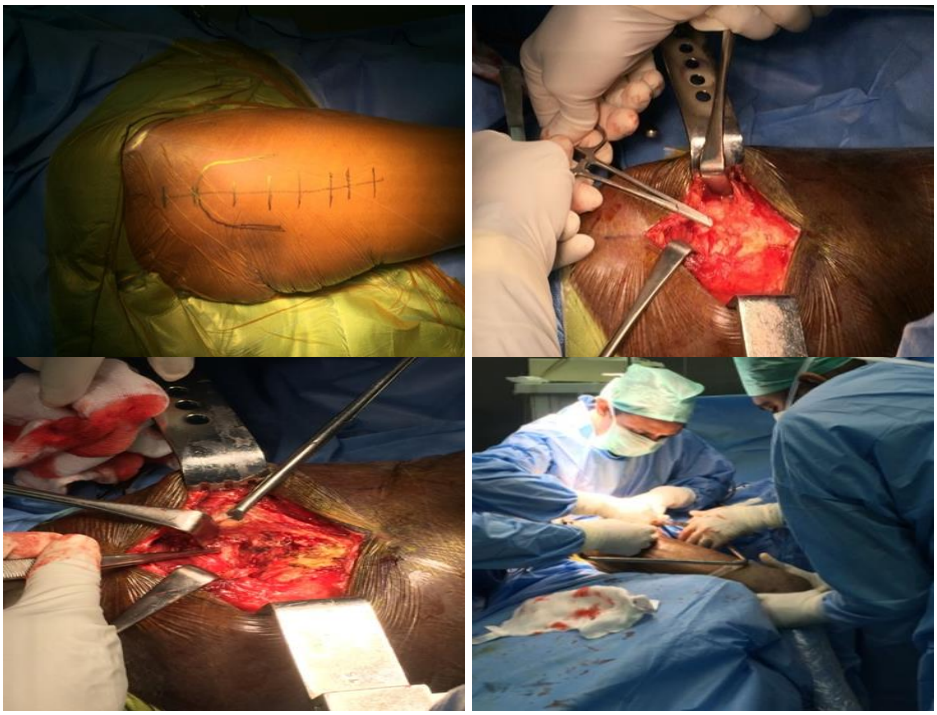

Fig 3-6: Shows marking of incision line with respect to greater trochanter, tendinous junction of gluteus medius and vastus lateralis and its incision ,dislocation of hip joint by flexion, adduction and internal rotation

Fascia lata is divided along skin incision. Tensor fascia lata is retracted anteriorly and gluteus maximus posteriorly. Tendinous junction of gluteus medius and vastuslateralis is exposed. An oblique incision is made over gluteus medius along the line of muscle fibres, across the greater trochanter leaving posterior two third still attached to the trochanter. This incision is carried proximally over the gluteus medius not more than 3 cms and distally in line with vastuslateralis.

The tendinous insertion of gluteus medius and vastuslateralis is elevated anteriorly. The capsule is visualised and 'T 'incision was made.

The hip and knee was flexed and the limb was externally rotated and adducted. Femoral head is extracted with a cork-screw extractor, taking care not to damage the articular surface of acetabulum. Acetabulum is inspected and all loose debris and bone fragments were removed, along with the remnants of the ligamentum teres. The entry in the proximal femur is made with a box cut and then the femoral canal is prepared taking care to give adequate lateralisation of rasp. The femoral canal is broached by hand with a rasp in 5 – 10° ante version and valgus position, During rasping decision is taken on use of cement depending on the size of the femoral canal. Head size of prosthesis was determined by measuring the head of femur, which was removed and measured with a measuring template. A trial reduction with the selected prosthesis was done. Range of movement, mobility and stability of the joint assessed. An appropriate size AMP/Bipolar Prosthesis is impacted with or without Bone cement in to the femoral canal. Care is taken while inserting the prosthesis to maintain adequate anteversion. Once the cement sets, prosthesis is then reduced by traction and internal rotation. The hip was tested for full range of movement and stability intra-operatively. Drill holes are made in the greater trochanter and 1 vicryl was used to anchor the abductors to the bone. The wound was closed meticulously in layers over suction drain maintaining haemostasis throughout the procedure and dressing was applied.

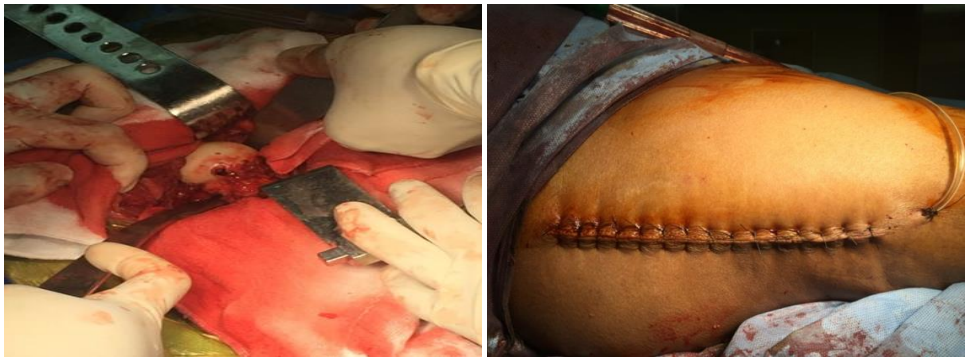

Fig 7 and 8: Shows exraction of femoral head and sutured surgical site respectively

3 doses of antibiotic were given post operatively. Analgesics were administered according to patient's analgesic requirements. The drain was removed on 2nd Postoperative day. Static quadriceps exercises were advised to all the patients as soon as they recovered from the anaesthesia. All the patients were advised to sit up with back rest from the 1st postoperative day. Deep breathing exercises were advised. A post-operative check x-ray was taken and the valgus seating with 10^0 anteversion was confirmed. Any limb length discrepancy was noted. Knee flexion and isometric quadriceps exercises were started on 2nd postoperative day and patients were mobilized with walkers with full weight bearing. They were discharged on post op Day 5.

The patient's were advised not to adduct or flex the hips beyond 90° or involve in activities that place heavy loads or stresses on the hip for the next 3 weeks. They are advised to carry out exercises as advised pre op and advised to come for follow up at the end of second week of post-operative period for suture removal. For further follow up at 1month, 3months and 6 months.At follow up, detailed clinical examination was done systematically. They were examined for gait, pain, tenderness, movements, deformities and length discrepancies. The distance the patient cover following surgery was questioned and compared to pre fracture state. The x-ray of the operated hip was taken at 1st, 3rd and 6th month.

Data Collection

All data was entered into a Data Collection Performa Sheet and were entered into Excel (MS Excel 2011). Other biographical details were also collected including date of birth, weight and height.

Statistical Methods

The data were analyzed in the study using proportion and Chi-Square test as the results were of categorical values. Values of $p<0.05$ was considered statistically significant.

Results and discussion

A total number of 30 patients were selected on the basis of pre-defined inclusion and exclusion criteria after informed consent. All patients were recruited through the out-patient and the emergency services department of Orthopaedics, MGMC &RI, SBV University, Pondicherry, INDIA.Majority of patients were between 61-70 years old (46.7%). and 30% of patients were between 71-80 years old and 13.3% of patients were between 50-60 years old. Females constituted 66.7% and Males 33.3%.Majority of patients had domestic fall (70%) and while 26.7% by RTA and 3.3% of patients by fall from height.

Table 1: Distribution by Mode of Injury

Mode of Injury	Frequency	Percentage
Domestic Fall	21	70%
Fall from Height	1	3.3%
RTA	8	26.7%
Total	30	100%

Left side constituted (60%) and 40% of the patients had injured their right side. Gardens type III fracture constituted (43.4%) and 30% of the patients had gardens type IV and 23.3% were under Garden's Type II and 3.3% under Type I fractures

Table 2: Distribution by Gardens Type

Gardens Type	Frequency	Percentage
I	1	3.3%
II	7	23.3%
III	13	43.4%
IV	9	30%
Total	30	100%

Uncemented hemiarthroplasty was done in 60%. While 40% required cement due to wide canal.

Outcome was evaluated by clinical and radiological means. Clinical assessment was done by using the Harris Hip Score and surgical site infection. Radiological assessment was done based on the presence or absence of myositis ossificans, Prosthesis alignment, peri-prosthetic fracture and loosening. 30 cases of intra-capsular fracture neck of femur were managed by hemiarthroplasty, through hardinge lateral approach. We had excellent results in 12 cases (42.9%), good in 12 cases (42.9%), fair in 3 cases (10.5%) and 1(3.5%) poor case, with an average score of 77 points according to the Harris hip rating system.

Table 3: Distribution by Harris Hip Score at 6 Months post op

HHS on 6th Month	Frequency	Percentage
<70	1	3.5%
70-79	4	10.5%
80-89	12	42.9%
90-100	12	42.9%
Total	28	100%

Among the 3 patients with fair results, one was a chronic alcoholic and did not fare better due to bad health and associated medical problems. The other was a 70 yrs old female, who was a housewife didn't fare well due to severe osteoarthritis knee which limited her mobility. Another patient developed myositis ossificans, which limited her hip abduction. Among the poor outcome group, patient had a proximal femur blowout due to domestic fall during her 1st month of post operative period.

We have got good (42.9%) to excellent(42.9%) results in 85.8% of the cases. In a series of 20 patients done by Dr.Sivakumar using lateral approach 20% of patients had excellent outcome,60% of patients had good outcome,20% had fair outcome.[12] We did total 30 cases of hemiarthroplasty in Hardinge's approach, at 3 months follow up we found excellent abductor muscle function in 20 patients, good in 5 patients and poor in 5 patients. After good physiotherapy, at 6 months' postoperative period we found excellent abductor muscle function in 26(85.7%) patients and poor in 2 (14.3%) patients. Picado had 7.5% abductor lurch at 6 months post op.[9]

Table 4: Distribution by Abductor Lurch at 6 months

Abductor Lurch	Frequency	Percentage
Yes	2	14.3%
No	26	85.7%
Total	28	100%

23 (76.6%) had no surgery related complications during the follow up period. 2 (6.7%) of patients had lengthening and 2 (6.7%) shortening and 1 had Myositis Ossificans which was detected at 3rd month and was nonprogressive at the end of six months.2 Patients lost their lives 3 months post surgery due to non surgery related health issues

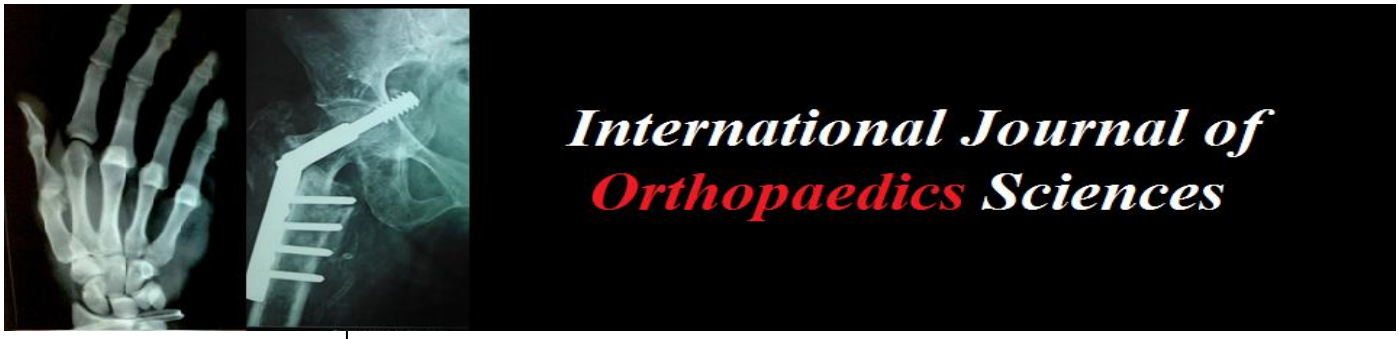
Table 5: Distribution by Complications

Complications	Frequency	Percentage
Lengthening	2	6.7%
Shortening	2	6.7%
Myositis	1	3.3%
Expired	2	6.7%
Nil	23	76.6%
Total	30	100%

In the reported series by Mulliken *et al*, in 770 patients operated using the above approach, they encountered 0.3% of dislocation rates, limp in 10%,myositis in 3%. [10] No Infection was encountered in our patients. In this study, there was no incidence of dislocation. We had limb length discrepancy in 4 (13.4%) patients which was due to excessive or inadequate neck resection this was not due to the surgical approach.A recent meta analysis on the anterolateral and posterior approach over a period of five years shows no significant differences in dislocation rate [11]

Conclusion

After treating 30 patients with intracapsular fracture neck of femur, by Hemiarthroplasty through lateral approach, it has better advantage in terms of stability and functional results. There is reduced morbidity, with excellent to good results in 85.8% and mean Harris hip score of 77 points. We did not encounter any dislocation in our series probably due to modified Hardinge Approach, better soft tissue balancing and as incision at non dependent part of body, better wound care and hence less chance of infection. Modified Hardinges approach is a excellent surgical approach if proper re-suturing of the abductor band and capsule closure is done. It requires a clear understanding of not to injure the superior gluteal nerve by limiting the proximal dissection of gluteus medius within 3 cm from tip of greater trochanter thus avoiding lurch in post operative period – the commonest complication of hardinge approach in early learners.



Limitations

We do not have a long term follow up to comment about the longevity of the prosthesis and the evidence on acetabular erosions. The study population of 30 patients is too small a number to give a statistically significant opinion and the study period was only for 6 months. Our early and short term results are encouraging and promising and long term results are awaited.

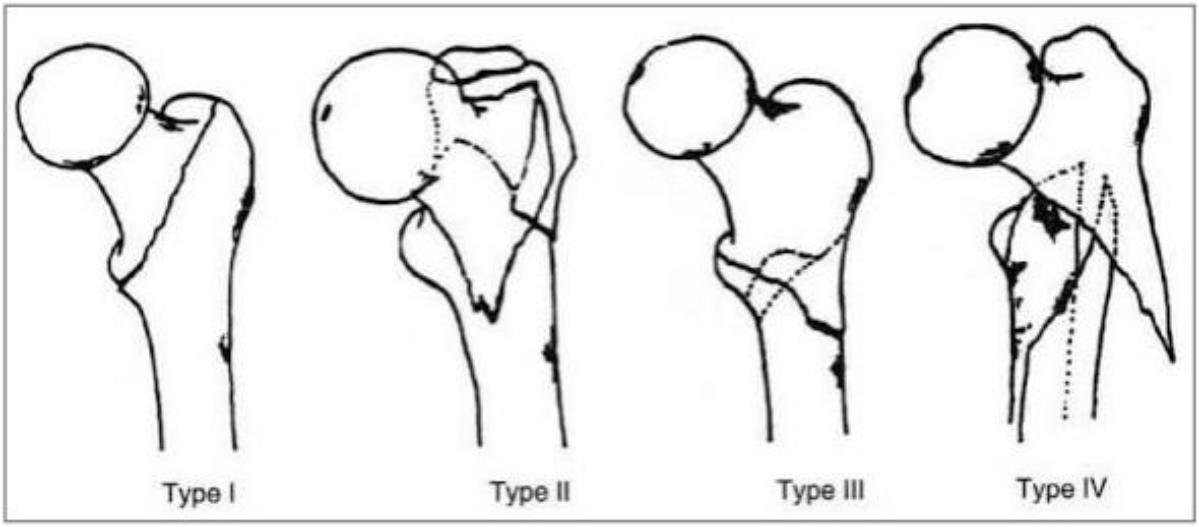
A modified dynamic hip screw in unstable intertrochanteric fracture: A retro-prospective study

Sandeep MMR and Dinakar Rai

DOI: https://doi.org/10.22271/ortho.2020.v6.i3m.2291

Abstract
Background: Intertrochanteric fractures occur mostly in elderly patients, and the outcome may be extremely poor if there is prolonged bed-rest.
Many treatment modalities have come up in management of these unstable intertrochanteric fractures. Sliding Hip Screw Fixation is still the gold standard in treatment of stable intertrochanteric fracture. In unstable comminuted intertrochanteric fractures, there is high incidence of failure in view of excessive collapse seen with Dynamic hip screw.
In order to limit the collapse we have done a modification on Dynamic Hip Screw implant. The aim of this study is to assess fracture healing, collapse and implant failure, in unstable intertrochanteric fractures (Boyd and Griffin type-2) treated by modified DHS fixation.
Methods: 23 patients who were operated with modified DHS for unstable intertrochanteric fracture were selected using random selection and following parameters were noted from the records.
Results: Out of 23 patients in this study, 20 patient showed fracture healing (87%) with or without minimal collapse and 3 patient had non-union (13%) at the end of 5 months follow up. Ultimately all fractures united at the end of 1 year followup.
Conclusion: Modified Dynamic Hip Screw has showed improved results as compared to normal Dynamic Hip Screw in treating communited intertrochanteric fracture, which limits the collapse at fracture site.

Keywords: Intertrochanteric fractures, modified DHS, collapse



Introduction
Intertrochanteric fractures occur mostly in elderly patients, and the outcome may be extremely poor if there is prolonged bed-rest. The best treatment for trochanteric fracture remains controversial [1-3]. Many methods have been recommended [4-6]. Early mobilization of these patients reduces the morbidity and mortality rate.
Intertrochanteric fractures with severe communition and displacement are commonly seen in elderly patients. Most of the elderly patients have poor bone quality due to which fractures are often associated with complications like non-union, implant failure and femoral head perforation.
Management of unstable intertrochanteric fractures is challenging because of excessive collapse, loss of fixation, implant failure, lag screw cut out and in addition osteoporosis also adds to the complication resulting in unpredictable outcome.
In order to limit the collapse we have done a modification on Dynamic Hip Screw implant. In this study we are assessing the outcome of unstable intertrochanteric fractures treated with modified dynamic hip screw fixation designed by us.
Boyd and Griffin (1949) classified fractures in the trochanteric area of femur into 4 types. Their classification included all fractures from extra capsular part of neck to a point 5cm below the lesser trochanter. Their classification is useful in planning treatment and estimating prognosis [7].

Type 1: Fractures that extend along the intertrochanteric line from the greater to the lesser trochanter. Reduction usually is simple and is maintained with little difficulty. Results generally are satisfactory.

Type 2: Comminuted fractures, the main fracture being along the line, but with multiple fractures in the cortex. Reduction of these fractures is more difficult because the comminution can vary from slight to extreme. A particularly deceptive form is the fracture in which an anteroposterior linear fracture occurs, as in type 1, but with an additional fracture in the coronal plane, which can be seen on the lateral radiograph.

Type 3: Fractures that are basically subtrochanteric with at least one fracture passing across the proximal end of the shaft just distal to or at the lesser trochanter. Varying degrees of comminution are associated. These fractures usually are more difficult to reduce and result in more complications during surgery and convalescence period.

Type 4: Fractures of the trochanteric region and the proximal shaft, with fracture in at least two planes, one of which usually is the sagittal plane and may be difficult to see on routine anteroposterior radiographs. If open reduction and internal fixation are used, twoplane fixation is required because of the spiral, oblique, or butterfly fracture of the shaft.

Aim of the study

The aim of this study is to assess fracture healing, collapse and implant failure, in unstable intertrochanteric fractures (Boyd and Griffin type-2) treated by modified DHS fixation.

Objectives

1. To assess fracture healing, collapse in management of communited intertrochanteric fracture with modified Dynamic Hip Screw.
2. To look for implant failure- migration of implant, implant loosening, implant cutout or non-union.

Materials and Methods

Study Design: Retrospective observational study population: Patients diagnosed to have intertrochanteric fractures and treated with Modified DHS Study Area : PSG Hospitals.

Inclusion criteria

1. Boyd and griffin classification type-2 fractures only
2. Patients willing for treatment and given written informed consent.

Exclusion criteria

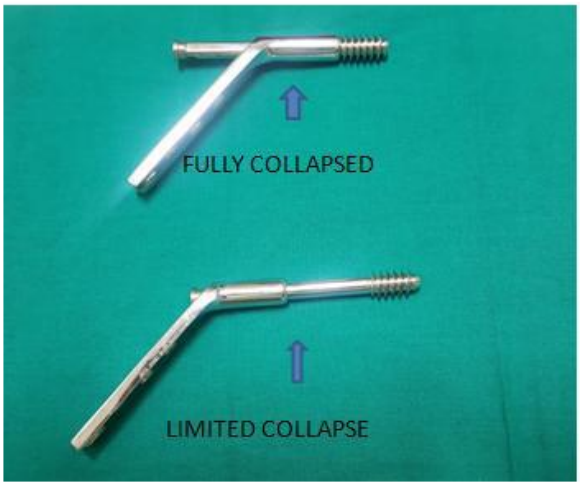
1. Boyd and griffin classification type-1, type-3 and type -4
2. Pathological fractures
3. Infection
4. Treated after 3 weeks of trauma.
5. Patients medically unfit for surgery.
6. Compound fractures associated with vascular injuries, ipsilateral femoral shaft fractures and pelvic fractures.
7. Patients not willing for treatment.

23 patients who were operated with modified DHS for unstable intertrochanteric fracture were selected using random selection and following parameters were noted from the records.

The criteria taken into consideration were fracture healing , collapse of fracture fragments, implant failure

About Modified Dynamic Hip Screw

One of the cause for failure of Dynamic Hip Screw is over collapse at fracture site [8].



In this study, we have used modified dynamic hip screw to limit the over collapse which is undesired in unstable intertrochanteric fractures. In this implant we have done modification in the shaft of lag screw, we have reduced the length of keyed screw system, so that we can have a maximum of 1 cm collapse, hence there will be limitation in collapse unlike the original implant.

Modified lag screw versus Normal lag screw

Before collapse

After collapse

Results

In this retro-prospective study a total of 23 patients were assessed. Pre-operative

AP radiographs of pelvis was taken for all the patients who were treated by modified dynamic hip screw fixation. All patients who underwent treatment were of age from 38 years to 90 years. Out of 23 patients in this study, 13 patients were male (56.5%) and 10 patients were female (43.5%). Only boyd and griffin type-2 fractures were taken in view of standardisation. Post-operatively follow up xray were taken at 1st month, 3rd month and 5th month and the outcome was assessed.

Factors assessed were

1. Fracture healing
2. Fracture collapse
3. Implant failure

Fracture Healing

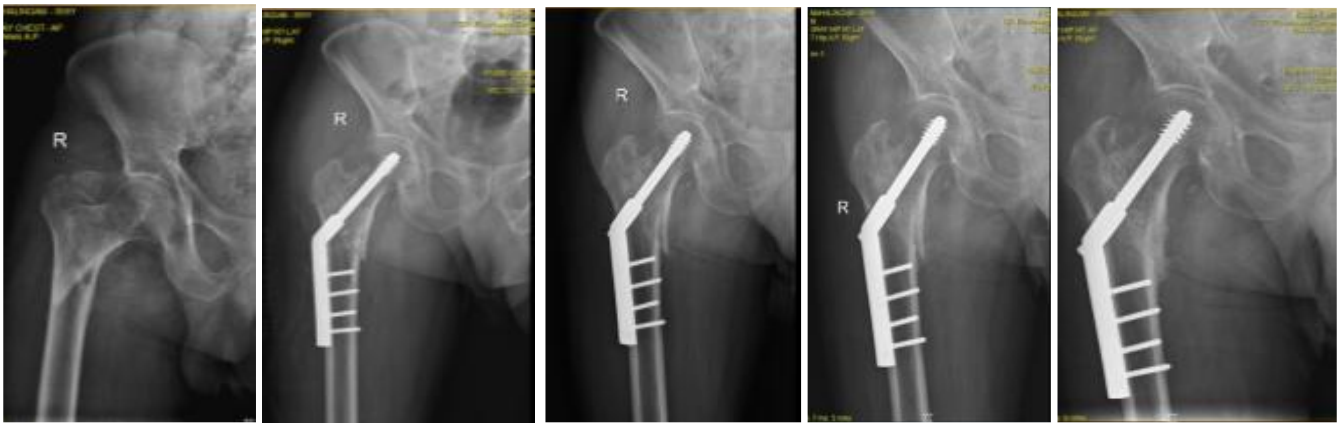
1st month 3rd month 5th month

	1st month	3rd month	5th month
Union	8(34.8%)	20(87%)	20(87%)
Non union	15(65.2%)	3(13%)	3(13%)
Total	23(100%)	23(100%)	23(100%)

Out of 23 patients in this study, at first month follow-up, 8 patients showed fracture healing (34.8%), at third month follow-up, 20 patients showed fracture healing (87%), at fifth month follow-up, 20 patient showed fracture healing (87%) and three patient had non-union (13%)

Fracture Collapse

	1st month
Minimal collapse	16(69.6%)
No collapse	7(30.4%)
Total	23(100%)



Out 23 patients in this study, at first month follow-up, 7 patients showed no Collapse (30.4%) and 16 patients showed minimal collapse (69.6%) [less than 1 cm], however the collapse rate remained same for all patients till end of this study.

Implant Failure

	1st month	3rd month	5th month
No implant failure	19(82.6%)	19(82.6%)	19(82.6%)
Lag screw migration not breaching cortex	4(17.4%)	4(17.4%)	4(17.4%)

At the end of 5 months followup out of 23 patients, 4 patient had implant migration not breaching cortex (17.3%).

Radiographs

Pre op Post op 1st month 3rd month 5th month

Discussion

Intertrochanteric fractures are mainly treated by surgical intervention. Despite longterm experience in many centres, there have been factors still contributing to pooroutcome of managing unstable intertrochanteric fractures.

Controversies persist because there is lack of proper per-

operative risk factors assessment that affect the outcome in these fractures treated by various methods. Failures of Dynamic hip screw in unstable intertrochanteric fracures are due toover collapse at fracture site [8].

In this study, we have used modified Dynamic Hip screw for treating comminuted intertrochanteric fractures, we have used this implant to limit the over collapse at fracture site.

Fracture united in 20 patients with minimal collapse and 3 patients had no signs of union at the end of 5 months. But all fractures united at the followup period of 1 year, lag screw migration occurred in 4 patients who started early weight bearing.

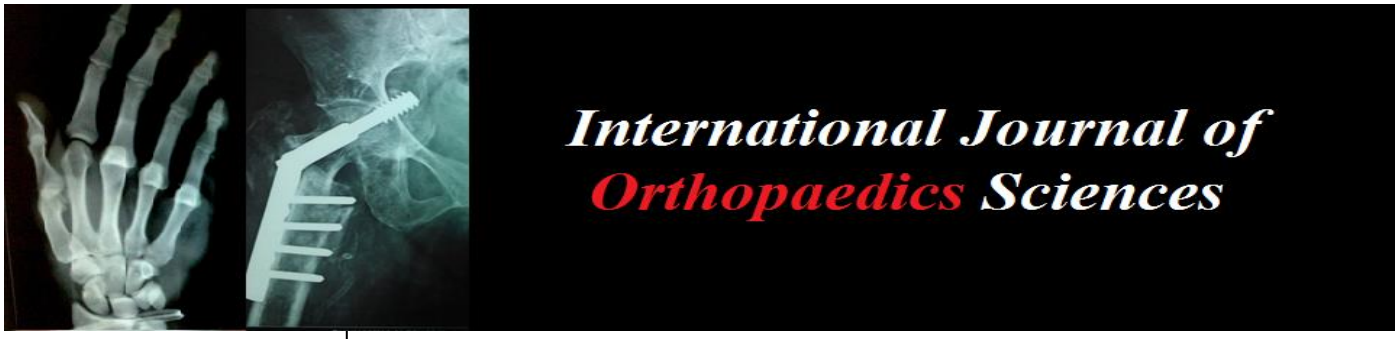
Nordin S in their study on treatment of intertrochanteric fractures with Dynamic Hip Screw, 83.3 percent of patients had fracture healing at one month [9]. In our seriesonly 34.8 percent of patients showed fracture healing at first month, however at the endof fifth month 87% fractures went on to heal. This delay in fracture healing relates to the modification in design of implant which limits the collapse at fracture site.

Sadowski cal *et al.* in their study on treatment of unstable intertrochanteric fractures with sliding hip screw, implant failure and non-union was noted in 7 of 19patients (38%) who had been treated with the sliding hip screw [10]. In our series, implant migration was noted in 3 out of 23 patients (13%) but no breaching of cortex occured. This results compare favourably and highlights the advantage of modified Dynamic Hip Screw in treatment of communited intertrochanteric fractures.

Conclusion

Modified Dynamic Hip Screw has showed improved results as compared to normal Dynamic Hip Screw in treating communited intertrochanteric fracture.

1. Fracture healing was slow in comparing with regular Dynamic hip screw.
2. Modified Dynamic hip screw significantly limits the collapse at fracture site.
3. When modified Dynamic Hip Screw is used in managed of communited intertrochanteric fracture, weight bearing mobilisation should be delayed to improve the outcome.



Limitations

Small sample size

Other forms of fixation of trochanteric fractures were not compared in this study.

□ □□□r □□□

□□r □d □□□□□□□Osteoporosis is a major health problem which has devastating health consequences through its association with osteoporotic fractures. Prevention of osteoporosis by identifying the risk factors is a major challenge in the field of medical science. Elevated homocysteine level in blood can be a potential risk factor for the development of osteoporosis. We aim to study if a person with high circulating level of homocysteine has a decreased Bone Mineral Density (BMD), thus establishing an association between homocysteine and the risk of developing osteoporosis.

M□□□□d□Patients between the age group of 40-70 years attending BMD camps between July 2019 and December 2019 were included in the study. All of them underwent BMD test and blood samples were sent to the laboratory for estimation of serum homocysteine levels. The results were collected and analyzed to see if there was any association between serum homocysteine levels and osteoporosis.

□ □□□□□□□Out of the 58 males and 20 females with normal BMD, none had elevated serum homocysteine. 21 out of the 58 males and 47 out of the 82 females with osteopenia had elevated serum homocysteine. Of the 27 males with osteoporosis, 25 had elevated serum homocysteine while among the 125 females with osteoporosis, all 125 had elevated serum homocysteine levels.

□ □□□□□□□□□□From our study we concluded that people with high circulating level of homocysteine had a decreased Bone Mineral Density (BMD), thus establishing an association between homocysteine and the risk of developing osteoporosis.

□ □□□ □rd □□Homocysteine, osteoporosis, BMD, serum homocysteine levels

□□r □d □□□□□□□

Osteoporosis is a major health problem characterized by low bone mineraldensity (BMD) and increased risk of fractures [1]. Osteoporotic fractures are associated with increased morbidity and mortality & cause substantial financial loss to the patients and their families [2, 3, 4].

Elevated levels of homocysteine in the blood is associated with an early onset of osteoporosis [5, 6]. An elevated plasma homocysteine level (>15 mmol/l) is prevalent in 30-50% population above 60 years [5, 6]. High homocysteine levels have been associated with an increased risk of fractures, although the factors that contribute to this fracture risk are not fully elucidated.

Homocysteine is an intermediary amino acid formed by the conversion of methionine to cysteine. Elevated serum homocysteine levels show clinical manifestations involving the eyes, blood vessels, nervous system and skeleton including the development of early osteoporotic fractures. Vitamin B12 and folic acid play an important role in homocysteine metabolism [7]. They are cofactors in homocysteine metabolism and their intake can help in reducing serum homocysteine levels [8, 9, 10].

We aim to study if a person with high circulating level of homocysteine has a decreased Bone Mineral Density (BMD), thus establishing an association between homocysteine and the risk of developing osteoporosis.

M□□□□d □□

The study population included patients between the age group of 40-70 years attending BMD camps organized by the department of Orthopaedics, PSG institute of medical science and research, coimbatore between July 2019 and December 2019. Both male and female patients were included in the study.

Patients with previous fractures and those on long term steroids were excluded from the study.All of them underwent BMD test by DEXA scan. Blood samples were collected and sent to the laboratory for estimation of serum homocysteine levels.

M r r **d**
Normal: 1 to -1
Osteopenia: -1 to -2.5
Osteoporosis: Below -2.5
The normal serum homocysteine level: 15 mmol/L
The results of both BMD scan and serum homocysteine levels were collected and analyzed to see if there was
any association between serum homocysteine levels and osteoporosis.

During the study period of 6 months, 370 patients attending the BMD camps fell into our inclusion criteria and wereincluded in our study. Of them 143 were males and 227 were females (Table 1).

40 – 50	-0.72	-1.6
51 – 60	-1.47	-2.53
61 – 70	-2.61	-3.4

In the patients with normal BMD the average serum homocysteine level was 5.4 mmol/L in males and 7.2 mmol/L in females. Osteopenic individuals showed an average serum homocysteine level of 14.1 mmol/L in males and 16.2 mmol/L in females. Those with osteoporosis showed average serum homocysteine level of 38.7 mmol/L in males and 46.1 mmol/L in females (Table 3).

Average serum homocysteine levels

M	**M**	
Normal	5.4	7.2
Osteopenia	14.1	16.2
Osteoporosis	38.7	46.1

Of the 43 males in the 40-50 years age group, 7 were osteopenic and the rest had normal BMD, while among the 61 females in the same age group, 35 were osteopenic and 6 were osteoporotic. Among the 73 males in the 51-60 years age group, 46 were osteopenic and 5 were osteoporotic, while among the 112 females in the same age group, 47 were osteopenic and 65 were osteoporotic. Out of the 27 males in the 61-70 years age group, 5 were osteopenic and 22 were osteoporotic, while among the 54 females in the same age group all 54 were found to have osteoporosis (Table 4).

Osteoporosis is a metabolic bone disease. It is the leading cause of fractures with advancing age leading to pain, hospitalization and increased financial burden to the patient and his family. Even though it is considered as a normalageing process, osteoporosis can be prevented and treated if detected early. Elevated serum homocysteine level or hyperhomocysteinemia is considered to be one of the possible modifiable risk factors of osteoporosis.
Homocysteine is a sulfur containing amino acid that is formed by methionine metabolism. It is metabolized in the body by remethylation or trans-sulfuration pathway (Fig.1).
The normal serum homocysteine level is considered to be below 15mmol/L. A raised serum homocysteine level can bedue to multiple factors – lifestyle, diet, hormonal [11]. Hyperhomocysteinemia is considered to be a potential risk factorfor the development of osteoporosis [12, 13]. Vitamin B12 acts as a co-factor in the remethylation of homocysteine to methylene [14]. Hence vitamin B12 deficiency can lead to elevated serum homocysteine levels.
A study done by van Meurs *et al.* concluded that elevated serum homocysteine levels lead to a 2 fold increase in the incidence of fractures [15]. Another study by Bucciarelli *et al.* showed inverse association of serum homocysteine and BMD in post- menopausal women [16]. Tyagi *et al.* concluded that hyperhomocysteinemia can lead to reduced blood flowin the bones compromising bone quality [17]. A study done by Enneman *et al.* in 2014 showed that elevated serum homocysteine was associated with a decreased BMD [18].
Similarly in our study we found an inverse correlation between serum homocysteine levels and BMD. Out of the 58 malesand 20 females with normal BMD, none had elevated serum homocysteine. 36% males (21 out of 58) and 57% females (47 out of 82) with osteopenia had elevated serum homocysteine levels. However when it came to people with osteoporosis on BMD, 93% males (25 out of 27) and 100% of females (125 out of 125) had elevated serum homocysteine levels. The average serum homocysteine levels in osteoporotic individuals were 38.7 mmol/L in males and46.1 mmol/L in females. Hence we see a definite relation between elevated serum homocysteine level and osteoporosis

□

□□□□□□□□□□

Osteoporosis is a major health problem which has devastating health consequences through its associationwith osteoporotic fractures. Prevention of osteoporosis by identifying the risk factors is a major challenge in the field of medicine. Bone metabolism is affected by homocysteine. Elevated homocysteine level in blood isa potential risk factor for the development of osteoporosis.

From our study we concluded that people with high circulating level of homocysteine had a decreased Bone Mineral Density (BMD), thus establishing an association between homocysteine and the risk of developing osteoporosis. Vitamin B12 and folic acid play an important role in homocysteine metabolism [7].

Supplementation with vitamin B12 and folic acid has been shown to normalize plasma homocysteine levels. This could reverse the problem of impaired bone health
and osteoporosis and help in preventing osteoporotic

ABSTRACT

Background: Ligament injuries apart from fractures are more common in the knee joint owing to its complex anatomy. They account for a large number of referrals to our hospital, both from the general practitioner and from the accident and emergency department. Although there have been studies in literature comparing MRI with arthroscopy, the continuing improvement in diagnostic methods now available makes it especially important to compare the results and recommendations offered in the literature.
Methods: The aim of this study was to find out the diagnostic accuracy of MRI scans and to examine the value of MRI as a standard preoperative examination correlating them with the gold standard of arthroscopy. This is a prospective study involving 57 patients who were admitted in Department of Orthopaedics, Mahatma Gandhi Medical College and Research Institute, with the history of injury to the knee and diagnosed to have internal derangement of the knee clinically, using standardized clinical tests. MRI of the affected knee joint was done for all these patients either before or after admission. The patients were then subjected to diagnostic and therapeutic arthroscopy.
Results: The sensitivity of MRI in comparison with Arthroscopy was 100% in all studied lesions. The specificity of MRI in comparison with Arthroscopy was 94.1%, 98.1%, 100% and 97.6% for ACL, PCL, Medial meniscus and Lateral meniscus respectively.
Conclusions: According to our study MRI is a very good at determining the normal anatomy of the intra articular structures of the knee joint and is highly reliable in excluding pathology, in our case tear in ligaments. Hence we recommend MRI in doubtful cases of internal derangement of the knee joint whereby unnecessary diagnostic arthroscopy can be avoided which can significantly bring down the economic burden among rural population.

Keywords: MRI, Arthroscopy, IDK

INTRODUCTION

The dramatic increase in road traffic accidents and the highly demanding sporting life style makes the knee joint one of the most commonly injured joints in the body, either as a frequent component in a polytrauma patient or as isolated injury. Ligament injuries apart from fractures are more common in the knee joint owing to its complex anatomy. They account for a large number of referrals to our hospital, both from the general practitioner and from the accident and emergency department.

The knee is a complex joint, consisting of two condylar joints between the corresponding condyles of femur and tibia and a sellar joint between the patella and femur.[1] The principal intraarticular structures in knee are the two menisci, the two cruciate ligaments, and the two collateral ligaments. The menisci serve to distribute joint fluid, cartilage nutrition, mechanical shock absorption, increasing the surface area of the joint and therefore the stresses, serve to stabilize the joint, and a weight bearing function. The cruciate ligaments function as stabilizers of the knee in both forward and backward motions of the

tibia on the femur and provide an axis around which both medial and lateral rotary movements are assisted.[2] The injury to these intraarticular structures is generally termed as "Internal derangement of knee" which was first coined by William Hey in 1784.[3]

The clinical evaluation of knee injuries remains a difficult problem even today. The accuracy of a clinical diagnosis, reported in various series, varies between 64-85 percent, which suggests that even in the most experienced hands, a clinical diagnosis cannot be ascertained in about 20 percent of cases.[4]

Magnetic resonance imaging (MRI) is a diagnostic method most often used in diagnosis of internal derangements of the knee, because it is non-invasive, painless and has no risk of radiation. However it's an expensive investigation and it has a tendency to be misused and overused, to confirm diagnosis before proceeding with surgical intervention. The accuracy rate of MRI scans also varies. As knee injuries are on the rise and with varied accuracy rates of scans, it would be useful to know the accuracy of the MRI findings and correlate this with arthroscopy findings.

Arthroscopy has been used for many years as a diagnostic and therapeutic tool in knee disorders. It is considered a gold standard for the same as it allows direct visualization of the interior of the knee. Although there have been studies in literature comparing MRI with arthroscopy, the continuing improvement in diagnostic methods now available makes it especially important to compare the results and recommendations offered in the literature.

The aim of this study was to find out the diagnostic accuracy of MRI scans and to examine the value of MRI as a standard preoperative examination correlating them with the gold standard of arthroscopy.

METHODS

The aim of this study was to study the efficacy of Arthroscopy over MRI in diagnosing meniscal and ligament injuries of the knee joint; to compare the sensitivity and specificity of MRI and knee arthroscopy & to emphasize the accuracy of diagnosis in knee arthroscopy.

Inclusion criteria

Patients between 18-45 years of age with knee pain with or without instability and patients with symptoms of locking of knee were included in the study.

Exclusion criteria

Patients with open fractures of the knee, patients with bony injuries of the affected limb, those below the age of 18yrs & above the age of 45 years, patients with previous surgeries to the knee, patients with signs of infection, patients with ankylosed knee joint and those unfit for MRI study were excluded from the study.

This is a prospective study involving 57 patients who were admitted in Department of Orthopaedics, Mahatma Gandhi Medical College and Research Institute, with the history of injury to the knee and was diagnosed to have internal derangement of the knee clinically, using standardized clinical tests. MRI of the affected knee joint was done for all these patients either before or after admission. The patients were then subjected to diagnostic and therapeutic arthroscopy. MRI was done in 1.5T field strength in our institution and was reported on an objective proforma by a single senior consultant radiologist. All the arthroscopies were performed by a single orthopaedic surgeon.

The findings of MRI and arthroscopy were compared and analyzed in detail. It is a prospective comparative study done in the Department of Orthopaedics, Mahatma Gandhi Medical College & Research Institute, Pondicherry from May 2010 to September 2012.

Methods of assessment

Prior to surgery

1. Presenting complaints, history of presenting complaints, past history, personal history, general physical examination and complete local examination of affected knee were done that included complete inspection, medial joint line tenderness, McMurrays test, Apleys grinding test, Lachmann's test, anterior and posterior drawer test, pivot shift & Mcintosh test.

2. Radiographs of the involved knee anteroposterior and lateral views to rule out any bony injury.

MRI of the affected knee with the following sequences

- Localizer sequences in sagittal, coronal and axial planes
- Fat suppressed T2 axial turbo spin echo
- T1 Spin echo Sagittal.

Preoperative workup

- Routine hemogram, urine routine, biochemical parameters of blood, ECG & chest radiographs.

Preanaesthetic check-up and ASA grading for fitness for surgery

Surgery

All the arthroscopic procedures were performed under spinal anaesthesia after applying pneumatic tourniquet with patient in supine position and knee in 90 degrees

flexion. 30° arthroscope was used in all cases and the operative findings were documented and recorded simultaneously by the floor assistant: anatomical structure viewed and the presence or absence of tears, its location and additional details wherever possible.

The composite data was tabulated and studied for correlation with MRI findings and grouped into four categories.

- True-Positive: If the MRI diagnosis was confirmed by arthroscopic evaluation.
- True-Negative: When MRI negative for lesion but arthroscopy was negative.
- False-Positive: When MRI shows lesion but arthroscopy was negative.
- False-Negative: When arthroscopy showed lesion but MRI was negative.

Statistical analysis was used to calculate the sensitivity, specificity, positive predictive value (PPV) and the negative predictive value (NPV), in order to assess the reliability of MRI results. Based on the above categories, five parameters were calculated to assess the reliability of the MRI results.

Sensitivity

Sensitivity of MRI is the ability of the MRI to detect an abnormality. It is determined by the equation:

True-positive/ (true positive + false negative) × 100 per cent.

Specificity

Specificity of MRI is the ability of MRI to give how many detected tears are usually accurate. It is determined by the equation:

True-negative/ (true negative + false positive) × 100 per cent.

Positive predictive value

It correlates a positive result of MRI with findings at arthroscopy. It is calculated by the equation:

True-positive/ (true positive + false positive) × 100 per cent.

Negative predictive value

It correlates a negative result on MRI with the findings at arthroscopy. It is calculated by the equation:

True-negative/ (true negative + false negative) × 100 per cent.

Accuracy

It is given by the equation:

True positive + true negative/ total number of patients in the study.

Statistical analysis

Collected data was presented in the form of tables. Data was analyzed for the significant correlation between MRI knee and arthroscopic findings. Pearson correlation coefficient and T test used as statistical tool to analyze the data in our study.

Interpretation of sensitivity

Table 1: Interpretation of sensitivity.

Percentage	Grade
90% - 100%	Excellent
80% - 90%	Very Good
70% - 80%	Good
70% - 60%	Average
< 60%	Poor

RESULT

Sex distribution

The study had 57 patients of which 15 were females and 42 males which accounts to about 26.3% females and 73.7% males respectively as given in Table 2.

Table 2: Sex distribution.

Sex	No of cases	Percentage
Male	42	73.7
Female	15	26.3

Age distribution

The patients who suffered injury were in the age group ranging from 18 to 45years. The mean age was around 33.58. Some of the other interesting observations noted in our study are, as age increases right side injuries are more compared to that of the left side and frequency of road traffic accidents are more.

There was an increase in frequency of knee injuries as age advanced in our study, 25 cases were in the age group of 18-27 years, 18 cases were in the age group of 28-37 years and 14 cases were in the age group of 18-27 years.

Side involved

The right knee joint was found to be more commonly involved 35 cases (61.4%), than the left knee joint, 22

cases (38.6%) and there were no cases with bilateral knee involvement in our series as shown in Table 3.

Table 3: Side involved.

	Frequency	Percentage
Left	22	38.6
Right	35	61.4
Total	57	100

Mode of injury

Road traffic accident was the most common mode of injury involving 47 cases (82.46%) followed by sport injury involving 10 cases (17.54%) as given in Table 4.

Table 4: Mode of injury.

	Frequency	Percentage
Sports injury	10	17.5
RTA	47	82.5
Total	57	100

Structures injured

There are several explanations for the misleading results of MRI regarding the menisci and cruciate ligaments. Firstly, meniscal tears and meniscus degenerative changes have the same appearance in MRI, by giving high signal within the meniscus. Diagnosis then depends on the expansion of the high signal line towards meniscus articular surface.

Table 5: Structures injured.

Structure injured	MRI	Arthroscopy
ACL	41	40
PCL	6	5
Medial meniscus	32	32
Lateral meniscus	16	15

Moreover, one of the most frequent causes for false positive MRI regarding the lateral meniscus is the misinterpretation of the signal coming from the inferior knee artery. McKenzie et al summarized the four most common reasons for false positive diagnosis; wrong diagnosis due to variable anatomic structures, overestimation of pathology countered as meniscus tear (for example chondral injuries that mimic meniscus tears) false negative arthroscopic findings and tears within the meniscus without expansion to the articular surface.

Statistical analysis of tear of individual structures

Anterior cruciate ligament

Observing the pattern of ACL tears revealed a total of 40 cases with torn ACL shown in Table 6.

Table 6: Comparing ACL in MRI vs. Arthroscopy.

MRI ACL	Scopy ACL		
	Tear	Normal	Total
Tear	40	1	41
Normal	0	16	16
Total	40	17	57

In our study there was one false positive result in MRI while diagnosing anterior cruciate ligament tear.

The sensitivity and specificity of MRI with respect to Arthroscopy is 100% and 94.1%.

The positive predictive value and negative predictive value is 97.6% and 100% respectively.

Posterior cruciate ligament

Total number of PCL tears accounted to about 5 cases out of the 57 studied as shown in Table 7.

Table 7: Comparing PCL in MRI vs. arthroscopy.

MRI PCL	Scopy PCL		
	Tear	Normal	Total
Tear	5	1	6
Normal	0	51	51
Total	5	52	57

In our study there was one false positive result in MRI while diagnosing posterior cruciate ligament tear, the loss of signal intensity near the femoral attachment was considered as partial tear of PCL but on arthroscopic evaluation there was no evidence of tear in PCL.

The sensitivity and specificity of MRI with respect to Arthroscopy is 100% and 98.1%.

The positive predictive value and negative predictive value is 83.3% and 100% respectively.

Medial meniscus

Out of the 57, 32 cases had torn medial meniscus and 25 normal medial meniscus as shown in Table 8.

Table 8: Comparing medial meniscus in MRI vs. arthroscopy.

MRI M.MEN	Scopy M. MEN		
	Tear	Normal	Total
Tear	32	0	32
Normal	0	25	25
Total	32	25	57

In our study there were no discrepancies in the diagnosis of tears in medial meniscus between MRI and

Arthroscopy. Both these modalities correlated well in the diagnosis of medial meniscal tears.

The sensitivity and specificity of MRI with respect to Arthroscopy is 100% and 100%.

The positive predictive value and negative predictive value is 100% and 100% respectively.

Lateral meniscus

Total number of lateral meniscal tears reported is 15 as shown in Table 9.

Table 9: Comparing lateral meniscus in MRI vs. arthroscopy.

MRI L.MEN	Scopy L. MEN		
	Tear	Normal	Total
Tear	15	1	16
Normal	0	41	41
Total	15	42	57

In our study there was 1 false positive result in the diagnosis of tears in lateral meniscus between MRI and Arthroscopy. The sensitivity and specificity of MRI with respect to Arthroscopy is 100% and 97.6% respectively.

The positive predictive value and negative predictive value is 97.6% and 100% respectively.

DISCUSSION

This study was a prospective study done among 57 patients who were admitted with provisional diagnosis of Internal Derangement of Knee in the Department of Orthopaedics, Mahatma Gandhi Medical College and Research Institute, Pondicherry

The current study was done to determine the efficacy of Arthroscopy over MRI in diagnosing meniscus and ligament injuries of the knee joint.

MRI of the knee joint was done in all these patients and then these patients underwent diagnostic and therapeutic arthroscopy whenever necessary in the same institution.

The main strength of the study is the use of only one MRI machine Philips 1.5 Tesla and interpretation of examination by a single radiologist, thus making the results more reproducible. This is in congruence with the analysis done by Runkel et al which showed arthroscopies done could be reduced if the MRI was reported by an experienced radiologist .[5]

MRI images were studied for evidence of injuries to menisci and cruciate ligaments and other associated structures and soft tissues around the knee joint. Diagnostic arthroscopy was performed on all these patients to confirm the MRI findings and results were documented.

In the present study, of the 57 patients 42 were male and 15 were female patients. The age groups were ranging from 18 to 45 years with mean age of 33.58. The youngest patient was 18 years and the oldest was 45 years of age. The youngest male patient was aged 18 years and the oldest male patient was 45 years old, likewise the youngest female patient was aged 18 years and the oldest female patient was 45 years old. This showed that the tendency of being injured and getting operated at an earlier age was common in both male and female patients.

A study by Munk et al showed males are most likely to suffer knee injuries since they are active in sports and the right knee was more frequently injured than the left knee.[6] As mentioned earlier in our study also males comprise the predominant number of patients who suffered knee injuries owing to their highly active social and sporting life style.

Sports injuries were more common in male patients than in females, out of the 10 cases who suffered injuries in this mode there was only 1 female patient in this category. The overall percentage of sports injuries were 17.5% (10 cases) when compared to 82.5% (47 cases) who sustained injury through road traffic accident.

Meniscal injuries, anterior cruciate ligament and posterior cruciate ligaments injuries were classed as either torn or not torn.

Anterior cruciate ligament injures occurred in about 40 patients (70.2%). Posterior cruciate ligament injuries occurred in 5 patients (8.8%). The frequencies of injuries to medial meniscus (56.1%), in 32 patients were almost one fold higher than that of injuries to lateral meniscus (26.3%), in 15 patients.

False positive and false negative results

MRI studies have higher false positives than false negative results confirmed by literature and it was the same finding in our study too, even though the false positive results were very minimal which accounts to only 3 cases out of the 57 cases evaluated. Each of the false positive results was encountered in ACL, PCL and Lateral meniscus respectively whereas there were no discrepancies in Medial meniscal lesions.

The false positive results in our study are described below:

- The reported degenerative tear of a lateral meniscus was not visualized in arthroscopic examination.
- A reported right side ACL tear in MRI showed mild laxity and increased signal intensity of ACL near its tibial attachment which was interpreted as partial ACL tear, but

in arthroscopic examination there was no evidence of tear at the given location.

- Posterior Cruciate ligament of the right knee in a patient showed an intrasubstance cyst / tear in MRI, was not revealed in arthroscopic examination.

Sensitivity and specificity

The sensitivity of MRI in comparison with Arthroscopy was 100% in all studied lesions.

The specificity of MRI in comparison with Arthroscopy was 94.1%, 98.1%, 100% and 97.6% for ACL, PCL, Medial meniscus and Lateral meniscus respectively.

Positive and negative predictive value

Statistics revealed MRI has 100% negative predictive value with a variable positive predictive value of 97.6%, 83.3%, 100%, and 97.6% for ACL, PCL, medial meniscus and lateral meniscus respectively.

Thus according to our study MRI is a very good at determining the normal anatomy of the intra articular structures of the knee joint and is highly reliable in excluding pathology, in our case tear in ligaments. Hence we recommend MRI in doubtful cases of internal derangement of the knee joint whereby unnecessary diagnostic arthroscopy can be avoided which can significantly bring down the economic burden among rural population.

CONCLUSION

The use of MRI and arthroscopy of the knee has evolved substantially over the last several decades and the advancement in surgical treatment of traumatic ligament injuries of the knee has been improved because of both technologies. The astute orthopaedic surgeon must be able to associate the findings on MRI in the decision making before and during arthroscopy. Moreover for a better correlation of findings the surgeon has to go through the complete set of images available in all possible views to come to a definitive conclusion on the pathology. An accurate understanding of the surgical anatomy and pathology found on both clinical examination and preoperative imaging will help the surgeon to improve the surgical technique at the time of arthroscopy and ultimately improve patient outcomes.

Abstract:

Background: Proximal tibial fractures involve a major weight-bearing joint and are serious injuries that frequently result in functional impairment. Treatment of proximal tibial fractures remains a challenge (intra articular and metaphyseal fractures) because the tibia is more superficial and has very little soft tissue cover. Minimally invasive percutaneous plate osteosynthesis (MIPPO) has been widely used in the treatment of long bone fractures in the recent years because of its technical advantages and satisfactory clinical outcome.

Methods: This study is conducted to evaluate the clinical and radiological outcome of proximal tibial fractures treated with minimally invasive percutaneous plate osteosynthesis (MIPPO). The plate is inserted by a percutaneous approach hence minimising the soft tissue disruption, periosteal injury, also preserves the fracture integrity and vascular integrity of bony fragments. MIPPO is a method that combines both principles of the biomechanical properties of fixation and an optimum bone-to-implant contact. Despite a plethora of articles, written in the past 50 years that have addressed the problems of classification and results of various treatments the optimal method of management remains controversial. It is a prospective study of 26 patients admitted in Mahatma Gandhi Medical College and Research Institute,Pondicherry between May 2010 and March 2012 with the diagnosis of tibial plateau fractures treated with MIPPO technique.

Results : 84% of our patients had excellent and good results in the functional outcome. These results were attributed to patients who underwent early surgery and early mobilisation. The average time taken for fracture healing was 15.34 weeks.

Conclusion: MIPPO technique gives good to excellent results even in high energy tibial condyle fractures (84% cases in our study) .Our patients were able to achieve a good functional range of movement, averaging 120 degrees. Those who were treated with early fixation and early mobilization were found to have a better functional outcome irrespective of the fracture type.

Key words: *MIPPO, Proximal Tibia Fracture, Tibial Plateau Fracture.*

Introduction

Proximal tibial fractures involve a major weight-bearing joint and are serious injuries that frequently result in functional impairment. They were originally described as "the fender fracture" because they resulted from low-energy pedestrian versus car accidents. In recent literature, majority are reported from high energy motor vehicle accidents, fall from height and industrial accidents. They can also be caused by sports injuries in younger individuals whereas less violent trauma produce them in elderly osteopenic/ osteoporotic patients. Proximaltibial fractures result from indirect coronal or direct axial compressive forces and comprises of 1% of all fractures and 8% of fractures in the elderly.[1,2] Treatment of proximal tibial fractures remains a challenge (intra articular and metaphyseal fractures) because the tibia is more superficial and has very little soft tissue cover.

Proximal tibial fractures are difficult to treat because of the involvement of articular surface, the often occurring comminution, and the precarious condition of the soft tissues, especially following high-energy trauma. Conservative treatment at any age may be complicated by knee stiffness, malunion,etc., whereas conventional operative treatment (open reduction and internal fixation) can lead to high rate of complications like, compartment syndrome,skindehi scence, infection and septic arthritis.

Aim of the treatment is to restore the congruence of the articular surface supporting the tibial plateau cartilage which is usually depressed; to fix the fracture with a stable device; to allow early rehabilitation. Conventional plating techniques remain the mainstay for managing proximal tibial fractures. However, moving towards more biologically appropriate plating techniques is occurring in an attempt to minimize soft-tissue stripping, decrease the need for bone grafting and improve union rates. Present concept of preservation of the blood supply and atraumatic surgical technique led to the biological fixation techniques.

Minimally invasive percutaneous plate osteosynthesis (MIPPO) has been widely used in the treatment of long bone fractures in the recent years because of its technical advantages and satisfactory clinical outcome.

The plate is inserted by a percutaneous approach hence minimising the soft tissue disruption, periosteal injury, also preserves the fracture integrity and vascular integrity of bony fragments. MIPPO is a new method that combines both principles of the biomechanical properties of fixation and an optimum bone-to-implant contact.[3] Despite a plethora of articles, written in the past 50 years that have addressed the problems of classification and results of various treatments the optimal method of management remains controversial.[4]

This study is conducted to evaluate the clinical and radiological outcome of proximal tibial fractures treated with minimally invasive percutaneous plate osteosynthesis (MIPPO).

Methods

Aims and objectives

To assess the clinical and radiological outcome following minimally invasive percutaneous plate osteosynthesis (MIPPO) for proximal tibial fractures and to evaluate the advantages, disadvantages in terms of success rates of fracture union,patient compliance and complications.

- Prospective study of 26 patients.
- All consecutive patients admitted in Mahatma Gandhi Medical College and Research Institute, Pondicherry between May 2010 and March 2012 with the diagnosis of tibial plateau fractures were included in the study.
- History and detailed physical examination were carried out to determine any associated ligamentous injuries,neurovascular injuries and compartment syndrome.
- Antero-posterior and lateral radiographs were taken to assess the type of tibial plateau fracture.
- All types of tibial plateau fractures(According to Schatzker classification type I to type VI of tibial plateau fractures) were taken into the study.
- All the patients diagnosed to have tibial plateau fractures were treated with Minimally invasive percutaneous plate osteosynthesis (MIPPO).
- Patients were followed up for a minimum period of 6 months with both clinical and radiological parameters according to Rasmussen's score.
- This study has been approved by the IHEC (Institutional human ethical committee) of Mahatma Gandhi medical college.

Inclusion criteria

- Age: Above 18 years (Skeletally matured).
- All types of tibial plateau fractures

Exclusion criteria:

- Age: Less than 18 years

(Skeletally immature).

- Other fractures in the ipsilateral limb.
- Compound fractures.

Initial Treatment

- All our patients underwent initial stabilization as per the ATLS guidelines.
- Patients with closed tibial plateau fractures associated with a tense haemarthrosis underwent aspiration of the joint under aseptic precautions.
- The limb was immobilised either in an above knee slab or through skeletal traction using a distal tibial or calcaneal pin traction on a Bohler Braun splint until definitive fixation was carried out.
- In patients complicated with excessive swelling and blistering, definitive fixation was delayed until the swelling/ blistering subsided.
- The patients were thoroughly evaluated from the systemic point of view and received appropriate treatment for existing co-morbidities like hypertension and diabetes prior to and after surgery.

Definitive management

In our study, all 30 patients with proximal tibial fractures underwent definitive fixation by Minimally Invasive Percutaneous Plate Osteosynthesis technique.

Operative technique

- The surgery was performed with the patient under spinal/ epidural anaesthesia.
- The patient was placed supine on a radiolucent operating table with the affected extremity in longitudinal manual traction.
- The affected limb prepared, painted and draped sterile.
- With the help of an image intensifier closed reduction was achieved by longitudinal traction. In certain cases percutaneous k-wires were introduced to aid in fracture alignment.
- A proximal tibial locking plate / L – Buttress locking plate or a T – Buttress locking plate of suitable length was used.
- An incision was made as large as necessary either medially or laterally, to help insert the plate, which is carefully slid in the submuscular plane, extraperiosteally and checked using image intensifier.
- Varus / valgus and rotational alignment were corrected.
- Cancellous and cortical screws were appropriately used to secure the plate adequately proximally and distally. These were introduced percutaneously through small stab incisions centered over the plate holes.
- A thorough wash with saline and betadine was given and the wounds closed. A sterile dressing was applied.
- Primary bone grafting was not done in any of the cases in this study.

Post operative protocol

- The patient received intravenous antibiotics for a minimum of 5 days. They also received analgesics / anti-inflammatory drugs.
- The limb was elevated on a Bohler Braun splint until edema subsided
- Knee mobilization was started once the acute pain subsided (ranged 3-7 days)
- Non weight bearing walking was permitted from 3rd post operative day with the help of a walker.
- Sutures were removed on the 12th post operative day.
- The patient was kept non weight bearing until radiological signs of union were evident, after which weight bearing was commenced initially from partial to full weight bearing in gradual progression depending on fracture consolidation.

Follow up

- Our patients were reviewed periodically after discharge at 6 weekly intervals for a minimum of 6 months or until complete radiological union.
- Knee movements were measured using a goniometer and the amount of extensor lag and flexion were recorded.
- Weight bearing was permitted only after radiological evidence of fracture union was present.
- At the time of follow up a functional assessment was done according to Rasmussen's clinical and radiological scoring system.
- Of the 30 patients operated 4 patients were lost to follow up.

We have followed the RASMUSSEN'S SCORING SYSTEM for our study.[5]

The criteria assessed in this scoring system include subjective complaints and clinical signs.

- The Subjective complaints assessed were Pain and Walking capacity
- The Clinical signs assessed were Extensor Lag, Range of Movement, Stability and Deformity.

Rasmussen's Score

Parameters	Points
Subjective complaints	
Pain [0-6]	
No pain	6
Occasional pain, bad weather pain	5
Stabbing pain in certain positions	4
Afternoon pain, intense, constant around the knee after activity	2
Night pain / rest pain	0
Walking capacity [0-6]	
Normal walking capacity [in relation to age]	6
Walking outdoors for at least 1 hour	4
Short walks outdoors >15 minutes	2
Walking indoors only	1
Wheelchair bound / Bed ridden	0
Clinical signs	
Extension [2-6]	
Normal / Full extension	6
Lack of extension [0 – 10 degrees]	4
Lack of extension > 10 degrees	2
Total Range of Motion [0-6]	
At least 140 degrees	6
At least 120 degrees	5
At least 90 degrees	4
At least 60 degrees	2
At least 30 degrees	1
No movement	0
Stability [2-6]	
Normal stability in extension and 20 degree flexion	6
Abnormal instability in 20 degree flexion	5
Instability in extension > 10 degrees	4
Instability in extension < 10 degrees	2

The resulting score obtained in each patient was graded into the following groups to categorise the functional outcome of the procedure.

- A score of 27 – 30 : Excellent
- A score of 20 – 26 : Good
- A score of 10 – 19 : Fair
- A score of <10 : Poor

Rasmussen's Radiological Score
Subjective Points

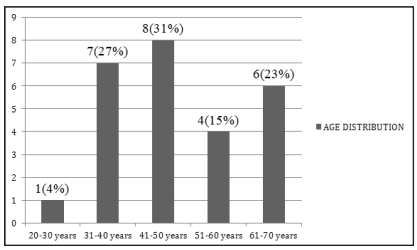
Poor	< 6

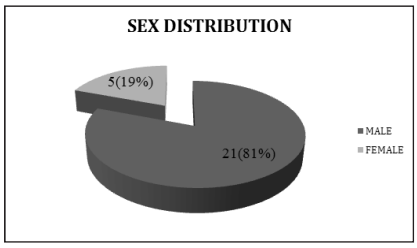


Observations

Patients Data

- Total number of patients : 26

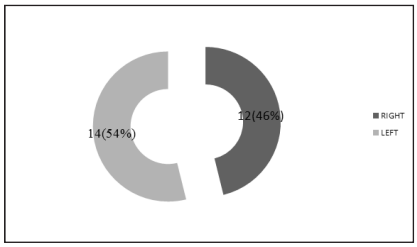
Age



We had 1 patient within the age group of 20 to 30 years, 7 patients between the age 31 to 40 years, 8 patients between the age 41 to 50 years, 4 patients between the age 51 to 60 years, 6 patients between the age 61 to 70 years. Patients were in the age group 23 to 69 years with average being 48.23 years (Graph 1).

Graph 1 (Age Distribution)

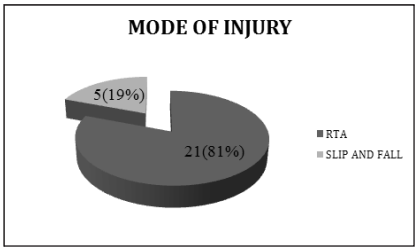
Sex Distribution :



In our study there were 21 male patients and 5 female patients (Graph 2).

Graph 2 (Sex Distribution)

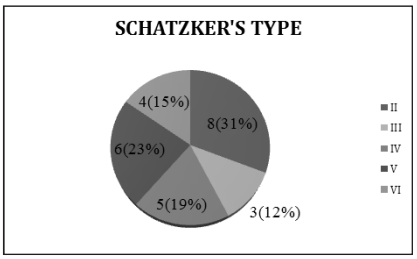
Side Involved



12 patients injured their right limb and 14 patients injured their right limb (Graph 3)

Graph - 3

Mode Of Injury



In our study the mode of injury of 21 patients was RTA, only 5 patients had slip and fall (Graph 4).

Graph- 4

Schatzker Classification

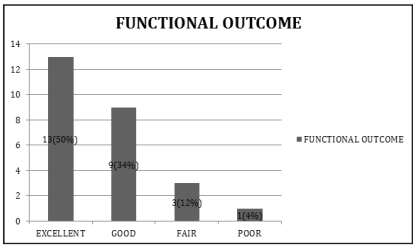
Based on Schatzker classification the maximum number of patients (31%) had type II fracture as shown in Graph 5.

Graph 5 :Schatzker classification

Duration of Follow Up

All our patients were followed up periodically with a minimum follow up duration of 6 months and a maximum follow up duration of 12 months (Fig 1,2,3).

Results



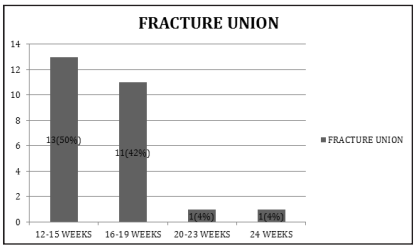
The post operative results were designated as excellent, good, fair and poor according to pain, walking capacity, range of motion and stability of the knee using Rasmussen's grading system. Similarly, Rasmussen's radiological scoring done by assessing articular congruity, condylar widening, Valgus/Varus angulation. In our study the average functional knee score was 25.61. Rasmussen's average radiological score was 15.76 .

Functional Outcome

In our study comprising of 26 patients, 13 patients [50%] had excellent results, 9 patients [35%] had good results, 3 patients [12%] had fair result and 1 patient [4%] had poor result as shown in the graph and Table 1 and Graph 6 below.

Results	No. of patients	Percentage (%)
Excellent	13	50
Good	9	34
Fair	3	12
Poor	1	4
Total	26	100

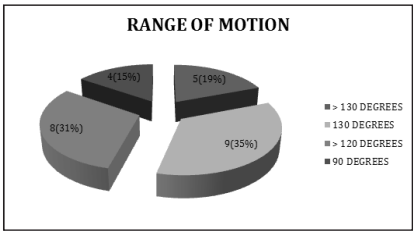
Table 1



Graph 6

Fracture Union

All fractures in this study united without requiring any additional procedures. The average time taken for fracture union was 15.34 weeks (Graph 7).

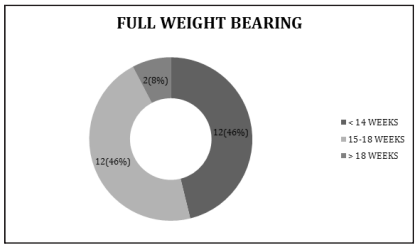


12-15 weeks : 13 patients
16-19 weeks : 11 patients
20-23 weeks : 1 patient
24 weeks : 1 patient

Graph 7

Range Of Motion [ROM]

The average range of movement achieved was 120 degrees. 5 patients achieved slightly more than 130 degrees of flexion, 9 achieved almost 130 degrees, 8 achieved almost 120 degrees, 4 patients had movement of only 90 degrees of flexion.



Graph 8

Full Weight Bearing Walking

In our study 24 patients walked full weight by eighteen weeks and 2 patients later than 18 weeks (20 and 24 weeks respectively) as shown in Table 2 and Graph 9.

Full Weight Bearing Walking	No. Of Patients
< 14 weeks	12
15 – 18 weeks	12
> 18 weeks	02

Discussion

Proximal tibial fractures due to high energy mechanisms (Schatzker type IV,V,VI) are inherently unstable injuries associated with fracture comminution, displacement, severe soft tissue injury and a higher incidence of complications.

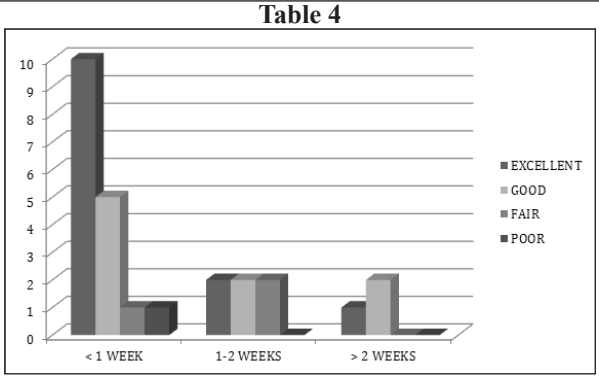
Closed treatment of these complex fractures have resulted in a high percentage of complications (upto 70%) as seen in long term follow up in other studies.[6] The most widely used method for treatment of displaced tibial plateau fractures has been Open Reduction and Internal Fixation. The main aim is restoration of the articular surface to as near anatomical position as possible and to maintain the reduction while early knee joint mobilization is commenced which is however possible only after extensive soft tissue dissection. Due to the association of soft tissue injuries with these fractures, additional soft tissue stripping involved in open reduction and internal fixation often render bony fragments avascular and also significantly increase the chance of infection.

Moore et al, in his series reported a 23% incidence of infection after ORIF in these complex fractures.[7] Mallik et al encountered 4 of his 5 cases being infected after ORIF for such fractures.[8] Barrak reported of deep infection in seven of eight fractures that were treated with a medial plate.[9]

To avoid soft tissue damage in addition to the pre existing soft tissue injury associated with these complex fractures, minimally invasive biological fixation procedures have evolved over the last couple of decades. Among these procedures, **Minimally Invasive Percutaneous Plate Osteosynthesis (MIPPO)** potentially has become a good option in the treatment of these complex fractures.

In our study comprising 26 patients treated by Minimally Invasive Percutaneous Plate Osteosynthesis we had 84.61% of excellent and good results in the functional outcome.

Analysis Of Results With Classification



- 1 poor and 1 fair result were seen in type 6 fracture.
- 2 fair results were seen in type 5 fracture.
- All other types results were excellent and good.
- No other fracture type had fair or poor result.

Analysis Of Result - Injury And Surgery Time Interval

- In our study, patients who were mobilized earlier had a better functional outcome irrespective of the fracture type and surgery interval as shown in the table &graph below.

Time Between Injury And Surgery	Result	Number	Percent
< 1Week	Excellent	10	65%
	Good	5	
	Fair Poor	1 1	
1 – 2 Weeks	Excellent	2	23%
	Good	2	
	Fair	2	
2 - 3 Weeks	Excellent	1	12%
	Good	2	
	Fair	0	

Table 4

Graph.10

Age

- In our study average age of the patient was 48 years.
- Age in our study is compared with other studies.

Christian Boldin,Florian Fankhauser[10]	Average Age 62 Years
Lee JA ,Papadakis SA[11]	Average Age 42 Years
ours	Average Age 48 Years

Table 5

We observed that all the fractures united without any need for secondaryprocedure. It has been compared with other studies.

Study	Result
Stannard JP, Wilson TC[12]	87%
Christian Boldin, Florian Fankhauser[10]	96%
Lee JA ,Papadakis SA[11]	100%
ours	100%

Table 6

Follow Up

Study	Average Follow Up
Stannard JP, Wilson TC[12]	26 Months
Christian Boldin, Florian Fankhauser[10]	38 Months
ours	8 Months

Table 7

- Average follow up in our study is 8 Months (6 - 12 Months).
- Follow up in other studies are compared.

Range Of Movement

Average range of movement in our study is 120^0, it has been compared with other following studies,

Study	Average Range Of Movement
Stannard JP, Wilson TC[12]	Average Rom 110^0
Christian Boldin, Florian Fankhauser[10]	Average Rom 117^0
Ours	Average Rom 120^0

Table 8

Union Time

Average union time in our study is 15.3 weeks

Study	Result
Stannard JP, Wilson TC[12]	15.6 weeks
Christian Boldin, Florian Fankhauser[10]	11 weeks
Lee JA, Papadakis SA[11]	18 weeks
ours	15.3 weeks

Table 9

Restricted Knee Range Of Movement :

There was restricted knee range of movementin four of our patients and all four were schatzker's type V and type VI (Type V-2 and Type VI-2).All the patients who developed restricted knee range of movement had high energy proximal tibialfractures.Because these patients were immobilized for longer period of time which contributed for the restricted knee ROM.All patients who developed restricted ROM were treated appropriately with regular physiotherapy.

Loss Of Reduction

- There was implant loosening in one case schatzker type V fracture following which patient was immobilised for longer period of time hence outcome was fair.
- There was no loss of reduction in our study in comparison with Stannard JP study.[12]
- But in Christian boldin et al study there was one loss of reduction , because patient started full weight bearing earlier against advice of the surgeon.[10]

Malunion

- Our study has 1malunion, one valgus angulation.
- Occurred in type V fractures and due to comminution.
- In our study no intervention for the patient was done and outcome was fair because patient was immobilized for a longer period of time.
- Our results were comparable with other studies.

Study	Complication
Stannard JP, Wilson TC[71]	1 Valgus 1 Varus
Christian Boldin, Florian Fankhauser[10]	1 Varus

Lee JA, Papadakis SA[11]	Nil
ours	Nil

Table 12

Conclusion

MIPPO technique gives good to excellent results even in high energytibial condyle fractures (84% cases in our study).Our patients were able to achieve a good functional range of movement, averaging 120 degrees (Krettek et al – 124 degrees[3]. Those who were treated with early fixation and early mobilization were found to have a better functional outcome irrespective of the fracture type. Patient compliance was good with MIPPO technique .No secondary bone grafting was required. The average time taken for fracture union was 15.3 weeks. [Krettek et al – 16 weeks][3]

From our study of 26 patients, we conclude MIPPO **(Minimally Invasive Percutaneous Plate Osteosynthesis)** technique is an effective method of treating proximal tibial fractures due to its overall good functional outcome. Average follow up in our study was only 8 months and long term follow up is needed to give a definitive opinion.

An absolute indication of Manipulation under Anesthesia (MUA) for frozen shoulder is not extracted from literature. Though advanced medical sciences now have an option for arthroscopic release of soft tissue of shoulder, the results are variable in literature and recurrence recorded in literature varies up 30 to 40 percent. We adopted a non invasive approach for 40 cases of frozen shoulder. A functional outcome of patients treated with MUA and intra-articular injection with Methylprednisolone with Lignocaine (MP) was evaluated. Patients with frozen shoulder including those with diabetes were analyzed clinically, radio logically and SPADI score prior and post procedure done. The percentage of recovery noted. We noticed favorable and positive outcome in 67% despite strictly restricting our follow up for 3 months. A reminder here is the natural course of history which is generally self limiting and varies from 16 to 24 months. In view of possible recovery time, range of motions would further improve with recovery from pain. More than 4 studies were comparable, in this study we found external and internal rotation of shoulder joint not fully recovering, but reaching a range of motion for activities of daily living. Our results were comparable to other studies and conclude that MUA with injection of steroid speeds up recovery in range of movements and provides relief of pain.

Peri Arthritescpulaheumarale was the term used by Duplay in 1872. For painful shoulder with restriction of movements. Over the years aeitipathogenesis evolved with newer terms. 1934 Codman coined the condition Frozen shoulder, and Neviaser 1945 coined the term Adhesive Capsulitis [1]. And other surgeons brought light and charted theoretically the stages of frozen shoulder currently also known as Adhesive Capsulitis. The incidence varies from 2-4% and in some general population 3-7% [1, 2, 3].

Clinically diagnosed as Adhesive Capsulitis, this is a condition where spontaneous adhesion of ligaments, capsule and fibrosis occurs. There are two claims, one suggest synovial inflammation and other a condition similar to Dupuytren's Contracture [2, 4, 11]. Contractures along the long head of Biceps, Infraspinatus, and Supraspinatus.

Treatment varies from NSAIDs, moist heat, physical therapy, oral steroids,

IA Injections, hydro dilation, nerve blocks, Manipulation, open and arthroscopic soft tissue release. Literature supports more incidences in Diabetic patients, females, non dominant hand with bilateral involvement in 12-16% in same individual [1, 2, 3, 4]. Our study was to do noninvasive therapy that is Manipulation under Anaesthesia (MUA) with intra articular injection of 80 mg of Methylprednisolone with 1ml of Lignocaine; which is economical, needs no highly skilled expertise and can be done with standard aseptic procedure even in a District hospital.

To determine the outcome of patients, after we assessed patients for pain, disability and Range of Movements (ROM). The study prospectively recorded the functional outcome of treatment after MUA. We analyzed 40 consecutive patients and outcomes were assessed clinically by SPADI Score.

The Shoulder Pain and Disability Index is the sum total of pain scale and Disability scale and total score is divided by 130 and multiplied by 100 to calculate percentage. Pain is measured by 0-10 with 5 questions. Disability is assessed by 8 questions, score 0-10. Where 0 means no pain and 10 means worst unbearable pain.

Activities of daily living were checked were 0 means no difficulty and 10 means severe difficulty. Higher scales on the subscale will indicate greater pain and disability. Prospective study of 40 patients was conducted in tertiary care Institution of Medical sciences. The study was between May 2019 and May 2020. 40 consecutive patients with painful loss of shoulder movements with limitations in their activities of daily living.

2.1 we included all patients, who have painful and stiff shoulders, with restricted active and passive motion, with normal glenohumeral joint radiologically.

2.2 Any calcific tendinitis, arthritis, traumatic conditions or any other surgeries around the shoulder.

Our study included 40 patients including those with diabetes. All patients gave detail history and evaluation of pain scale and disability done using SPADI score. Clinical Examination and their record of shoulder movements and strength of muscle power were recorded. Only a single X ray in Anteroposterior (AP) view was taken. No patient underwent ultrasound or MRI.

40 patients were hospitalized, and physiotherapy started and all patients were educated for self-mobilization of shoulder. With strict emphasis on avoiding shrugging.

Wall climbing exercise, Pendulum, and other exercises were taught to the patients.

All patients underwent MUA within 5 days and at the same sitting injection 80 mg of Methylprednisolone (MP) mixed with 1 ml of Xyclocaine given anteriorly into gleno humeral joint.

Patient was supine, scapula fixed and pressed with thoracic cage and border of scapula. With help of an assistant. Holding the short lever arm gradual abduction, external rotation adduction and lastly internally rotation movement were done sequentially until audible click was heard.

We had no prior knowledge of pathological thickness of Corocohumeral ligaments, thickness of the capsule, and extent of pathological contractures. Irrespective of the duration we treated all patients with a standard protocol, so intervention rate could be accessed based on outcome at end of 3 months. Out of 40 patients, there were 18 male and 22 females. Out of

40 patients 27 patients were diabetic. 19 patients had right shoulder involvement and 21 left.

The average duration of symptoms like pain and disability was 2.5 months; least duration was 1 month and maximum 7 months. 31 patients after MUA and Inj MP of 80 mg underwent physiotherapy which was supervised for 1 week. 9 patients did not attend supervised physiotherapy at the hospital.

All patients underwent clinical examination at time of MUA, immediately after MUA, after 1st month, 2th month and 3rd month. SPADI score was calculated before procedure immediately after procedure and for each month. The percentage of recovery calculated to merely reflect functional outcome.

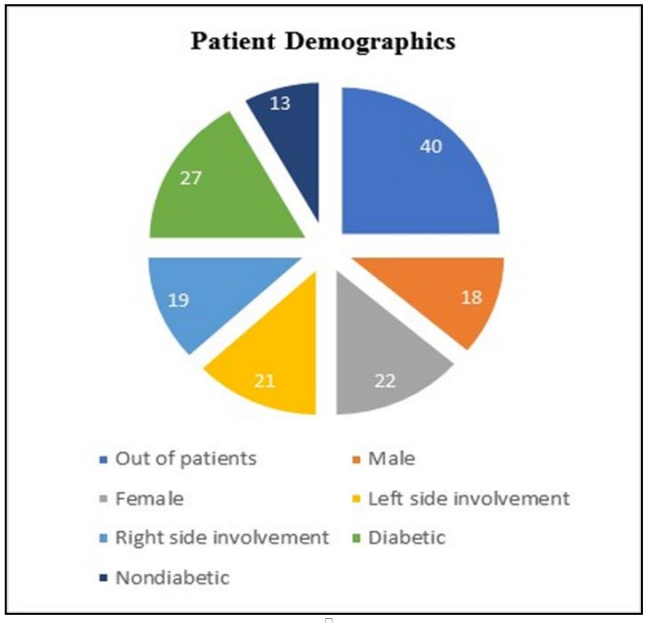

Table 1: Patient Demographics

Male	18
Female	22
Left side involvement	21
Right side involvement	19
Diabetic	27
Nondiabetic	13

Our work sheet tabulated the results in our study with average range of shoulder motions as follows: Abduction 60*, External Rotation (ER) 31°, Internal Rotation 30 (IR), and Flexion 66* at first examination.

We had one patient 55/F who had stiffness and pain who did not respond to treatment, not diabetic, her duration of symptoms was only for 3 months and was of left side. Our hypothesis that it would be like pathogenesis like Duptruyen Contracture in this particular case [4]. Immediately after MUA and injection MP Abduction (Abd) improved to 109.5 EXT rotation (ER) 59.6 Internal rotation (IR) 51° and flexion (FI) 106*

Table 2: Range of motion of shoulder at 3 months

1st month	Abd 125.2°	ER 65.25°	IR 56.5°	FL 123°
2nd month	Abd 132.7°	ER 67.5°	IR 60.2°	FL 130°
3rd month	Abd 135°	ER 68.2°	IR 61°	FL 134°

In our study by using SPADI score for pain and disability we calculated prior to SPADI, Post MUA, and at end of 3 months. In span of 3 months post MUA with injection the range of movements doubled.

The percentage of recovery calculated and averages taken, Preop SPADI Score was

70.7 and Post op 21.45 and the percentage of 67.1%. The predominant range of motions of external and internal rotations were quite resistant to MUA and the underlying pathology of shoulder rotators, their anatomy and pathological changes around them, probably is resistant to MUA.

Statistical Analysis with paired groups were done with comparison before and after MUA of shoulder.

Statistical Analysis paired test of Range of Movements

Abd	Pair 1 Before	VAR00001	110.7692	39	28.50527	7.332	0.000

Discussion

The Frozen shoulder is a condition where in, there is slowly progressive loss of movements of shoulder both active and passive, associated with pain and restriction of activities of daily living. The Natural History of Adhesive Capsulitis is that it is self-limiting. Recovery can take from 24-26 months [1, 2, 3, 4].

However Literature quotes various Surgeons who currently contradict this statement [6], several authors claim pain and loss of range of movements with disability of shoulder. Treatment varies from simple NSAID with moist heat, physiotherapy, oral steroids, intrarticular injections with steroid, hydrodialation, nerve blocks, manipulation, open surgical release and arthroscopic release. Contractures in shoulder may be responsible for ineffectiveness of any treatment. We don't know whether synovial inflammation is the cause or 'Duptruyens type' of capsule of shoulder.

We compared our results with Heidi Vastamaki, and Marti Vasatamaki' study [7].

In their study prior to MUA, Abduction was 75° (ABD), Eternal Rotation 21° (ER), Internal Rotation level of buttock (IR), and Flexion 99° (FL), in our result prior to MUA Abduction was 60°, External was 31°, IR 30° and FL 66°.

End of 8.8 months Vastamaki's study [7] showed in their patients Abduction 167°,

ER 51°, IR level L5 and Flexion 156°. In Our study we obtained at 3rd month on follow up ABD 135°, ER 68°, IR 61° and FI 134°.

Comparing with Thomas[8] et al ABD was 62°, ER 17° IR 17°, FI 165° (pre MUA)

Post MUA at one year follow up was ABD 168°, ER 65°, IR 65°, FL 169°. In our study

ABD 135°, ER 68°, IR 61° and FI 134° at end of 3rd month.

Studies by various authors showed good recovery but they assumed that elderly patients have restricted movements, we stand to contradict to their statements that 90% improvement in pain and range of movements.

Jenkins *et al.*, in their retrospectively had analyzed that 36% had unsatisfactory outcomes [8], in our study it was 33%. The natural history claimed to be self-limiting, can take prolonged duration of time between 14-32 months. Adhesive capsulitis of shoulder with pain and disability would require medication and pose risk of drug induced Nephropathy.

Though optimal time suggested by Vastamaki, and Vajonen is between 6-9 months for MUA, clinical outcome was questionable by many authors. Dodenoff, Levy, Wilson and Copeland in one series, and Janada and Hawins [9] proved that pain and disability can be reduced after MUA. This shortens the time interval of patients to resume work, disease itself cannot be evaluated merely on duration of months and prevailing changes for staging purpose cannot be guessed. Clinical importance of outcome can be questioned and hence its variable. To achieve necessary functional activities there has to be range of motion which is free.

1. Early Recovery

Hence irrespective of duration of symptoms all patients were hospitalized and for 5 days physiotherapy given and then taken up for MUA and Injection MP 80 mg with 1ml of 2% Xyclocaine into the joint.

To enable eating approximately 60-100 of abduction, horizontal abduction about

40-70 degrees. Rotations about lessor range. For reaching perineum 40-60 of abduction and 90 of Internal rotation. Similarly, for combing hair, tucking shirt, or putting on pants, etc.

A range of movements which are not full and free but can able patients do activities of daily living which are pain free [8, 9, 17].

Pain and Disability prior to MUA on Average score was 70.7 (SPADI) after MUA at 12 weeks the score was 21.45. Post SPADI score of 21.45 denotes some residual pain and disability, but with useful functional outcome.

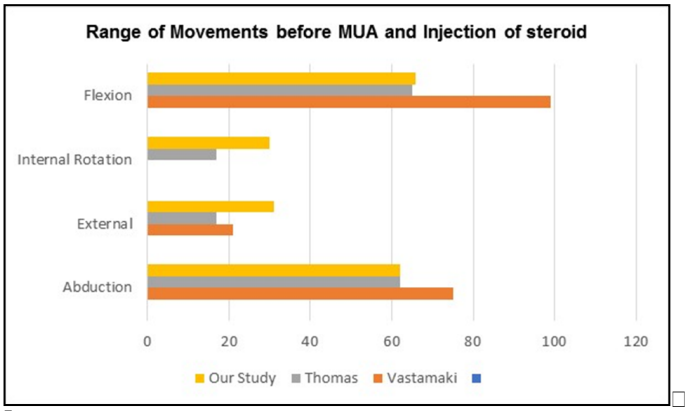
There was no complication in our cases. Grant *et al.* [10] compared MUA with arthroscopically done surgical release and reported that there was not much difference [10]. Arthroscopically done release has risks like chondrolysis due to thermal heat, risk of infection, risk of accidental axillary nerve damage. Open Release with manipulation offers no advantage on the contrary it reduces the speed of recovery. Also risk of infection introduced into the joint.

Rotator Cuff was analysed by Atoun et al with ultrasound before and after MUA and found cuff undamaged [12].

Sasanuma *et al.* [13] found no rotator cuff tears on MRI after Manipulation.

2. Cuff Tear Arthropathy

In a Retrospective study of 51 patients' frozen shoulders done by Wang *et al.* [14] after MUA reported 89% of cases had good results. In our series 67% had good results.



The difference of 22% in the outcome was because all patients were followed up to 3 months strictly. Whereas Wang followed up to 1 year. In their study patients were immediately mobilized, in our study all patients were given rest post of period for 24 hours, to enable them recover from pain.

Another probable cause is 9 patients dropping out of supervised physiotherapy at OPD for 5 days. One patient had

absolutely no recovery, few others had a slow start, our follow up was limited strictly till 12 weeks. We assume out of 22% of cases if given more time recovery rate would improve.

ROM after MUA and Injection of steroid

The study shows functional outcomes is improved after MUA and after Intra articular Inj of MP. Recovery of External rotation and Internal Rotation takes a longer time and their range of movements is again dependent on retraction of capsule and narrowing of clear space around ligaments. Non reversible pathological changes like fibrosis and capsular thickening with adhesions of glenohumeral ligaments.

Farrell *et al.* [15] their study of 19 shoulders after MUA, followed up for 7 years. They obtained Abduction 155°, External Rotation 76°, Internal Rotation 73° and Flexion 159°.

In our study we obtained 135° of abduction, 68° of External Rotation, 61° of Internal Rotation and 134° of Flexion at 3rd month which is beneficial to be patient.

Our study follows up limited up to 3 months. It is evident by MUA and inj of steroid the pain and stiffness improves, the shoulder recovers functional range of movements. However the limitations of this study: 40 patients and follow up to 3 months. No control group of patients, Non divided into 2 groups that is diabetic and non diabetic. Standard and same protocol of treatment followed. No 2 different methods of treatment. Our prospective study included both diabetic and non diabetic patients.

Manipulation of shoulder with injection of Steroid is a good method of treatment.

It's cost effective and speeds up recovery from pain and disability. It can be done safely as a day care procedure, and even in district Hospital. MUA carries little risk, without any need for expert technical skill. Majority of patients are happy for the range of movements recovered.

It is unnecessary to wait and observe for prolonged time or do prolonged follow up. Recurrence rate is low compared to arthroscopic surgical release and is subject to further trials and comparative studies.

Here by thank the librarian Mr. J. Mahendran of PSG Institute of Medical Science and Research.

I acknowledge the help from Dr. Vibaha, intern for helping in calculating averages on excel sheet and also Dr. Anil Mathew, Professor of Community Medicine, PSG, for his statistical analysis and advice.

Abstract

Introduction: Voice is a natural medium adapted to communicate emotional contact. Hoarseness is a common symptom that otolaryngologist come across. **Aims and Objectives:** This study aims at studying the etiology predisposing factors and clinical profile of patients presenting with hoarseness. **Materials and Methods:** This study was carried out in department of ENT, PSG medical college, Coimabatore in the period of July 2015 to July 2017. A total of 100 cases presenting with hoarseness were studied. **Results:** The most common etiology was found to be malignancy of larynx with incidence of 33% among the hoarseness of voice patients. The incidence of hoarseness was 0.27% among the total ENT cases. **Conclusion:** The symptom of hoarseness of voice should not be ignored as it might be an indication of laryngeal malignancy. Any patient with hoarseness should be thoroughly investigated to rule out laryngeal malignancy, that might cause respiratory distress leading to life threatening complications.

Keywords: Hoarseness of voice, Laryngeal malignancy, indirect laryngoscopy, direct laryngoscopy, Video laryngoscopy

Introduction

Voice is an integral part of human attribute known as speech. A person with voice problem may present with hoarseness, voice fatigue, breathy voice, reduced phonational range, pitch breaks etc. Hoarseness is a coarse, scratchy sound most often associated with abnormalities of the vibratory margins of the vocal cords. Hoarseness of voice describes the voice quality that is noticeably evident in its lack of clarity and discordance. In Otorhinolaryngological practice one of the commonest symptoms encountered is hoarseness of voice.

It is more common in certain groups like teachers and voice professionals. Both males and females are affected, and it can be a presenting symptom in any age group. In addition to impact of health, it has an effect on quality of life. Hoarseness can be due to both benign and malignant conditions which requires promt diagnosis and appropriate management. If hoarseness of the voice persists for more than two weeks, then it should be investigated properly to find the cause [1]. The etiology of hoarseness is very diverse, and it varies greatly. Hoarseness can be divided into acute and chronic onset [2]. The acute onset of hoarseness may be secondary to viral infection, voice abuse, trauma to the larynx and thyroid surgery [3]. Chronic onset may be due to vocal polyps, vocal cord nodules, laryngeal papillomatosis, laryngeal neoplasms, tumors of the vocal cords, functional dysphonia, smoking, gastroesophageal reflux, post nasal drip, malignant neoplasms of the thyroid, oesophagus, lungs and neurological involvement by systemic diseases like diabetes mellitus and chronic granulomatous diseases like tuberculosis [4]. Hoarseness can be identified just by hearing to the spoken voice. It is a common symptom which warrants investigation to rule out many local and systemic causes [5]. The present study is an attempt to analyze the clinical profile, incidence of common etiological factors and the association of common predisposing factors for hoarseness of voice.

Manuscript received: 20th September 2019
Reviewed: 30th September 2019
Author Corrected: 8th October 2019
Accepted for Publication: 12th October 2019

Aims and Objective

1.To analyze clinical profile of hoarseness of voice
2.To find out incidence of common etiological factors of hoarseness
3.To find out the association of common predisposing factors leading to hoarseness

Materials and Methods

This was a prospective observational study conducted during July 2015 to July 2017 in department of Otorhinolaryngology, PSG institute of medical sciences and research. This study includes 100 patients with various laryngeal pathologies on the basis of inclusion and exclusion criteria. All cases presented with change in voice.

Inclusion criteria for cases considered in the study

1. Patients presenting with hoarseness of voice.
2. Both genders

Exclusion Criteria for cases considered in the study

1. Age group below 5 years.
2. Voice disorders other than hoarseness like rhinolaliaaperta, rhinolaliaclausa, articulation disorders and central nervous system like bulbar palsy, multiple sclerosis, stroke and Parkinson's disease.

Methods of data collection: Proforma was designed based on the objective of the study and it was pretested and used after modification. As per the proforma detailed clinical history was taken followed by thorough ENT examination and systemic examination and clinical diagnosis was arrived in support with the relevant investigations.

Videolaryngoscopy under local anaesthesia was carried out in all 100 patients as a part of local examination. Out of which many patients required surgical intervention for both diagnostic and therapeutic purposes.

When the findings were inadequate to arrive at a clinical diagnosis, direct laryngoscopic examination with or without biopsy, microlaryngoscopy with or without biopsy, flexible endoscopy with or without biopsy was performed. The biopsy specimen was sent for histopathological examination.

Results

In our present study incidence of hoarseness voice was 0.27% of total ENT cases, with incidence of laryngeal malignancy in 33% of cases.

Cases: Maximum number of cases (31%) were between the age group of 41-50 years. Among males 41-50 years and females 31-40 years were the common age group of presentation. Hoarseness was commonly found in labourer class (48%). Both among males and females this was commonest group.

Lower socio-economic group was commonly noted among patients (40.00%) both in males and females. Majority patients were from rural area (59%). Smoking was commonly encountered habit among males (30.00%) and no habits among females.

Along with hoarseness (100%) other symptom with which patient presented were dysphagia (25%), cough (41%), breathlessness (14%), foreign body sensation in throat (10%), neck mass (5%) and Hemoptysis (5%). Maximum number of patients presented with hoarseness of voice with duration of 1-3 months. On video laryngoscopic examination commonest finding was laryngeal growth (33.33%).

Among histopathological (47pts) studies, commonest finding was squamous cell carcinoma in 70%.

The present study showed following aetiological factors for hoarseness of voice.

Laryngeal malignancy	:	33%
Chronic laryngitis	:	22%
Vocal cord paralysis	:	15%
Vocal cord nodules	:	10%
Tuberculosis of larynx	:	8%
Vocal cord papilloma	:	5%
Vocal cord polyp	:	3%
Vocal cord cyst	:	2%
Laryngeal trauma	:	2%

Laryngeal malignancy was the commonest cause of hoarseness of voice (33%) and males were commonly affected. Smoking was noted in all male patients with malignancy (80%), along with alcohol consumption in (70%) and chewing tobacco preparation in (65%) of cases.

Chronic laryngitis was next common cause for hoarseness of voice (22%) and was fond in 23% among males and 18% among females, with male to female ratio 1:1.

Vocal cord palsy was found in 15% of cases and was common in females (29%). Vocal cord nodules were found in 10% of patient and was common among female patients (24%) and with male to female ratio 1:2.

Tuberculosis was found in 8% all cases were males, with pulmonary tuberculosis and showed AFB on sputum examination.

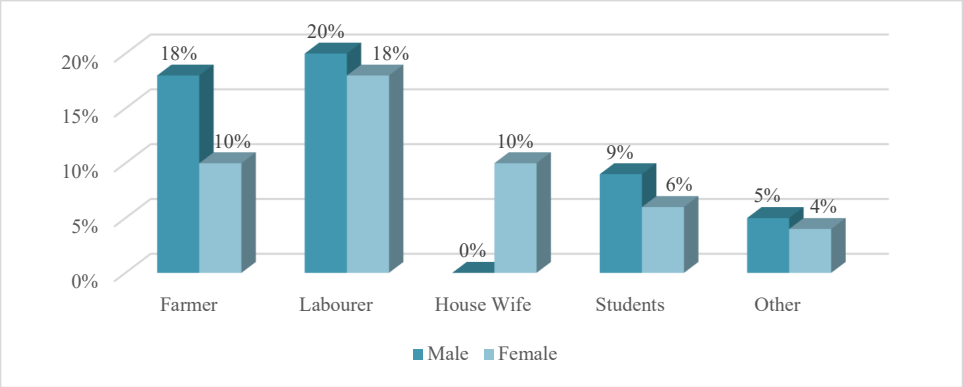

Figure 1: Occupation and sex wise distribution of hoarseness of voice.

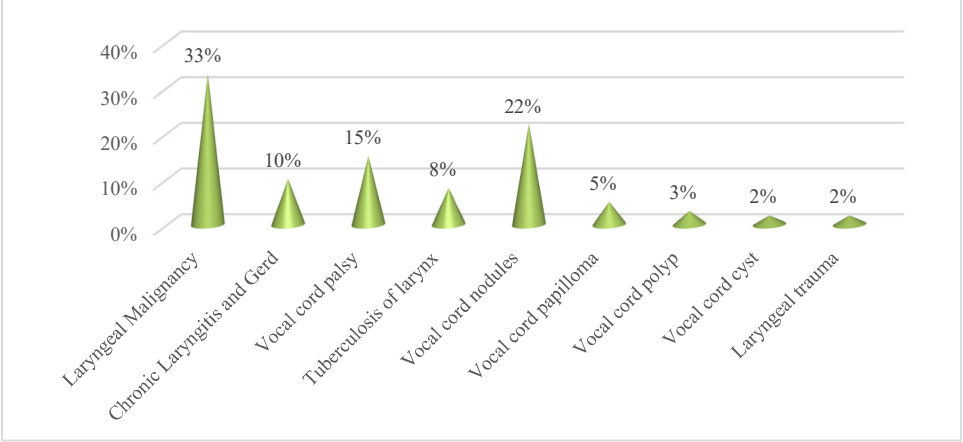

Figure 2: Aetiology of hoarseness of voice.

Table 1: Histopathology.

Histopathology	No. of cases (73pts)	Percentage
Squamous cell carcinoma (keratin pearls)	33	45.2
caseating granuloma and acid-fast bacilli	8	10.96
Hyperplastic stratified squamous epithelium with pigment laden macrophags	24	32.88
Squamous papilloma	5	6.85
Dense fibrin deposition with stellate cells with hemorrhages	3	4.11

Vocal cord papilloma presented in 5% of cases and females were commonly affected (66%) with male to female ration 1:2. Vocal fold polyp was found in 3% of cases, each one in male (33%) and two in female (67%). Vocal cord cyst was presented in 2% of cases. Two cases (2%) presented with laryngeal trauma.

Discussion

Hoarseness is considered a presenting symptom of a disease and not a disease by itself. It is one of the most common symptoms in conditions affecting laryngeal apparatus. Usually Benign pathologies are more common than malignant pathologies in patients with hoarseness and early diagnosis and treatment aids in good voice quality. Hoarseness lasting longer than two weeks needs complete evaluation to rule out malignancy as a cause.

A total 100 cases of hoarseness of voice were studied during study period. In the present study period incidence of hoarseness voice was 0.27% with laryngeal malignancy being the most common cause. while in a study by Shambhu Baitha (6) incidence of hoarseness was 0.32%, which nearly coincides with the present study.

Age and Sex: In the present study age of patients with hoarseness of voice ranged from 8 years to 78 years majority of patients i.e. 31 cases were in the group of 41-50 years and minimum number of patients i.e. 2 case was in the age of group of <10 years. In a study by Shambhu Baitha [6] majority of patients i.e. 31 cases (28.18%) were in the age group of 31-40 years. In a study by Swapan Ghosh [7] maximum patients i.e. 28 cases (28%) were in the age group of 21-30 years.

In our present study 66 patients were males and 34 patients were females, thus male to female ratio of approximately 2:1 was observed. This finding was similar to the study done by Shambhu Baitha [8] where males 74 cases (67.27%) and female 36 cases (32.72%) were noted. But in a study done by Parikh and Sudhir babu where the male to female ratio was 1:1. and 1.89:1, which was found to be little bit lower than the present study [8, 9].

Occupation: In the present study majority of patients of about 48 cases were of labourer class and least i.e. 5 cases were in the others group. In a study by Shambhu Baitha al the same observation was made i.e. majority of patients were of labourer class (36.36%). In the present study group among males and females labour classes, male was found to be predominated i.e. male 52.63% and female 48.30%. In females next common group was housewife (27.28%) least which was contrast to the study done by Swapan Ghosh where majority of patients were housewife (29%).

Socio economic status: In the present study, majority of patients (40.00%) belonged to low socio-economic status and also majority of patients among males (36.84%) and females (45.45%) belong to lower socio-economic status. Upper lower group was next common (30.00%), other groups with decreasing frequency were lower middle (18%), upper middle (8%) and upper (4%).

Residence: In the present study about 59 patients were from rural area and minimum cases of 41patients were from urban area. This was similar and coincides with the study done by Shambhu Baita [6] were predominantly patients were from rural areas comprising of 83 cases (75.5%).

Habits: Brock has mentioned inhaled irritants especially cigarette smoke as most important predisposing factors for hoarseness (10). In our present study commonest habit noted was smoking which was seen in 30 patients and the alcohol was the lowest habit seen in 8% of patients. The present study was similar to the study done Sambhu Baitha [6]. In the study done by Swapna Ghosh [7] vocal abuse was noted in 72% of cases which was contrast to the present study. In the study done by Shambhu Baitha [6] smoking was noted in 25.45% of cases, chewing tobacco preparation was noted in 17.27% and alcohol in 12.72% similar to the present study. Parik [3] has found that smoking was associated with hoarseness in about 20% of cases only and vocal abuse was found in 56% which was contrast to ours.

Videolaryngoscopic examination: On videolaryngoscopic examination commonest finding was – Ulcero-proliferative growth involving larynx and laryngo-pharynx which was seen in 41% of cases. And the rare finding is the vocal folds cyst and submucosal haemorrhage of vocal folds and false cords were noted in 2%. In a study by Shambhu Baitha [6], congestion of vocal cords noted in 34.54%, growth in only 9% of cases on IDL examination. This was contrast to the present study. This may be due to patients' habits.

Etiology of hoarseness of voice: In the present study, commonest etiology observed was malignancy of larynx and laryngopharynx in about 33% 0f patients. Among males commonest etiology was malignancy of larynx and laryngopharynx 29 cases (41.86%) and among

females' malignancy of larynx and laryngopharynx was only 11.77% (4 cases).Among patients with malignancy males were common 29 cases (92.86%) and females 4 cases (7.14%) with male to female ratio as 13:1. In study by Shambhu Bhaita [6] Incidence of malignancy was 14.54% with male to female ratio as 15:1. In a study done by Kadambari [11] incidence of malignancy was 18% and in study by Swapan Ghosh [7] incidence of malignancy was only 8% and in Parikh [8] incidence of malignancy was 12%. When compared to the other study, incidence of malignancy in patients presenting with hoarseness was found to be high this may be due to their socioeconomic status and habit related.

In the present study next common etiology was chronic laryngitis 22 cases. Among females it was common etiology 11cases (17.65%). Male to female ratio was found to be 1:1 as 11 cases of males had chronic laryngitis. In both studies of Parikh [8] and Shambhu Baitha [6] chronic laryngitis was commonest aetiology comprising of 48% in each, whereas in study by Swapan Ghosh [7], it was only 6% and in study by Kadambari [11] it was 8%. The present study was similar to the study done by Swapna Ghosh [7] and Kadambari [11] but contrast to the other studies like Parikh [8] and Shambhu Baitha [6].

Third common etiology was vocal cord paralysis noted in 15 cases. Among males the incidence was 9.30% (7 cases) and among female 29.41% (8 cases), with male to female ratio as 0.8:1. In study by Parikh [8], Kadambari [11] and Shambhu Baitha [6], It was only 3%, 9% and 9% respectively, with male to female ratio in Shambhu Baitha [6] study was 9:1. The present study had a very lower male female ratio. The present study showed clearly that females have a higher vocal cord palsy rate compared to male.

The fourth common etiology was vocal cord nodules, 10 cases with male to female ratio 1:2. Among males 4.65% (3 cases) were affected and among females 23.53% (7 cases) patients had vocal nodules. In all cases vocal nodules were bilateral.

Vocal nodules were the commonest aetiology in the studies done by Parikh [8] (50%) with males 43.3% and females 56.7% and also in Swapna Ghosh [8] with incidence of 30% with male to female ratio 1:1.5.

In study by Shambhu Baitha [6] incidence was only 12.72% with male to female ratio 1:1.3. in the present study also, it was clearly defined that vocal nodule is more common in female than male but the ratio is found to be higher when compared to other studies.

The fifth common etiology was tuberculosis of larynx 8 cases. All the patients were males with pulmonary tuberculosis. In study by Parik [8]· Shambhu Baitha [6] and Kadambari [11] incidence of tuberculosis was 23%, 5.45% and 1% respectively.

Vocal cord papilloma was found in 5 cases with male to female ratio as 1:2. Vocal cord polyp was presented in 3 patients with male to female ratio as 1:2 as one male and two female had vocal cord polyp. In the study done by Swapan Ghosh [7], Parikh [8] and Shambhu Baitha [6] incidence of vocal cord polyp were 23%, 15%, and 4.54% with male to female ratio as 3.6:1, in Swapan Ghosh Study [7] and 1:1.5 in Parikh et al study. Only Parikh [8] study was similar to the present study whereas in other studies the vocal cord polyp had a higher incidence than others. Other cases, which presented with hoarseness, were vocal cord cyst in 2 patients and laryngeal trauma in 2 patients which was similar to above study [8].

Conclusion

Thus, from this study it was found that the incidence of hoarseness of voice in the present study is 0.27%. Laryngeal malignancy (squamous cell carcinoma) was found to be the most common cause of hoarseness of voice (33%). Smoking was found to be the most common etiological factor for squamous cell carcinoma of Larynx (30%). In the present study, male patients were found to be affected more in laryngeal carcinoma than females with male female ratio of 13: 1. Rural population and patients in low socio-economic status were the most affected. Finally, it can be concluded that, the symptom of hoarseness of voice should not be ignored as it might be an indication of laryngeal malignancy. Any patient with hoarseness should be thoroughly investigated to rule out laryngeal malignancy, that might cause respiratory distress leading to life threatening complications.

What the study adds to the existing knowledge?

The importance of the present study is to highlight the importance of not neglecting hoarseness of voice lasting for more than a week.

A Study on Prevalence of Hearing Loss as a Complication of Diabetes

A. Dayanand, J. Dheebika, S. Prathula and S. Palaninathan

***Abstract* —**

***Index Terms* —**

I. Introduction

Hearing impairment is the most frequent sensory deficit in human populations, affecting more than 250 million people in the world. Diabetes Mellitus is a metabolic disorder, due to relative or absolute lack of insulin resulting in elevated blood glucose levels associated with long term vascular and neurological complications. Among glucose metabolism disorders, diabetes mellitus is the one most commonly related with auditory disorders. The complex arrangement of inner ear makes it potential target of hyperglycemic damage. Diabetic patients are more prone to complications of hyperglycemic, as all body cells are exposed to high levels of plasma glucose. The organ of corti cells are important structures for hearing mechanism and turn out to be the potential target for damage, due to high glycemic levels, micro vascular compromise, their complex structure and arrangement. Thus, screening of these patients at a high risk of developing sensory neural hearing loss, will aid in early diagnosis and management.

II. Aim Of The Study

- To Study the prevalence of Hearing loss its association with Diabetes.
- To assess the hearing loss in diabetics and correlate it with age and duration of diabetes.

III. Materials

This is a cross-sectional study in which evaluation of study population who were diagnosed with diabetes mellitus study method undergoing treatment on Out-Patient or In-Patient basis in department of ENT and Endocrinology. In PSG Institute of Medical Science & Research. Coimbatore, Tamilnadu from July 2012 to July 2014 were considered.

- History of every patient was taken in detail and importance was given on their presenting complaints. Any significant past history of ear discharge. Hearing loss or previous ear surgeries were elicited. History of duration of diabetes and mode of treatment were given importance.
- All the patients were taken up for Otoscopic examination, in which the ear canal and status of tympanic membrane were assessed.

Inclusion Criteria for cases considered in the study

- Known cases of Diabetes mellitus
- Age-group > 30 years to < 60 years
- Both genders

Exclusion Criteria for cases

- Individuals involved in occupations exposing to loud noise.
- Individuals with previous history of ear discharge/hearing loss/ tinnitus/ear surgery
- Otoscopic examination showing any ear pathology like wax, discharge, retracted tympanic membrane, perforated tympanic membrane or tympanosclerosis.
- Patients unwilling to comply with the study.

IV. Methodology

All 200 patients were worked up with a pure tone audiometry. The audiogram was analyzed for hearing loss and if present it will be classified according to WHO classification. Pure Tone Audiometry is a routine audiometric evaluation and the resulting pure tone audiogram is used as a basic description of the degree of hearing loss. Audiological examination was performed using a Pure Tone Audiometer model GS1 61, in a soundproof room in the ENT department, PSG Institute of Medical Sciences & research. Earphones were used to test hearing by air conduction and a small vibrator, which was placed over the mastoid was used to test hearing by bone conduction. All audiometers are incorporated with a calibration circuit, which allows the output sound level to be set at particular frequency. The signals presented to the subject by the audiometer were all characterized by its sound pressure level, frequency and wave form which were all delivered at

controlled rates.

The entire procedure and purpose of the test was explained in detail to the patients. Biological calibration of the system was done on daily basis before starting the procedure. Both air and bone conduction were tested for each ear.

V. RESULT

In this study, analysis of 200 patients diagnosed mellitus was done in the Department of E.N.T, PSG Institute of Medical Sciences& Research from July 2012 to July 2014 to determine the incidence of hearing loss as a complication of diabetes mellitus. Detailed evaluation of each case was done comprising of the history, clinical examination including otoscopic examination with otoscopic and pure tone audiometry. The clinical data was collected by means of a proforma and the observations from the audiogram were analyzed with the Master chart as shown in the Annexure. In our study of 200 diabetic patients, 110 (55%) cases out to have sensorineural hearing loss.

VI. Discussion

Hearing loss is important of hearing and its severity varies from mild to severe or profound and in general hearing loss may be conductive, sensorineural, or mixed. The typical hearing impairment described in diabetic patients is a bilateral sensorineural hearing loss. Diabetes mellitus has been implicated as independent causative factor of sensorineural hearing loss [14].

A. Age

Our study has evaluated the hearing loss in the patients with diabetes and the influence of hyperglycemia on hearing and it shows 55% incidence of deafness. And the peak age group being affected with hearing loss in our study was between 50-53 years of age.

In contrast a study conducted by Rajendran S. Anandhalakshmi et a1 [16] showed maximum incidence between 40-50 years of age. On further review, we realize that acquired on set sensorineural hearing loss can occur early in diabetic patients. Usually age-related sensorineural deafness is more common in people more than 60 years of age. But here it is seen that diabetic patients are higher risk of developing this sensory loss at a much younger age group.

It is also that in our study there were more people with diabetes among the age group 51-60 years of age (50%). The p value is 0.05, which makes it statistically significant.

B. Sex

In our study it was noted that a greater number of diabetic males were affected with hearing loss, than females. In contrast Taylor and Irwin (1978) observed that female patients with diabetes had significantly greater hearing loss when compared with male patients with diabetes.

But according to Cullen and Cinnamond [17], Male patients with diabetes had worse hearing than female patients with diabetes.

From our study, we conclude that sex of an individual is not statistically significant ($p>0.05$) parameter in considering the males are more prone to develop Diabetes mellitus.

C. Overall incidence of hearing loss in diabetics

In our study, we evaluated the hearing loss in the patients and the influence of hyperglycemia on hearing and it shows a 55% incidence of deafness. Friedman at al [18] showed a 55% incidence of hearing loss in diabetic patients. Which is the same incidence found in our study.

Kakarlapudi et a1 [19] found that hearing loss was more common in diabetic patients (13.1%) than the control nondiabetic healthy subjects.

Wenget a1 [20] noted that among the 67 diabetic subjects examined, 44.8% of them had profound hearing loss. This is much lesser comparing to our study.

D. Duration of diabetes

In our study a greater number of patients with diabetes were found 3-5 years group, about 48%, followed by less than 2 years duration 31%.

Comparing with, the duration of diabetes and hearing loss, more patients in the group 3-5 years had hearing loss, around 49%, followed by less than 2 years, around 32 years. Whereas only 20% patients were found to have hearing loss in 5-10 years group.

In study it is seen that the duration of diabetes is not a significant criteria for developing sensoineural hearing loss. The p value is <0.05, making it statically significant.

A study by Celik et al [21] observed that as the duration of diabetes increased to 15 years, the incidence of hearing loss also increased. After 15 years of diabetes, the influence on hearing loss was not significant. This change was not observed in our study as cases in our study were all mostly found to be less than 15 years.

E. Overall severity of hearing in individual ear

It is noted that in the right ear 95 cases had normal hearing, 84 cases had mild hearing loss, 15 had moderate and 3 cases had moderately severe and severe hearing loss respectively.

It is noted that in the left ear, 92 cases had normal hearing, 81 had minimal hearing loss, 16 had moderate loss 8 moderately severe, 2 with severe and 1 with profound hearing loss. Thus, making it statically not significant ($p>0.05$). The above data was calculated taking the gender as consideration and compared the hearing. But no significant changes were noted in severity of hearing.

Taking into consideration the duration of diabetes, it is noted that in right ear maximum of 58 (30%) cases had hearing loss among the group 3-5 years, among which 49 (25%) cases had mild hearing loss; 6 (3%) cases had moderate hearing loss and 3 cases (2%) had moderately severe loss, followed by 5-10 years group where 31 cases (16%) had hearing loss

And in left ear it is noted that , maximum of 59(30%) cases had hearing loss among the group 3-5 years, among which 44(22%) cases had mild hearing loss; 8 (4%) cases had moderate hearing loss and 5 cases (3%) had moderately serve loss, followed by 5-10 years group where 32 cases (17%) had hearing loss.

Thus, we conclude that predominantly mild sensorineural hearing loss in both ears. The p value is <0.01, making it statistically significant.

F. Overall severity of hearing loss

In our study, 72% of individuals with diabetes were noted to have mild sensorineural hearing loss, followed by 20% with moderate sensorineural hearing loss. Only 1% had profound hearing loss.

A study conducted by Rajendran at al showed a result similar to our study. The diabetic individuals showed significant high frequency, bilateral, mild to moderate sensorineural hearing loss (73.3%) as compared to controls of similar age.

Whereas Weng at al [14] observed that among the 67 diabetic subjects examined, 44.8% of them had profound hearing loss.

Many studies were conducted to observe the pathogenesis of this sensorineural loss observed in diabetics. During this course, many studies suggested that diabetes is a cause of hearing loss. The probable mechanisms suggested were microangiopathy in the inner ear, neuropathy of cochlear nerve, or even a combination of both. Outer hair cell dysfunction and disruption of endolymphatic potential were noted in some noted in some studies. Some of the tissue effects of diabetes are considered to be related to the polyol pathway, in which glucose is reduced to sorbital.

Generally, the accumulation of Sorbitol is implicated in neuropathy as it causes a decrease in myo inositol content and further leads to decrease in Na+K+ATPase activity [22].

Makishima and Tanaka [23] observed that there was serere atrophy of the spiral ganglion in the basal lamina and the middle turns of cochlea in diabetic individuals with sensorineural hearing loss. It was also observed that 8th nerve reviled changes in the myelin sheath, which showed degeneration and fibrosis of perineurium

Jorgensen [24] in his story noted thickening in the walls of the vasa nervorum in the 8th nerve which lead to the development of acoustic neuropathy.

In the study by Wackym and Linthicum [25] noted small microanogopathic changes in the regions of endolymphatic sac, the stria vascularis and basilar membrance.

Van den Ouweland et al [26] observed mutational changes in the mitochondrial RNA. It was also observed that in a small subset of patients, with maternally inherited diabetes showed some degree of sensorineural hearing loss.

Lisowska et al [27] in their study noted that in diabetic patients, there was abnormality in the function of hair cells in auditory brain stem responses.

Fukushima et al [28] concluded that Type 2 Diabetes lead to changes in cochlea, like significant atrophy of stria vascularies and basal turn, which was the likelihood of hearing loss in their patients.

In our study, we conclude that after analyzing the audiograms of the diabetic patients, it is noted that they are more prone to develop mild to moderate sensorineural hearing loss. The duration of diabetes as well as sex of the individual were found to have no effect on the incidence of hearing loss.

Abstract

Background: The aim of this analytical study is to compare the hearing improvement in type I Tympanoplasty between Temporalis Fascia used alone and temporalis Fascia with cartilage as graft material. **Material and Methods:** The study was done in ENT department at PSGIMSR, from October 2016 to July 2018. A total of 21,453 cases attended the ENT Outpatient department during the study period. Out of these, 75 cases with dry perforation of the tympanic membrane were chosen for the study. Patients were selected in random, excluding ear discharge, Attico-antral disease, and complications of chronic otitis media. **Results:** In the study population, disease afflicting the nose and throat were also ruled out. Detailed evaluation of each case was done comprising of history taking, clinical examination, investigations including pure tone audiometry. Patients were divided into 2 groups. Group A consist of 50 patients underwent type I Tympanoplasty with temporalis fascia alone. Group B consist of 25 patients underwent type I Tympanoplasty with combined Temporalis Fascia & Conchal Cartilage. Post-operative hearing improvement measured by Audiometry is compared among the two groups and found that small perforations had best improvement with Temporalis Fascia graft, large and subtotal perforation had good improvement in postoperative hearing with combined Temporalis Fascia and Conchal Cartilage graft. **Conclusion:** Mean hearing improvement in Group A with temporalis graft was 12.98 dB (better) than Group B, with Temporalis Fascia & Cochal Cartilage graft mean hearing improvement was 8.96 dB.

Keywords: Temporalis Fascia, Conchal Cartilage, Type I Tympanoplasty.

Introduction

Tympanoplasty is done primarily to achieve a dry ear by eradicating middle ear disease and hearing improvement by closure of any Tympanic Membrane perforation by grafting with/without Ossicular reconstruction. The result of Tympanoplasty is measured by the success or failure of the graft uptake and hearing improvement. Various graft materials had been used by trial and error. These materials ranged from skin grafted from other areas of the body such as Thiersch graft, Split-skin graft, Pedicle graft from canal skin, Vein graft, Temporalis fascia graft, Scleral and Corneal graft, Perichondrial tissue, Cartilage [1-5].. Cartilage graft also provides firm support to prevent retraction formation. The greatest advantage of the Cartilage graft is its very low metabolic rate.

Cartilage receives its nutrients by diffusion, is easy to work with because of its pliability, and its resistance to deformation from pressure variations.

Perichondrium and Cartilage [2] share with fascia the quality of being mesenchymal tissue. Cartilage are inherently thicker and stiffer compared to temporalis fascia. They mechanically reduce the vibratory pattern of the tympanic membrane in response to sound waves, contributing to some impairment in functional results.

This phenomenon is seen more in relation to higher tones. The mass effect of the cartilage over the prosthesis is always a concern. Cartilage has comparatively lower compliance than fascia. Cartilage is preferred in case of large or anteriorly placed perforations or associated eustachian tube dysfunction but at the cost of delayed hearing restoration for six months.

Temporalis fascia is generally considered to be superior with respect to the take-up rate.

Materials and Methods

Objective

1. To assess the hearing outcome after Type-1 Tympanoplasty.
2. To compare the hearing improvement by the type of material used for graft
3. To evaluate the results of this study and compare it with similar studies

Study design: Analytical and follow up study.
Period of study: October 2016 to July 2018
Study population: Patients of 20-60 years age group.
Study area: Department of Otorhinolaryngology, PSGIMS&R
Sample size: 5 Individuals.

Justification : This sample size correlates with the amount of patients with similar disease profile consulting at the ENT OPD

Subjects and selection method: 75 patients with perforated tympanic membrane due to Chronic Otitis Media, Trauma, recurrent middle ear infection presenting to ENT outpatient department at PSG IMS&R will be taken up for study.

As soon as the patient presents to the hospital, detailed clinical history and examination will be carried out as per the proforma prepared. Laboratory investigations will be done. All patients will be subjected to pre-operative Audiometric evaluation (PTA).

Type 1 Tympanoplasty will be done using different graft materials once the pre-operative investigations are noted and extent of disease established.

Follow up with audiometric evaluations will be conducted at the end of 3rd month following surgery and results will be compared with pre-operative Audiogram results

Inclusion criteria

Patients of age between 20 to 60 years presenting with

1. Perforated tympanic membrane due to Chronic Otitis media, Trauma, Recurrent middle ear infection
2. Intact ossicular chain
3. Dry ear
4. Intact Eustachian tube function

Exclusion criteria

1. Patients with Sensory neural hearing loss (SNHL)
2. CSOM with attico-antral type of disease.
3.Tympanosclerosis, middle ear Atelectasis, Middle ear tumours, Congenital Cholesteatoma.

Potential benefits

1. Improvement in hearing outcome of patients, will be helpful in proper diagnosis and better treatment of patients having conductive hearing loss.
2. Knowledge of the level of improvement of hearing and the rate of healing using different graft materials will be known.

Risks

1) Graft Failure
2) Minimal discomfort to the patient at the time of audiological testing performed post surgery.

Method of collection of data

Group A – 50 patients in which Temporalis Fascia was used as graft material
Group B– 25 patients in which Conchal Cartilage with fascia used as graft material

Results

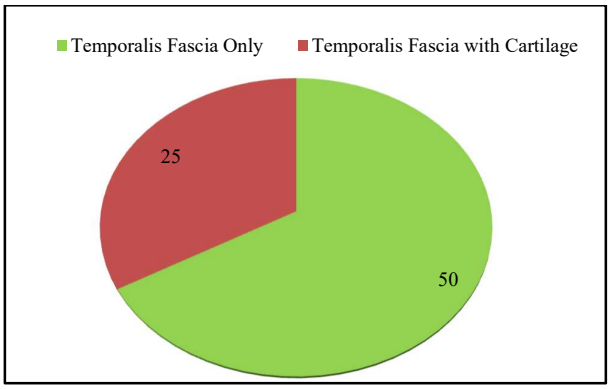

Figure 1: Distribution of graft material.

In a total of 75 patients, temporalis fascia was used as graft material in 50 patients (66.7%) and Conchal cartilage with fascia was used as graft in 25 patients (33.3%) (Figure 1).

Table 1: Surgical Approach

			Surgical approach		Total
			Endaural	Retroauricular	
Type of Perforation	Small	No	12	17	29
		%	41.4%	58.6%	100.0%
	Medium	No	2	24	26
		%	7.7%	92.3%	100.0%

	Sub-total	No	0	4	4
		%	.0%	100.0%	100.0%
Total		No	14	61	75
		%	18.7%	81.3%	100.0%

Retroauricular approach was used in 24 cases (92.3%) with medium perforation of the tympanic membrane, which was the most. Endaural approach for surgery was used in 12 patients (41.4%) with small perforations of the tympanic membrane, which was the most (Table 2).

Table-2: Type of perforation.

	Frequency	Percent
Small	29	38.7
Medium	26	34.7
Large	16	21.3
Sub-total	4	5.3
Total	75	100.0

In a total of 75 cases, small perforation of the tympanic membrane was present in 29 individuals (38.7%) which was the highest. Subtotal perforation was present in 4 individuals (5.3%) which was the low (Table 3).

Table-3: Graft material

			Surgical approach		Total
			Endaural	Retroauricular	
Type of Perforation	Small	No	12	17	29

Total		No	14	61	75
		%	18.7%	81.3%	100.0%

Graft material used based on type of perforation- 29 Individuals had a small perforation of the tympanic membrane. Temporalis fascia was used in all 29 cases (100%). In cases with medium perforation, 19 cases (73.1%) had temporalis fascia as graft and 7 cases (26.9%) had fascia with cartilage as graft.

In cases with large perforations, 2 cases (12.5%) had temporalis fascia and 14 cases (87.5%) had fascia with cartilage as graft. All 4 individuals (100%) had cartilage with fascia as graft material in subtotal perforation.

Table-4: Graft material used based on surgical approach.

			Surgical approach		Total
			Endaural	Retroauricular	
Type of Perforation	Small	No	12	17	29
		%	41.4%	58.6%	100.0%
	Medium	No	2	24	26
		%	7.7%	92.3%	100.0%
	Large	No	0	16	16
		%	.0%	100.0%	100.0%
	Sub-total	No	0	4	4

		%	18.7%	81.3%	100.0%

Out of the total 75 cases, both endaural and retroauricular approach for surgery was used. Temporalis fascia was used in 50 cases (66.7%), out of which endaural approach and retroauricular approach was used in 14 cases and 36 cases respectively (Table 4).

Temporalis fascia with cartilage graft was used in 25 cases (33.3%) in which all cases were operated using retroauricular approach.

Table-5: Correlation between post-operative hearing and graft material.

Post-operative hearing (db) * Graft Material					
			Graft Material		Total
			Temporalis Fascia Only	Temporalis Fascia with Cartilage	
Post-operative hearing (db)	0-10	No	16	0	16
		%	100.0%	.0%	100.0%
	11-20	No	28	0	28
		%	100.0%	.0%	100.0%

		%	**66.7%**	**33.3%**	**100.0%**

Post-operative hearing when temporalis fascia was used as graft material was 11-20 dB in 28 individuals which was the highest and was lowest in 1 individual (7.1%) with post-operative hearing of 31-40 dB (Table 5).

In the group in which cartilage with fascia was used, highest individuals was 13 (92.9%), where the post-operative hearing was 31-40 dB. The post-operative hearing was 41-50 dB in 3 individuals which was the lowest.

Table 5: Hearing improvement based on graft material.

Post-operative hearing (db) * Graft Material					
			Graft Material		Total
			Temporalis Fascia Only	Temporalis Fascia with Cartilage	
Improvement (db)	0-5	No	4	5	9
		%	44.4%	55.6%	100.0%
	6-10	No	7	11	18
		%	38.9%	61.1%	100.0%

When temporalis fascia alone was used as graft, Post-operative hearing improvement was observed in 26 individuals (74.3%) with an improvement of 11-15 dB. In the group with fascia and cartilage graft, the highest individuals was 11 (61.1%) with an improvement of 6-10 dB (Table 6).

The most improvement in hearing when temporalis fascia is used, was observed in 2 cases (100%) with 21-25 dB of hearing improvement. 11-15 dB was the maximum improvement observed when fascia with cartilage was used in 9 cases (25.7%).

Table 7: Post-operative hearing improvement.

Improvement (dB)			
Graft Material	Mean	N	Std. Deviation
Temporalis Fascia Only	12.9800	50	4.20636
Temporalis Fascia with Cartilage	8.9600	25	3.24654
Total	**11.6400**	**75**	**4.33290**

Mean hearing improvement in Group A was 12.98 dB and in Group B, mean hearing improvement was 8.96 Db (Table 7).

Discussion

A total of 21,453 cases attended the ENT Outpatient department during the study period. Out of these, 75 cases with dry perforation of the tympanic membrane were chosen for the study. Patients were selected in random, excluding patients with active ear discharge, attico-antral disease, and complications of chronic otitis media. In the study population, disease afflicting the nose and throat were also ruled out.

Detailed evaluation of each case was done comprising of history taking, clinical examination, investigations. Pre-operative as well as hearing assessment after the patients underwent type-1 tympanoplasty was performed using underlay technique.

Tympanic membrane perforation: Tympanic membrane perforation was present in all 75 patients in the study. Ear discharge was not seen in any of the patients. Based on the quadrant of tympanic membrane involved, perforation was graded into small, medium, large and subtotal perforation. Perforation of the Pars Flaccida was ruled out in all 75 of the participants in this study [6-10].

In the present study of 75 participants, small perforation was seen in 29 cases (38.6%), medium perforation was present in 26 cases (34.6%), large perforation was present in 16 cases (21.3%) and subtotal perforation was present in 4 cases (5.3%).

In a study done by Kshitij Patil [1], maximum number of cases had subtotal perforation, i.e., 59 cases (49.17%), followed by large central perforation in 51 cases (42.5%), while 10 cases (8.33%) had total perforation.

Surgical approach: In the present study, both endaural and retroauricular approach were used for different patients. 61 patients (81.3%) underwent surgery through retroauricular approach and 14 patients (18.7%) underwent surgery by endaural approach.

In the study done by Ramagiri Vijay Kumar [11], in patients of group A 14 (70%) were operated by postaural route, 5 patients (25%) by permeatal route and 1 patient (5%) by endaural route. 13 patients (65%) of group B were operated using endaural route and 7 patients (35%) by using postaural route. All the patients of group C were taken by permeatal route. So permeatal route was used in 63.3% of all cases.

Graft Material: The study participants of the present study were divided into two groups based on usage of graft material namely temporalis fascia alone and temporalis fascia used along with conchal cartilage. In the present study, 50 individuals (60.66%) underwent type-1 tympanoplasty using temporalis fascia alone as graft material. 25 individuals (39.44%) underwent surgery by using temporalis fascia along with conchal cartilage.

The usage of graft material and size of perforation had a correlation in the present study [12]. Temporalis fascia was used to close small and medium sized perforations. Small perforations of the tympanic membrane was present in 29 cases (100%), temporalis fascia alone was used in all of those cases.

In patients with medium perforation of the tympanic membrane, out of a total 26 cases 19 individuals (73.1%) underwent closure of perforation using temporalis fascia alone and in 7 individuals (26.9%) temporalis fascia with conchal cartilage was used as graft material.

In a study done by Ramagiri Vijay Kumar [11] participants were split into 3 groups of 20 patients in each group. Grouping of patients were based on graft material used, i.e. temporalis fascia, tragal perichondrium and ear lobule fat graft into group A, B and C respectively

Pre-operative hearing: In a total study population of 75 individuals, the participants were divided into group A and group B based on usage of graft material to repair the tympanic membrane perforation. Patients in Group A underwent type-I tympanoplasty with temporalis fascia used as graft material, in Group B patients were operated with conchal cartilage and fascia used as graft.

The pre-operative hearing in dB was noted for all participants before surgery. The maximum number of participants i.e. 27 patients (36%) had a pre-operative hearing loss of 21-30 dB. The least number was 5 patients (6.66%), who had a pre-operative hearing loss of 51-60 dB.

In group A, the total number of participants were 50 individuals (66.7%) who underwent surgery using temporalis fascia as graft. In that group, the mean pre-operative hearing was 26.9 dB. In group B, where conchal cartilage with fascia was used as graft material, the mean pre-operative hearing was 42.7 dB.

In a study done by Kshitij Patil [1], the mean pre-operative hearing loss was found to be maximum for cases with total perforations which were 49.15±7.34 dB, followed by subtotal perforations of 35.38±10.10 dB and for large perforations it was 31.73±9.84 dB. The overall mean pre-operative hearing loss was 34.72±10.4 dB.

Post-operative hearing: In the present study, group A participants who underwent type-1 tympanoplasty using temporalis fascia as graft, the highest improvement in post-operative hearing was 21-25 dB observed in 2 patients. In the same group, the greatest number of participants with hearing improvement was 26 patients (74.3%), with a hearing improvement of 11-15 dB.

In group B conchal cartilage with fascia was used as graft material. Here, the highest improvement in post-operative hearing was observed in 9 patients (25.7%) with hearing improvement of 11-15 dB. The most number of participants with hearing improvement was 11 patients (61.1%) with a hearing improvement of 6-10 dB.

In a study done by Gaurav Batni [9], in which type-1 tympanoplasty was performed on 100 patients. The mean pre-operative air conduction was 38.47±11.25 dB. The mean post-operative air conduction was 23.92±13.80 dB. Mean air bone gap pre-operatively was 23.55±7.56 dB and post operatively was 11.60±7.70 dB.

In a study done by Sharan kumar Shetty [10], 50 cases ofchronic suppurative otitis media with tubotympanic disease were used as participants.

The mean pre-operative hearing loss was 42.50 dB and mean post-operative hearing was 20.41 dB. In a study done by Mallikarjun S. Tegnoor [13], 50 patients underwent type-1 tympanoplasty. The mean pre-operative hearing was 33.34 dB and mean post-operative hearing was 20.20 dB with a mean audiological improvement of around 13 dB. The best mean hearing gain was 14.64 dB in age group of 24-34 years, while lesser gains are noted in 38-50 years age group.

Conclusion

1. Small perforation of the tympanic membrane is more common (38.6%)
2. Small and medium perforations can be repaired better using temporalis fascia alone than conchal cartilage with fascia
3. Post-operative Hearing improvement is comparatively better when temporalis fascia is used alone (14.0 dB)
4. Conchal cartilage is better in repair of large and subtotal perforations but hearing improvement post-operatively is comparatively less (33.7 dB)

Thus, from this study it can be concluded that repair of tympanic membrane perforations should be decided on size of perforation and appropriate grafting material. Small and medium perforations are best repaired using temporalis fascia alone which gives the best hearing improvement and large, subtotal perforations can be repaired using conchal cartilage and fascia but hearing improvement would be comparatively low.

What the study adds to the existing knowledge?

This study adds knowledge of graft-based hearing improvement apart from graft takeup and healing.

Inverse Association between Serum Bilirubin Levels and Retinopathy in Patients with Type 2 Diabetes Mellitus.

DIVYA KARUPPANNASAMY[1], RAGHURAM VENKATESAN[2], LEKHA THANKAPPAN[3], RAGHURAM ANDAVAR[4], SUNDAR DEVISUNDARAM[5]

ABSTRACT

Introduction: Oxidative stress plays a central role in the pathogenesis of Diabetic Retinopathy (DR) and serum bilirubin has been shown to have antioxidant properties.

Aim: To investigate the association between serum bilirubin concentration and DR in patients with Type 2 diabetes Mellitus (DM).

Materials and Methods: This was a hospital based, cross-sectional study where in 86 patients with Type 2 DM and 30 controls were recruited. The study was conducted at a tertiary care centre in South India between January 2014 and December 2014. The presence and the severity of DR were determined by fundus examination and grading of colour fundus photographs using the international clinical disease severity scale for diabetic retinopathy. Serum total, direct and indirect bilirubin levels were determined in all subjects and the association between bilirubin levels and severity of DR was studied.

Results: Among the 86 diabetics, 24 had no retinopathy and 62 had diabetic retinopathy of varying grades. The mean total bilirubin level among diabetic subjects (0.52±0.17) and controls (0.51±0.19) were found to be similar. The mean total as well as direct bilirubin levels were found to be lower in patients with retinopathy as compared to no retinopathy group ($p \leq 0.001$). The severity of DR was inversely proportional to the serum bilirubin levels ($p=0.010$). Serum total bilirubin was found to have a negative association with glycosylated haemoglobin and served as an independent determinant of diabetic retinopathy even after adjusting for risk factors known to be associated with DR ($p=0.001$).

Conclusion: Low serum bilirubin levels are significantly associated with increased risk of diabetic retinopathy independent of classic risk factors. Serum bilirubin can serve as a useful biomarker in identifying patients at risk for developing proliferative diabetic retinopathy.

INTRODUCTION

Diabetes Mellitus (DM) has assumed the proportions of a global epidemic and the number of diabetics in the world today is 415 million. This number is being projected to increase to 642 million by 2040 [1]. India leads the world in terms of its diabetic population and estimates have revealed that there are 62.4 million people with diabetes, and 77.2 million with prediabetes in India [2]. It is predicted that by 2030, DM may affect up to 79.4 million in India [3]. Due to these sheer numbers, the socioeconomic burden as a result of diabetes in India is among the highest in the world [4].

Along with this rapidly increasing disease, there is an increase in the associated microvascular complication DR, which is said to affect more than 93 million people worldwide [5]. Almost all patients with Type 1 DM and over 60% of the patients with Type 2 DM will develop DR in 20 years. DR is the most frequent cause of preventable blindness in middle aged population and therefore,represents a major public health issue [6].

Oxidative stress is considered to be one of the key factors in the pathogenesis of DR [7]. The retina is especially more susceptible to oxidative damage because of its high energy demands and exposure to light [8]. Various mechanisms contributing to the pathogenesis of DR such as inflammation, polyol pathway, accumulation of Advanced Glycation End Products (AGEs), flux of hexosamine Pathway and Protein Kinase C (PKC) activation are associated with overproduction of Reactive Oxygen Species (ROS) by the mitochondria [9].

Although, bilirubin has long been considered as a toxic waste product of heme catabolism, its role as a potential endogenous anti-oxidant under physiological conditions is being increasingly recognized [10]. Apart from its ability to scavenge over produced ROS, bilirubin is also said to have anti inflammatory effects [11]. Based on these physiological effects of bilirubin, several population-based studies have reported a negative association between serum bilirubin concentrations and the risk of diabetes [12], coronary artery disease [13], chronic kidney disease [14], peripheral arterial disease [15] and diabetic peripheral neuropathy [16].

Few studies in literature have shown, the association between serum bilirubin and DR [17-20]. Apart from age, gender, smoking and intake of drugs serum bilirubin concentrations are also affected by factors such as altitude and ethnicity and these are likely to influence the biological effects of bilirubin on human body.

Considering the potential role of oxidative stress in the pathogenesis of DR and the antioxidant and cytoprotective effects of bilirubin, this cross-sectional study aimed to evaluate the association between serum bilirubin and severity of retinopathy in patients with Type 2 DM from South India.

MATERIALS AND METHODS

This was a hospital-based cross-sectional study which included patients with Type 2 DM who were referred to the Ophthalmology Department of a tertiary care centre in South India between January 2014 and December 2014 for screening of DR. Exclusion criteria included history of chronic alcohol intake, smoking, intake of hepatotoxic medications within past six months, preexisting hepatobiliary abnormalities or chronic liver disease. Patients with preexisting ocular diseases like glaucoma, high myopia, previous ocular surgery or photocoagulation were excluded from the study. Patients with hypertension (>160/90 mmHg), anaemia or other systemic diseases like nephropathy which can accelerate the progression of DR were also excluded from the study. The study protocol was approved by the Institutional Ethics Committee and this study was conducted according to the principles of the Declaration of Helsinki. Informed consent was obtained from all participants.

Information on age, gender, duration of diabetes, blood pressure and body mass index was obtained from all participants.

All participants underwent a complete ocular examination including fundus examination with slit lamp biomicroscope using a 90 diopter lens after dilatation of pupils using 1% tropicamide eyedrops. This was followed by 30 degree colour stereoscopic fundus photography of 7 standard Early Treatment Diabetic Retinopathy Study (ETDRS) fields using a digital fundus camera (TRC-50 DX Mydriatic retinal camera; Topcon Medical Systems, Oakland, NJ).The severity of DR was determined by grading of colour fundus photographs following the international clinical disease severity scale for diabetic retinopathy which is based upon the findings of WESDR (Wisconsin Epidemiological Study of Diabetic Retinopathy) and ETDRS [21].

The diabetic patients were assigned to one of the following groups based on presence and severity of retinopathy.

1. Diabetic patients with no retinopathy.
2. Mild Non-Proliferative Diabetic Retinopathy (NPDR)
3. Moderate NPDR.
4. Severe NPDR and
5. Proliferative Diabetic Retinopathy (PDR)

The eye with worse retinopathy was chosen for inclusion in the study examinations. If both eyes had equal retinopathy, the right eye was assigned to the study.

Fasting venous blood samples were collected for the determination of serum total, direct and indirect bilirubin, blood glucose and Glycosylated Haemoglobin (HbA1c). The normal range of total serum bilirubin levels used in the study was 0.2 to 1.2 mg/dl.

STATISTICAL ANALYSIS

Statistical analysis was performed using SPSS version 19. The baseline characteristics of patients were presented as mean±standard deviation and n (%). Data on the patient's clinical characteristics were compared using One-way Analysis of Variance (ANOVA) as well as an independent sample Student's t-test. The serum bilirubin levels were divided into quartiles and Chi-square test was used to see the comparison between the proportions. Multiple logistic regression analysis was performed to assess independent associations between the presence of key risk factors of DR including the statistically significant factors in univariate analysis. All tests for statistical significance were two-tailed, and performed assuming a Type I error probability of <0.05.

RESULTS

A total of 116 subjects were included in the study out of whom 86 were patients with Type 2 diabetes and 30 were controls.

The mean total bilirubin level among diabetic subjects (0.52±0.17) and controls (0.51±0.19) were found to be similar. The direct bilirubin level was found to be higher in diabetics (0.29±0.13) as compared to controls (0.18±0.06, p=0.000). The indirect bilirubin level was lower in diabetics (0.23±0.07) as compared to healthy controls (0.33±0.13, p=0.000).

[Table/Fig-1] shows the clinical characteristics of the study population.

The mean duration of diabetes and HbA1c were significantly higher among patients with DR compared to those without retinopathy (p<0.001). We compared the serum total, direct and indirect bilirubin levels for diabetics without retinopathy (n=24) and those with DR (n=62). The total bilirubin was 0.65±0.16 in patients with no retinopathy and 0.47±0.16 in patients with DR. The mean total as well as direct bilirubin levels were found to be lower in patients with retinopathy as compared to no retinopathy group (p=0.000). There was no statistically significant difference in the levels of indirect bilirubin among both groups (p=0.100).

Characteristic	Controls (n=30)	Diabetics with no retinopathy (n=24)	Diabetics with retinopathy (n=62)
Age (yr)	52.97±8.95	57.63±10.54	57.29±8.5
Females, no. (%)	18 (60%)	9 (37.5%)	23 (37.1%)

[Table/Fig-4]: Scatter diagram showing negative association between serum total bilirubin and HbA1c (glycosylated haemoglobin) in diabetics.
TOT BR-Total bilirubin; HBA1C-glycosylated haemoglobin

Of the 62 diabetic patients with retinopathy, 15 patients had mild NPDR, 22 had moderate NPDR and 9 had severe NPDR. PDR was noted in 16 patients. We divided the study participants into quartiles on the basis of serum total bilirubin concentration (quartile 1=<0.40 mg/dl, quartile 2= 0.41-0.50 mg/dl, quartile 3= 0.51-0.60 mg/dl, quartile 4=>0.61 mg/dl).

[Table/Fig-2] shows the correlation between serum total bilirubin and severity of DR.

The percentage of DR in persons with lowest bilirubin quartile was 36.04%, compared with the percentage of 19.8%, 8.1% and 8.1% respectively in the second, third and fourth quartiles. Thus, the proportion of patients with DR was significantly higher in quartile 1 with lower levels of bilirubin as compared to the other three quartiles [Table/Fig-2]. The severity of DR was inversely proportional to the serum bilirubin levels (p=0.010) and none of the patients in the last quartile (>0.61) had proliferative retinopathy.

On multiple logistic regression analysis the duration of diabetes, HbA1c and total serum bilirubin were found to be independently associated with DR [Table/Fig-3]

Also, serum total bilirubin in diabetic subjects was found to have negative association with HbA1c [Table/Fig-4].

DISCUSSION

In the present, study serum bilirubin concentration correlated negatively with the severity of retinopathy in patients with Type 2 DM. Multiple regression analysis also revealed serum total bilirubin as an independent risk factor associated with diabetic retinopathy.

Bilirubin is generated when the enzyme Heme Oxygenase (HO) catalyzes the degradation of heme. This leads to the formation of biliverdin which is converted to bilirubin by biliverdin reductase. In the hepatocytes, unconjugated (lipid-soluble) bilirubin is conjugated by uridine diphosphate glucuronyl transferase (UDP-GT) to a water soluble form for excretion. Total bilirubin is the sum of unconjugated (indirect) and conjugated (direct) bilirubin and generally ranges from 0.2 to 1.2 mg/dl in healthy individuals.

Ever since the description of beneficial role of bilirubin as a physiologic antioxidant, several clinical studies evaluating, the possible associations between serum bilirubin and the risk of diabetes (and its complications) have been published [22-24].

In this observational study, we noted that Type 2 diabetics with retinopathy had significantly lower serum bilirubin concentrations than those without retinopathy. Our observations are in line with epidemiologic and hospital based studies elsewhere which have suggested an inverse relation between serum total bilirubin and DR [17-20]. There has been only one study on the association between serum bilirubin and DR from Indian population by Dave et al., [25]. They noted higher levels of total, direct and indirect bilirubin in patients without DR as compared to patients with retinopathy. However, in our study only total and direct bilirubin concentrations were found to be higher in patients without DR. Serum indirect bilirubin concentration was similar in both groups. Most studies on serum bilirubin and DR have focused on only total bilirubin without separating bilirubin types. Limited studies have shown a differentially protective effect of direct bilirubin on metabolic syndrome [26] and chronic kidney disease [27]. Further studies on the relation between bilirubin subtypes and DR are clearly needed.

In this study, we divided bilirubin levels into quartiles (<0.40, 0.41-0.50, 0.51-0.60 and >0.61 mg/dl and considered the lowest quartile as reference. This approach was to maintain adequate numbers within each quartile. The absolute values of serum bilirubin were low in our study compared to studies by Yasuda et al., and Najam et al., where the value of serum bilirubin in the lowest and highest quartile observed were<0.60 and >0.90 mg/dl respectively [17,18]. There are several potential reasons for the observed findings. Apart from differences in ethnicity, our hospital based study population was very much different from the above said epidemiologic studies in age distribution, anthropometry, comorbidities such as hypertension, cardiovascular disease and smoking habits, all factors that may affect the bilirubin levels and potentially the association between bilirubin and DR. Our study participants were non smokers and had no history of major systemic diseases.

Several potential mechanisms have been proposed for the observed relationship between serum bilirubin concentration and DR. Excessive production of free radicals and resultant oxidative stress has been said to contribute significantly to worsening of DR [28,29]. Bilirubin has been postulated as a potent antioxidant and cytoprotective agent that can protect cells from a 10,000 fold excess of hydrogen peroxide [30]. Therefore, lower serum bilirubin concentration would be expected to be associated with increased oxidative stress and thereby, accelerated progression of DR. Additionally clinical studies have demonstrated elevated levels of inflammatory markers like C-reactive protein and vascular cell adhesion molecules in patients with DR suggesting that inflammation is a critical factor leading to endothelial dysfunction in diabetic retinopathy [31,32]. Bilirubin has been proven to have anti-inflammatory properties and in-vitro studies have shown that bilirubin inhibited tumour necrosis factor α –induced upregulation of vascular cell adhesion molecules [33]. Hence, it could be hypothesized that higher serum bilirubin concentration is associated with a lower risk of development and progression of DR through its anti-inflammatory effects. Further, recent animal studies have shown that, increasing serum bilirubin levels either through endogenous synthesis or exogenous administration improves endothelial dysfunction in diabetes by activation of protein kinase B [34].

Considering these physiologic effects of bilirubin it can be postulated that bilirubin can effectively retard or interrupt the pathways to development of DR and therefore serve as a potential biomarker for risk of diabetic retinopathy.

We observed an inverse and graded association between serum total bilirubin and severity of DR in this study and the strength of serum total bilirubin concentration as an independent determinant of DR was similar to those of conventional risk factors such as HbA1c and duration of diabetes in multiple regression analysis. Serum total bilirubin concentration was an independent determinant of DR even after adjustment for other risk factors (p=0.001).

We also observed a negative association between serum total bilirubin and HbA1c among diabetic subjects. Our data are consistent with observations of Choi et al., who have also noted a significant inverse association between serum total bilirubin and HbA1c in their study on 690 Korean patients with Type 2 DM [35].

This can be partly explained by the fact that, increased serum bilirubin reduces the oxidative stress and thereby, inhibits the glycosylation of haemoglobin. Also, upregulation of the heme oxygenase system and increased generation of bilirubin/biliverdin have been proven to enhance insulin production and sensitivity in diabetic rats [36]. Therefore, it can be suggested that bilirubin improves glycaemic control through its effects on insulin. Further studies are needed to precisely elucidate the mechanism behind this association.

The strength of our study is based on the fact that our study participants were non-smokers and did not have other systemic diseases. We excluded these patients to focus on the association between serum bilirubin and retinopathy in patients with Type 2 diabetes.

LIMITATION

Our study has some limitations. First, our sample size was limited and the cross-sectional design of our study prevents determination of a temporal association or the cause-effect relationship between serum total bilirubin and the development of retinopathy. Only prospective studies can reveal whether serum bilirubin predicts the development of DR. Second, we performed only a single measurement of serum bilirubin which might have within subject variation. However, all subjects including controls were examined after overnight fast.

CONCLUSION

In conclusion, our cross-sectional study suggested that low total serum bilirubin level was independently associated with higher risk of DR in patients with type 2 diabetes, regardless of other conventional risk factors. Further, prospective studies on large samples are required to better assess the effects of bilirubin on diabetic retinopathy.

Brief Communication

Needs Assessment of Ophthalmology Education for Undergraduate Medical Students – A Study from a Medical College in South India

Karuppannasamy Divya[1], Kannappan Suvetha[2], Alo Sen[1], Devisundaram Sundar[1]

Departments of [1]Ophthalmology and [2]Community Medicine, PSG Institute of Medical Sciences and Research, Coimbatore, Tamil Nadu, India

ABSTRACT

Background: Adequate ophthalmic diagnostic and clinical skills are essential for practitioners in primary care settings as well as specialty care physicians. The objectives of this study were to assess the adequacy of ophthalmology teaching in undergraduate medical education and to evaluate the comfort of medical students in diagnosing common eye problems and performing ophthalmic skills. **Methods:** A questionnaire based, cross-sectional survey was conducted among third-year undergraduate students from a medical college in South India at the end of ophthalmology training from February 2014 to December 2014. The main outcome measures were hours of classroom-based instruction and clinical exposure to ophthalmology received by the students and their comfort level in diagnosing common eye problems and performing ophthalmic skills. **Results:** 134 students participated in the study. They had received an average of 96.2 ± 5.9 and 112.5 ± 11.3 hours of classroom and clinic-based instruction, respectively. The participants' comfort in diagnosing eye problems was satisfactory for cataract and eyelid disorders but not for ophthalmic emergencies. Only 45.5% had satisfactory knowledge in community ophthalmology. Respondents were more proficient in visual acuity testing (93.3%) and assessment of pupillary reaction (80.6%) than direct ophthalmoscopy (41%). **Discussion:** Undergraduate medical students from India received a greater amount of ophthalmology instruction compared to the International Council of Ophthalmology task force recommendations. Gaps in community ophthalmology and knowledge-skills discrepancies were noted. Review of curriculum, appropriate training resources, and effective teaching methods tailored towards primary care may be useful to improve the training.

Keywords: Comfort, knowledge, ophthalmology, undergraduate medical education

Background

Ophthalmology makes up a significant proportion of primary care consultations.[1] A basic knowledge of ophthalmology is essential in the management of several neurologic, endocrine, rheumatic, and infectious conditions. Despite the relevance of ophthalmology to medical practice, little time is allocated to teaching of ophthalmology in undergraduate medical education and the majority of primary care physicians do not feel that they have received adequate undergraduate ophthalmic education.[2] Also several studies have noted that medical students receive too little ophthalmic training.[3-5]

In India, the five and one-half year undergraduate medical training consists of four and one-half years of teaching of subjects comprising the medical curriculum and one year of internship. Ophthalmology is being taught in the third year after preclinical and paraclinical subjects.

The state of undergraduate ophthalmology training from medical colleges in India has not been studied so far. Evaluation

of ophthalmic knowledge and skills of undergraduates at the end of ophthalmology training would help in generating critical feedback on undergraduate ophthalmic curriculum planning. The objectives of this study were:

1. To assess the adequacy of ophthalmology teaching in undergraduate medical education
2. To assess the comfort level of medical students in diagnosing and treating common eye problems and performing ophthalmic skills.

Methods

After approval from the institutional review board, undergraduate medical students from a medical college in South India were included in the study at the end of their ophthalmology training (February 2014 to December 2014). The adequacy of ophthalmology education was quantified by determining the hours of classroom-based instruction and clinical exposure to ophthalmology received by the students and comparing these with the recommendations of the Medical Council of India (MCI) as well as the International Council of Ophthalmology (ICO).

A validated questionnaire [Appendix 1] was given to the students and their responses collected anonymously. The questionnaire consisted of three parts. Parts 1 and 3 assessed the students' comfort with respect to diagnosing specific ophthalmology conditions and performing ophthalmology-related skills on a Likert scale from 1 to 5 (1 = not at all comfortable, 2 = somewhat comfortable, 3 = moderately comfortable, 4 = comfortable, and 5 = very comfortable). In terms of comfort level, we examined the ease with which study participants reported they were able to diagnose common eye problems and perform ophthalmic skills.

The second part assessed knowledge on certain topics on a Likert scale, also from 1 to 5 (1 = very poor, 2 = poor, 3 = average, 4 = good, and 5 = very good). The conditions and skills covered in the questionnaire were based on the topics covered in the undergraduate ophthalmology curriculum recommended by the MCI.[6]

Participants were also asked about the number of hours spent in self-directed learning and how comfortable they felt in managing ophthalmology-associated issues overall.

Likert scale-based responses were subsequently dichotomized and reduced to proportions by categorizing scores 1–2 as unsatisfactory or inadequate and 3–5 as satisfactory or adequate. Data were entered using the Statistical Package for the Social Sciences (version 19 (SPSS, Inc., Chicago, IL, USA) and examined using descriptive and analytical statistics to yield frequencies, percentages, and proportions.

Results

Of the 150 undergraduate medical students, 134 responded to the questionnaire (response rate = 89.6%).

The main modes of ophthalmology exposure were didactic lectures (35 hours), tutorials (37.5 ± 3.8 hours), seminars (23.7 ± 2.2 hours), and clinic-based learning. Our study participants had received an average of 96.2 ± 5.9 hours of classroom-based instruction. They also had received 112.5 ± 11.3 hours of clinic-based instruction in the eight weeks of clinical posting. 121 participants (90.3%) had spent up to 10 hours in self-directed learning while 13 participants (9.7%) had spent more than 10 hours in self-directed learning.

The results of the participants' comfort in diagnosing ophthalmic conditions are presented in Figure 1. Figure 2 shows the students' adequacy of knowledge in community and systemic ophthalmology as well as indications for ophthalmic referral. Figure 3 shows the study participants' comfort in performing MCI recommended clinical skills. Tables 1-3 show the numerical data for the corresponding figures. Finally, 101 participants (75.4%) felt comfortable in managing ophthalmology associated issues overall.

Discussion

This cross-sectional observational study attempted to quantify the adequacy of undergraduate ophthalmic education and students' comfort with regard to the management of ocular conditions.

In comparison with MCI recommendations, our study participants received a satisfactory number of hours of both classroom and clinic-based instruction. The MCI recommends clinical training of 8 weeks and a total of 100 teaching hours in ophthalmology, which includes 30 h of didactic lectures,

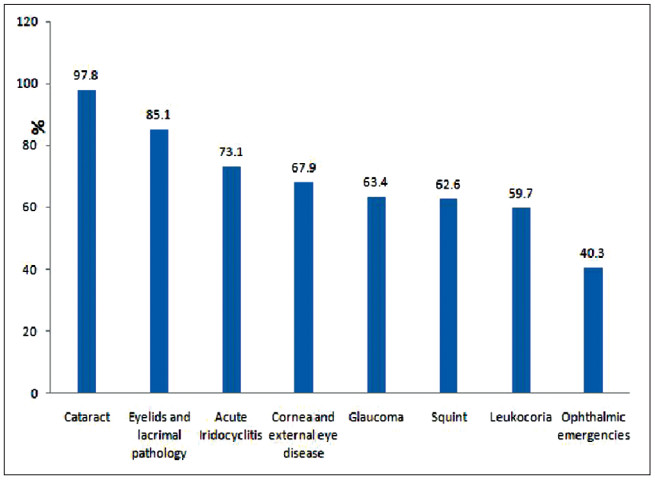

Figure 1: Medical students' comfort in diagnosing common ophthalmic conditions

[Downloaded free from http://www.educationforhealth.net on Sunday, April 22, 2018, IP: 192.168.10.239]

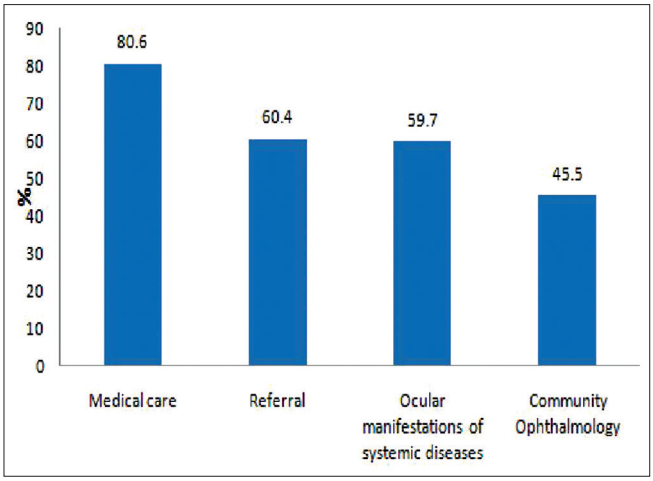

Figure 2: Students' adequacy of ophthalmic knowledge

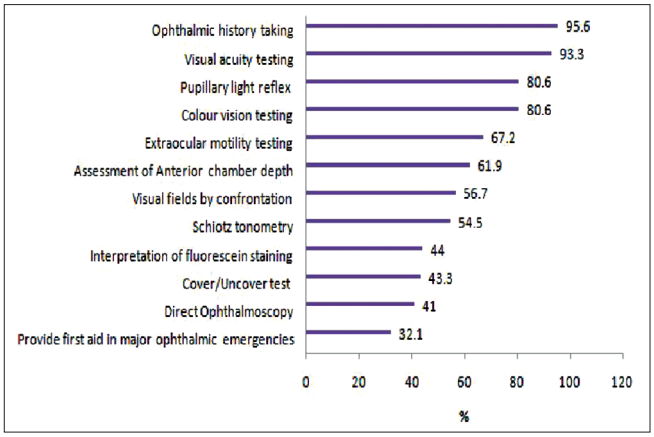

Figure 3: Students' self-reported proficiency in performance of ophthalmic skills

Table 1: Students' comfort in diagnosing common ophthalmic conditions

Ophthalmic conditions	Participants with adequate comfort in diagnosing common ophthalmic conditions (n=134), n (%)
Cataract	131 (97.8)
Eyelids and lacrimal pathology	114 (85.1)
Acute iridocyclitis	98 (73.1)
Cornea and external eye disease	91 (67.9)
Glaucoma	85 (63.4)
Squint	84 (62.6)
Leukocoria	80 (59.7)
Ophthalmic emergencies	54 (40.3)

60 h of tutorials and seminars (including integrated learning), and 10 h of self-directed learning.[7] These guidelines suggest a greater amount of ophthalmology exposure in undergraduate medical education in India when compared with ICO guidelines. The ICO recommends 40–60 h of ophthalmology exposure during undergraduate training.[8]

According to the curriculum recommended by the MCI, the goal of teaching ophthalmology to undergraduate medical students is to provide such knowledge and skills to the students that shall enable them to practice as a clinical and primary eye care physician.[6] The curriculum provides a list of competencies which need to be demonstrated by the student at the end of ophthalmology training. These include knowledge of common eye problems in the community; ability to manage common eye problems and identify indications for referral; recognize visual impairment and blindness in the community; and implement the National programme as applicable in the primary care setting.[7]

Most of the participants in the study reported a satisfactory level of comfort in diagnosing common ophthalmic problems. The fact that 97.8% reported a satisfactory level of comfort in diagnosing cataract is encouraging since cataract is the leading cause of preventable blindness in the developing world. Yet, despite this satisfactory level of comfort in managing common eye problems, most study participants' comfort in diagnosing ophthalmic emergencies such as endophthalmitis, rupture globe, and chemical injuries was found to be inadequate.

Nearly 60% reported to have adequate knowledge in ocular manifestations of systemic diseases. This could be because of better teaching resources as well as integration of ophthalmology topics into other subjects of the medical curriculum horizontally and longitudinally. The self-rated knowledge of more than one-half of the study participants was found to be unsatisfactory in community ophthalmology. With greater emphasis placed on teaching disorders of the eye, in theory lectures as well as in hospital settings, community ophthalmology is often neglected. A study on the status of ophthalmic medical education in the South-East Asia Region of World Health Organization has also highlighted this concern, where students have little exposure to community ophthalmology.[9]

The knowledge of most study participants on the indications of medical treatment and referral to eye clinics was adequate. With a significant shortage of ophthalmologists in developing countries, an adequate level of comfort of primary care physicians in providing medical care and accuracy in referral is essential. A high rate of referral places pressure on the limited resources of ophthalmic casualty departments and outpatient clinics.

More than 80% reported competency in ophthalmic history taking, visual acuity and color vision testing, and pupil examination. These are relevant not only in ophthalmology but also in general medicine, neurology, and trauma care. However, only 44% reported an adequate level of comfort in interpretation of fluorescein staining and 54.5% in Schiotz tonometry. This is an area of concern because corneal blindness

Cover/uncover test	58 (43.3)
Direct ophthalmoscopy	55 (41)
First aid in major ophthalmic emergencies	43 (32.1)

and glaucoma contribute to a major extent to the burden of blindness in India; adequate proficiency of the primary care physician in these skills will help in early diagnosis and treatment or referral, thereby reducing the risk of visual loss.

Only 41% of respondents indicated that they had adequate proficiency in performing direct ophthalmoscopy which is consistent with studies elsewhere.[2,10] This could be because of the limited time devoted to teaching ophthalmoscopy in the medical school curriculum as well as the technical challenges involved.

Although most students were comfortable in managing ophthalmology associated issues overall, gaps were noted in certain key areas. Review of the curriculum with greater emphasis on community eye care and blindness control strategies, adequate training resources, and effective teaching methods tailored toward primary care would help to increase the medical students' comfort in managing common eye problems.

Since our observations are from a single center, generalization of results is limited. Subjective bias due to the candidates varying ability to accurately self-evaluate is also a limitation. The choice of the study population was medical students at the end of ophthalmology training rather than interns because of the possibility of recollection bias. A similar study on interns or junior medical officers would provide more insight into the knowledge and gaps in training.

In spite of these limitations, this needs assessment study is the first of its kind in India to assess the adequacy of ophthalmic teaching and the knowledge and clinical skills of undergraduate medical students. Ophthalmology in India is being taught as part of the essential undergraduate medical curriculum and not exclusively as an elective. Students receive adequate exposure to ophthalmology, and the undergraduate curricular hours are greater than the guidelines published by the ICO. Since ophthalmology related topics and examination skills are included in most of the standardized medical licensing examinations and internal medicine boards, medical graduates from India are at a distinct advantage.

Case Report

Periorbital and Mediastinal Emphysema after Upper Gastrointestinal Endoscopy: Case Report of a Rare Complication

Thankappan Lekha[1], FRCS; Leelakrishnan Venkatakrishnan[2], DM; Karuppannasamy Divya[1], MS Perumal Lavanya[1], MBBS

[1]Department of Ophthalmology, PSG Institute of Medical Sciences and Research, Coimbatore, Tamilnadu, India
[2]Department of Gastroenterology, PSG Institute of Medical Sciences and Research, Coimbatore, Tamilnadu, India

Abstract

Purpose: To report a rare case of periorbital emphysema concurrent with cervicofacial and mediastinal emphysema in an elderly woman who underwent upper gastrointestinal endoscopy for chronic liver disease.
Case Report: An elderly woman with decompensated chronic liver disease presented with features of periorbital, facial, and mediastinal emphysema, characterized with crepitant swelling over the right periorbital area, face, neck, and mediastinum after undergoing upper gastrointestinal endoscopy. There was no history of trauma or Valsalva maneuver. Ocular findings were stable with no evidence of orbital compartmental syndrome. Urgent computed tomography scans of the orbit and chest were performed, and emergency systemic treatment with nasogastric decompression and antibiotics was initiated. However, she suddenly collapsed and succumbed despite all resuscitative efforts.
Conclusion: Our case demonstrates that periorbital emphysema can occur following procedures such as upper gastrointestinal endoscopy, in the eyes without history of local trauma. This complication should be suspected especially if there is associated cervicofacial and mediastinal emphysema. Subcutaneous emphysema is usually self-resolving; however, extension of air into deeper planes can cause dangerous complications such as blindness due to orbital emphysema or mortality due to mediastinal emphysema. Hence, prompt diagnosis and urgent intervention are crucial to avoid vision and life threatening complications.

Keywords: Mediastinal Emphysema; Periorbital Emphysema; Upper Gastrointestinal Endoscopy

J Ophthalmic Vis Res 2017; 12 (3): 345-347

INTRODUCTION

Periorbital emphysema or abnormal presence of air within the soft tissues of the orbit most commonly results from orbital fracture with a paranasal sinus communication.[1,2] It presents as a transient, crepitant swelling of the lids and periorbital areas. Rarely, trapped intraorbital air can lead to compressive orbital emphysema, which can threaten vision due to central retinal artery occlusion or ischemic optic neuropathy. Mediastinal emphysema is the presence of extra-alveolar air in the mediastinum and can be spontaneous or due to severe thoraco-abdominal injury.[3] The patient may be asymptomatic or develop

chest pain, cough, vomiting, and even cardiopulmonary distress, which can be fatal. Prompt diagnosis using Computed Tomography (CT) and urgent intervention of these conditions by decompression is paramount to prevent blindness due to orbital emphysema or fatality due to mediastinal emphysema. We describe a case of an elderly woman who developed simultaneous periorbital and mediastinal emphysema following upper gastrointestinal endoscopy with a fatal outcome. To the best of our knowledge, this is the first report of such a rare complication.

CASE REPORT

Our patient was a 74-year-old woman, who underwent treatment in the gastroenterology department of our hospital for decompensated chronic liver disease, cirrhosis of liver with portal hypertension, volume overload status, and dysphagia. An ophthalmology consultation was arranged when she complained of swelling of the right upper and lower eyelids following a routine upper gastrointestinal endoscopy. It was not associated with defective vision, diplopia, pain, or redness. She also complained of hoarseness of voice without breathing difficulties. There was no history of trauma, forceful nose blowing, or Valsalva maneuver. Past medical history revealed cataract surgery in both eyes four years ago.

On examination, she was conscious, oriented, and afebrile with no respiratory distress. She was obese with ascites, pedal edema, and puffiness of face. There was swelling of the right upper and lower lids and periorbital area with mechanical ptosis. Palpation revealed crepitus suggestive of emphysema. Generalized swelling and crepitus were also noted over the face, neck, and front of the chest [Figures 1 and 2]. On ocular examination, vision was 6/9, N.6 in both eyes. Pupils were briskly reacting, and the extraocular movements were full. There was no proptosis, conjunctival congestion, chemosis, or discharge. Both eyes were pseudophakic with normal intraocular pressure and fundus. As there was no pressure effect on the globe, she was treated conservatively with antibiotics and decongestants. She was advised to avoid nose blowing or straining and to inform immediately if any visual change is noticed. Nevertheless, considering the features of periorbital and mediastinal emphysema, she was advised to undergo emergency CT scan of the orbit and chest, and immediate gastric aspiration and antibiotic therapy were initiated by the physician. However, the patient developed sudden seizures followed by collapse, and, could not be revived despite aggressive resuscitative efforts.

Figure 1. External photograph of the face showing corrugated appearance of the right upper eyelid due to the presence of subcutaneous air, suggesting emphysema.

DISCUSSION

Subcutaneous emphysema in the head and neck region occurs when air is introduced into the fascial planes of the connective tissue through a site of trauma.[4,5] The trapped air may sometimes extend deep along the facial planes of the neck causing para- and retropharyngeal emphysema with possible extension into the thorax and mediastinum. This complication, although rare, can be life threatening due to close proximity to vital structures in the neck and mediastinum. Orbital and cervicofacial emphysema extending into the mediastinum have been reported following orofacial trauma including fractures, compressed air injuries, and dental procedures involving the use of high speed air-driven hand pieces.[3,5–7] Similarly pneumomediastinum, pneumoperitoneum, and subcutaneous emphysema are known complications following procedures such as upper endoscopy, endoscopic retrograde cholangiopancreatography (ERCP), and colonoscopy, and can occur with or without perforation.[8–10] Pathophysiology of these complications is explained by the anatomical connections between the deep neck fascia, mediastinum, and retroperitoneum, and continuous air insufflations during procedures such as ERCP. When a perforation occurs, free air flows from the duodenum to the retroperitoneal space

Figure 2. External photograph of the face and upper part of chest showing emphysema involving the right periorbital area, face, and neck.

[Downloaded free from http://www.jovr.org on Thursday, July 13, 2017, IP: 172.17.4.150]

and then extends to diaphragmatic hiatus causing pneumomediastinum, pneumothorax, and cervical subcutaneous emphysema.[8,11] In those cases without overt perforation, it is postulated that trauma to the duodenal wall by the endoscope causes the insufflated air under pressure to enter the mucosa and track along the perineural and perivascular sheaths to enter the mediastinum.[12] However, pneumomediastinum with associated orbital emphysema without any cervicofacial trauma is extremely rare. Aydin et al reported the case of a 63-year-old woman who developed bilateral periorbital emphysema associated with diffuse mediastinal and subcutaneous emphysema following ERCP.[11] The findings were confirmed using imaging, and she recovered following nasogastric decompression and antibiotic therapy.

We report a case of right-sided periorbital emphysema with cervicofacial and mediastinal emphysema following routine upper gastrointestinal endoscopy, which has not been reported so far. In our patient with chronic liver disease and volume overload status, lid swelling and facial puffiness could have been mistaken as passive edema due to the systemic comorbidities; however, the characteristic crepitus felt on palpation was pathognomonic of emphysema. It also ruled out any allergic causes and angioedema. Negative history of trauma or straining and lack of inflammation on ocular examination excluded local causes of orbital emphysema. A CT scan of the orbit and thorax would have been informative but was precluded by her sudden death. High index of suspicion and prompt and aggressive management is required to prevent vision threatening as well as life threatening sequelae in such scenarios. Ocular management includes close observation for pressure effect on the orbit manifested by increasing proptosis, intraocular pressure, or worsening of vision.[1] If any of these symptoms develop, emergency orbital decompression should be performed by lateral canthotomy/cantholysis, needle aspiration, or bony decompression depending on the severity. Similarly, those with pneumomediastinum should be evaluated for any aero-digestive tract injury and monitored for potential airway obstruction, air embolism, cardiovascular, or infectious processes.[5]

Identification of emphysema should prompt the search for associated injury, and ophthalmologists should be aware that periorbital emphysema can develop due to remote causes without direct or indirect periorbital trauma. Fatal outcome in our patient emphasizes the need for prompt recognition with urgent intervention to prevent disastrous consequences.

Declaration of patient consent

The authors certify that they have obtained all appropriate patient consent forms. In the form the patient(s) has/have given his/her/their consent for his/her/their images and other clinical information to be reported in the journal. The patients understand that their names and initials will not be published and due efforts will be made to conceal their identity, but anonymity cannot be guaranteed.

Clinicopathological Conference

An unusual cause of breathlessness and profuse micronodules

Srinivas Rajagopala, Roopa Kancherla, Nidhya Ganesan[1], Devanand Balalakshmoji[2], Divya Karuppannasamy[3], Ramanathan Palaniappan Ramanathan, Rajendiran Gopalan[4]

ABSTRACT

We describe a 21-year-old male with a history of smoking and subacute onset of breathlessness with normal cardiorespiratory examination. The presence of "track marks" and digital infarcts prompted evaluation for infective endocarditis and confrontational history taking revealed anorexia, weight loss over 3 months along with intravenous drug abuse of reconstituted tablets of tapentadol. Echocardiography was normal and blood cultures were sterile; computed tomography showed bilateral, diffuse, small centrilobular nodules with "tree-in-bud" appearance. In this clinicopathologic conference, we discuss the clinical and radiological differential diagnosis of centrilobular nodules, lung biopsy findings, and management options for patients with such a presentation.

KEY WORDS: Excipient lung disease, intravascular talcosis, pulmonary foreign body angiogranulomatosis, talc granulomatosis

Address for correspondence: Dr. Srinivas Rajagopala, Department of Pulmonary Medicine, PSG Institute of Medical Sciences and Research, Peelamedu, Coimbatore - 641 004, Tamil Nadu, India. E-mail: visitsrinivasan@gmail.com

PRESENTATION OF THE CASE

A 21-year-old college student presented with breathlessness and left-sided chest pain for a week. Breathlessness was insidious in onset and persisted on walking at own speed at level. Chest pain was left-sided, intermittent, pricking and non-exertional. There was no history of fever, rhinitis, headache, hemoptysis, cough, or joint pains. He did not raise pets but admitted to smoking 7–8 cigarettes/day and consuming whisky (192 g of alcohol weekly). He denied any recent worsening of educational performance. He did not report any significant prior medical illness or pertinent illness in family or occupational dust exposure. He was initially seen in cardiology and evaluation showed normal cardiac and respiratory examination without any pallor, clubbing, or organomegaly. Body mass index was 18.6 kg/m^2. The examination also showed extensive track marks over both arms with evidence of multiple peripheral digital infarcts [Figure 1], raising suspicion for infective endocarditis (IE). On confronting, he disclosed daily intravenous self-injections of three–four powdered and reconstituted 50 mg tablets of Tapentadol (Tydol, Sun Pharma) in sterile distilled water two–three times a day over the last 2 years. He also admitted to using inhaled cannabis twice weekly over the last 2 years. There was associated anorexia and unquantified weight loss over the last 3 months. Three sets of blood cultures were sterile. Electrocardiography showed T-wave inversions in leads V3–V6 and II, III, and aVF. Transthoracic echocardiography (TTE) showed normal valves without any evidence of vegetations or pulmonary hypertension and normal left ventricular function. Serum creatinine

Figure 1: Composite image of the clinical photographs (left) of the right forearm showing "track marks," indicating healed superficial septic thrombophlebitis and (right) both hands showing multiple bilateral distal digital pulp infarcts. Similar findings were also seen in both plantar surfaces (not shown)

was 0.6 mg/dL; urine microscopy was normal without any albuminuria. Hemoglobin was 14.2 g/dL with normal leukocyte and platelet counts. He remained afebrile. Transesophageal echocardiography (TEE) was planned; in the meanwhile, review of his chest radiographs showed diffusely scattered fine nodules bilaterally [Figure 2, left]. Spirometry showed mild restriction with reduced diffusion capacity for carbon monoxide (forced expiratory volumes at 1 s 2.25 L [65%]%, forced vital capacity 2.87 L [71%], DLco 62%). There was desaturation to 92% while walking 6 minutes, with preserved walk distance (545 meters, 89% predicted). Human immunodeficiency virus (HIV), anti-nuclear antibodies, hepatitis B, and hepatitis C antibodies were negative by enzyme-linked immunosorbent assay. Immunoglobulin E levels were 9 IU/mL (normal <100 IU/mL). High-resolution computed tomography (HRCT) of the thorax showed bilateral profuse evenly distributed micronodules with "tree-in-bud" [Figure 2, right]. There was no sputum production on induction with 3% saline. A procedure was planned for diagnosis.

DIFFERENTIAL DIAGNOSIS

Important features of this case

This HIV-negative young adult with significant smoking history, cannabis use, and intravenous drug abuse with reconstituted tablets over 2 years has breathlessness, anorexia, and weight loss with radiological findings of micronodules. There is evidence of distal embolic infarcts, but initial evaluation for endocarditis was negative. The reduced DLco, restriction on spirometry and unexpectedly low walk distance in a young individual with desaturation on walking implies extensive parenchymal and/or pulmonary vascular disease. The differential diagnosis of profuse bilateral micronodules is extensive [Table 1] but can be narrowed by careful history and analysis of HRCT findings in conjunction with the expected pulmonary complications of intravenous drug abuse [Table 2].[1] The first step is to characterize the

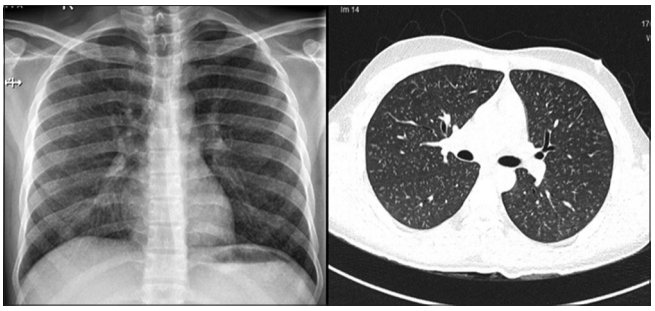

Figure 2: Composite image of the chest radiograph (left) showing small nodular opacities and high-resolution computed tomography of the thorax (right) showed bilateral profuse evenly distributed micronodules with tree-in-budding; pulmonary artery was normal in size, and there were no associated lymphadenopathy. Expiratory computed tomography did not show any air trapping (not shown)

distribution of the micronodules spatially within the lung and also the secondary pulmonary lobule. These nodules were uniform in size and were distributed evenly in a cephalocaudal direction, without any preferential lobar involvement. None of the nodules abut the pleural surface or the fissures [Figure 3]; there is clear evidence of extensive bilateral branching nodules in centrilobular distribution. There is no evidence of bronchiectasis; while no contrast was administered, in conjunction with echocardiography, there is no dilated pulmonary artery or lymphadenopathy. These findings limit the radiological differentials to causes of micronodules in a centrilobular distribution and extensive uniform "tree-in-bud" appearance. "Tree-in-bud" indicates the presence of dilated centrilobular bronchioles with lumen impacted by mucus, fluid, or pus and associated with peribronchiolar inflammation. "Tree-in-bud" indicates small airway disease and is associated with airway infection in the large majority but can also be rarely caused by arteriolar disease.[2] Its presence makes three common causes of centrilobular nodules unlikely: hypersensitivity pneumonitis, follicular bronchiolitis, and respiratory bronchiolitis.

Endobronchial tuberculosis

Mycobacterium tuberculosis is endemic in India, with more than 2.2 million new cases each year. Delayed recognition

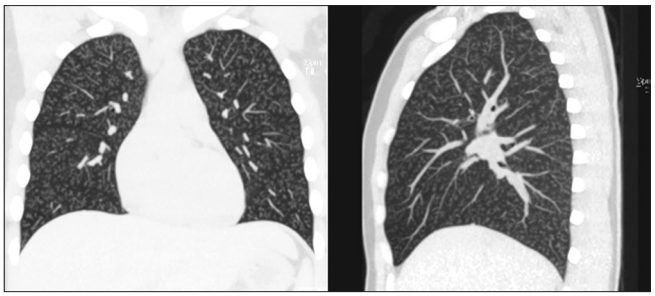

Figure 3: Coronal and sagittal reconstruction of the maximum intensity projection formatting of the high-resolution computed tomography images of the thorax showing diffuse, extensive, bilateral centrilobular nodules with branching and without any lobar predominance

and extensive disease are related to associated substance abuse, poverty, and malnutrition, all of which were present in this patient. Extensive endobronchial spread of tuberculosis can cause extensive tree-in-bud opacities although asymmetry is usually seen.[3] Tuberculosis is also the most common cause of micronodules with a random pattern (miliary). Even though the "pretest probability" of tuberculosis is high in this patient, the marked symmetry and the absence of any cavitation or consolidation is odd; digital infarcts are unusual but could be caused by an associated immune complex phenomenon that can occur with tuberculosis. *Mycobacterium avium*-intracellulare infection can also cause centrilobular nodules with "tree-in-bud," bronchiectasis, and consolidation. While it can be seen in immunocompetent patients, the classic phenotype is a middle-aged woman with slender build and without any constitutional symptoms.

Bronchopneumonia and viral bronchiolitis

Infectious bronchiolitis due to viruses, *Mycoplasma*, and chlamydia is a common cause of profuse and symmetric centrilobular nodules with "tree-in-bud;"[3] however, the prolonged illness and associated embolic phenomenon are unusual.

Allergic bronchopulmonary aspergillosis

Centrilobular nodules with "tree-in-bud" or miliary nodules can be caused by allergic bronchopulmonary aspergillosis but the absence of asthma, central bronchiectasis, and normal IgE levels rule out this diagnosis.[2,4]

Diffuse panbronchiolitis

Diffuse panbronchiolitis (DPB) is a rare disease of unknown cause presenting in males between the second and fifth decade with productive cough, diffuse bilateral centrilobular nodules with "tree-in-bud" and sinusitis. While reported in Indians,[5] it is extremely rare in our population but can explain all the clinical and radiological features.[6] Cold agglutinins are frequent in DPB and pulp infarcts may be due to an associated connective tissue disease. The absence of productive sputum, obstruction on spirometry, sinusitis, and air trapping on expiratory CT are unusual in DPB and necessitate further evaluation with surgical lung biopsy to establish the diagnosis.[6]

[Downloaded free from http://www.lungindia.com on Monday, September 10, 2018, IP: 192.168.10.239]

Excipient lung disease

Centrilobular nodules are usually caused by bronchiolar disease but can rarely be caused by arteriolar disease. Arteriolar causes include pulmonary edema and hemorrhage, excipient lung disease (ELD), granulomatosis with polyangiitis (GPA), plexogenic arteriopathy (PH), veno-occlusive disease (VOD), pulmonary capillary hemangiomatosis (PCH), and metastatic calcification.[2] There was no evidence of heart failure, renal failure or anemia and hemoptysis to suggest alveolar hemorrhage. The absence of pulmonary hypertension makes centrilobular nodules due to PH, VOD, and PCH very unlikely. Nodules due to GPA are larger, fewer, and associated with cavitation. Excipients are insoluble inert particulate filler materials that bind and protect the active drug during production as well as shape and lubricate tablets for easy swallowing. Excipients include talc (hydrated magnesium silicate), microcrystalline cellulose, crospovidone, and starch. Typically, excipients constitute 5% of a tablet's mass. On intravenous injection, excipient particles lodge in pulmonary arterioles and trigger an angiogranulomatous reaction; progressive disease is associated with dyspnea and pulmonary hypertension.[7] However, the presence of finger pulp infarcts, "tree-in-bud" appearance and absence of pulmonary hypertension are unusual in ELD.

CLINICAL DIAGNOSIS

In summary, the differential diagnosis of extensive centrilobular nodules with "tree-in-bud" without bronchiectasis or pulmonary hypertension in this young adult with smoking, cannabis use, and intravenous drug abuse of reconstituted tablets can be narrowed down to extensive endobronchial tuberculosis, diffuse panbronchiolitis, and ELD.

Dr. RM. PL. Ramanthan: With these clinicoradiological possibilities in mind, this patient underwent fundus examination and bronchoscopy with bronchoalveolar lavage (BAL) and transbronchial lung biopsy, with a plan for surgical biopsy if evaluation was inconclusive. Can we now have the findings?

Dr. K. Divya: Dilated fundus examination confirmed refractile particles scattered along both the retinal arteries and retinal veins [Figure 4], confirming systemic embolization of small (<5 μm) talc particles, consistent with intravenous talcosis. Inhalational talc exposure does not cause such marked retinal deposition as the inhaled particles are larger and are restricted by bronchioles and pulmonary circulation.[8,9]

Dr. Nidhya Ganesan: BAL was negative for acid-fast bacilli and for *M. tuberculosis* by Xpert MTB/RIF; occasional needle-shaped crystals were seen on cytology. The transbronchial lung biopsy specimen confirmed perivascular granulomatous reaction to talc particles [Figure 5, left] that appear as birefringent needle-shaped crystals within the granulomas under polarized light [Figure 5, right]. Review of the composition of Tydol confirmed the presence of talc as excipient. Microcrystalline cellulose appears rod like while starch has a maltese cross pattern and crospovidone is nonbirefringent on polarization.[7]

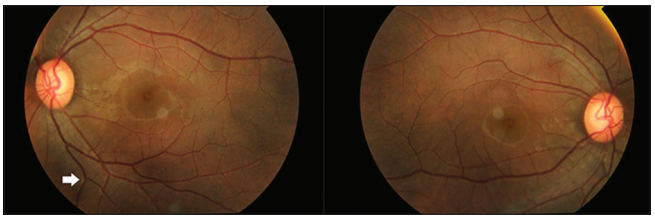

Figure 4: Fundus photograph of both eyes showing refractile particles scattered along both the retinal arteries and retinal veins, confirming the diagnosis of intravenous talcosis

Dr. Srinivas Rajagopala: A diagnosis of ELD (talc granulomatosis) was made. Psychiatry services were involved, and the patient underwent counseling, arrangement for family supervision, and daily-observed methadone replacement. He has successfully discontinued intravenous drug abuse and remains stable at 3 months of follow-up. Serial spirometry, DLco, and radiographs have been advised at 6 monthly intervals. Three unusual findings need an explantation; 1) The presence of "tree-in-bud" in a process that is hematogenous in origin 2)The absence of pulmonary hypertension in ELD and 3)The cause of the bilateral digital infarcts observed.

Dr. B. Devanand: Diseases involving pulmonary arterioles can cause centrilobular nodules as arterioles run in the peribronchovascular interstitium adjacent to bronchioles. Talcosis associated with intravenous abuse is most commonly associated with diffuse fine centrilobular nodules, ground-glass abnormalities or a combination of nodules and lower-lobe emphysema (Ritalin lung with methylphenidate).[9,10] The "tree-in-bud" pattern is unusual for arteriolar disease; it can be caused by intra-arteriolar accumulation of talc with associated adjacent perivascular granulomatous reaction giving the appearance of branching centrilobular nodules and has been described in a few cases of ELD earlier.[11]

Dr. Srinivas Rajagopala: What is the course of ELD? Can the disease progress despite cessation of abuse?

Dr. Kancherla Roopa: Lung fibrosis and pulmonary hypertension are related to the extent of vascular obstruction and granulomatous inflammation and are usually irreversible with talc, cellulose, and crospovidone as these cannot be mobilized; starch can be removed by metabolism and pulmonary hypertension can be reversible to a large degree. Disease progression can occur despite cessation due to ongoing granulomatous foreign-body reaction to the deposited, unmobilizable talc. The initial series of patients described all had progressive symptoms leading to death over 9 months to 5 years.[10,12] The index

[Downloaded free from http://www.lungindia.com on Monday, September 10, 2018, IP: 192.168.10.239]

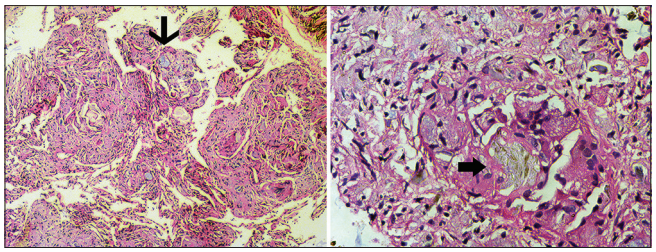

Figure 5: Photomicrographs of the transbronchial lung tissue biopsy specimen (left) demonstrating perivascular foreign body granulomatous reaction to the talc particles (thin arrow, H and E, ×100). Under polarized light, birefringent 20–95 μm needle-shaped crystals were seen in the granuloma, consistent with talc (block arrow, H and E, ×400)

patient has a large load of perivascular disease and is at risk for pulmonary hypertension and disease progression despite cessation of further abuse.

Dr. Srinivas Rajagopala: How common is systemic embolization of talc given that the lung acts as an effective filter?

Dr. K. Divya: The talc that is trapped in the pulmonary arterioles is typically around 10 μm, but smaller particles can escape to the systemic circulation and be detected in the retina, spleen, and virtually every organ on autopsy.[12] Finding excipient crystals in fundoscopy is a rapid noninvasive method to confirm intravenous talcosis.

Dr. Srinivas Rajagopala: Given the presence of digital infarcts, is TEE needed to exclude IE in this patient?

Dr. G. Rajendiran: The first consideration in this patient with possible unsafe needle practices, no murmurs, weight loss, breathlessness, and digital embolic manifestations was subacute native valve IE. TTE has low sensitivity compared to TEE (46% vs. 93%) although both are highly specific (96%).[13] Embolic manifestations are seen in about half of patients with IE.[14] He was not administered any antibiotics, three sets of blood cultures were sterile, and TTE showed all valves clearly without any vegetations. TEE is restricted in our practice to high probability for IE or in whom TTE is rendered less sensitive due to obesity, lung hyperinflation, or prosthetic valves. The index patient met only 2 minor Modified Duke's criteria and was considered low risk for IE after the initial evaluation and TEE deferred.[15] Furthermore, a clear alternative explanation for the observed distal infarcts in the form of talc deposition in the distal microcirculation with thrombosis is available and corroborated by fundoscopy. While this physical finding has not been described in ELD previously, it is consistent with the distal digital embolization and subsequent microthrombosis caused by talc.

Dr. Srinivas Rajagopala: What are the options for those with progressive breathlessness despite cessation of intravenous drug abuse?

Dr. RM. PL. Ramanthan: There are previous small series of lung allografts after a careful selection process in ELD with excellent outcomes.[16] Cadaveric bilateral sequential lung transplantation is a reality in our country today, and he can be listed for the same at our center if he meets criteria and remains free of substance abuse for at least 6 months with adequate psychiatry counseling.

SUMMARY

Clinical examination findings continue to have relevance in this era of investigation-driven medicine. Excipient lung disease can result from intravenous injection of reconstituted tablets and can present with ground glass opacities, small nodules, and emphysema. Pulmonary arteriolar diseases must be considered in the differential diagnosis of centrilobular nodules on CT.

Acknowledgments

The authors would like to thank Jagadeshwari, Research coordinator, and Nissy, Nurse, PSG Institute of Pulmonology, for their help in completing the paperwork for Ethics approval and collating the images for the manuscript.

Declaration of patient consent

The authors certify that they have obtained all appropriate patient consent forms. In the form, the patient has given his consent for his images and other clinical information to be reported in the journal. The patient understands that names, identifying marks, and initials will not be published and due efforts will be made to conceal identity, but anonymity cannot be guaranteed.

Abstract

Purpose: Drug reaction with eosinophilia and systemic symptoms (DRESS) syndrome is a rare, life-threatening multi-system adverse drug reaction characterized by febrile skin rash, hematologic abnormalities, and involvement of internal organs. We report a case of DRESS syndrome in a child presenting with primary ophthalmic manifestations.
Case Report: An 11-year-old boy presented with severe pain and diminished vision in both eyes six weeks after starting carbamazepine therapy for seizure disorder. Ocular examination revealed features of bilateral acute anterior uveitis, acute onset myopia, and angle closure glaucoma secondary to uveal effusion. Additionally, the patient was febrile with a generalized maculopapular rash, and blood investigations revealed eosinophilic leukocytosis. A diagnosis of carbamazepine-induced DRESS syndrome was made, and carbamazepine therapy was discontinued. Treatment with cycloplegics, topical, and systemic steroids resulted in prompt clinical recovery.
Conclusion: Ophthalmologists should be aware that hypersensitivity to anticonvulsants, such as carbamazepine, can present with bilateral uveitis and uveal effusion along with systemic symptoms. Prompt diagnosis and treatment can prevent vision loss and life-threatening complications. Patients should be counselled about potential adverse effects of anticonvulsants before therapy.

INTRODUCTION

Drug reaction with eosinophilia and systemic symptoms (DRESS) syndrome is a rare, potentially fatal idiosyncratic reaction characterized by cutaneous manifestations, hematological changes, and involvement of internal organs.[1] The incidence of this syndrome ranges from 1 in 1000 to 1 in 10,000 drug exposures. The liver is the most commonly affected visceral organ.[2] Primary ocular involvement is uncommon, and only a few cases have been reported in adults.[3–7] Here, we report the occurrence of bilateral acute anterior uveitis and angle closure glaucoma associated with carbamazepine-induced DRESS syndrome in a child.

CASE REPORT

An 11-year-old boy was admitted at the ophthalmology department with complaints of severe pain and diminished vision in both eyes for two days. He had never worn glasses, and his ocular history was unremarkable. Six weeks earlier, he had been diagnosed with a seizure disorder by a pediatrician; oral carbamazepine therapy (200 mg twice daily) was started. Three weeks before the onset of ocular symptoms, he had developed fever and generalized skin rash, which was diagnosed as a viral exanthem and managed with supportive therapy.

Ophthalmic examination revealed a best corrected visual acuity of 20/120 in the right eye and 20/60 in the left eye with −9.0 diopters spherical (DSph) and −1.0 diopters cylinder (DCyl) at 90° in the right eye and −10.0 DSph and −1.0 DCyl at 90° in the left eye. The eyelids were swollen, and chemosis was noted in both eyes. Anterior segment examination revealed corneal epithelial edema, shallow anterior chamber with 3 plus cells, sluggishly reacting pupil, and clear crystalline lens in both eyes. Intraocular pressure by Goldmann applanation tonometry was 45 and 40 mmHg in the right and left eyes, respectively. Gonioscopy revealed bilateral 360° appositional angle closure, and no angle structures were visible. Fundus examination revealed normal optic disc and vessels with a cup-to-disc ratio of 0.3. The axial length of the right eye was 21.91 mm and that of the left eye was 22.05 mm. Considering the acute onset of myopia, bilateral shallow anterior chambers, and angle-closure glaucoma, ciliochoroidal effusion, probably due to carbamazepine, was diagnosed.

Figure 1. Clinical photograph showing swollen eyelids and crusted lesions on lips.

In addition to the ocular findings, the child was febrile with a temperature of 39.8°C and had a generalized maculopapular rash. The lips were swollen with crusted lesions [Figure 1]. Systemic examination revealed no abnormalities. Investigations revealed leukocytosis ($18.9\times10^3/\mu$L) with increased neutrophils ($14.0 \times 10^3/\mu$L) and eosinophils ($1.8 \times 10^3/\mu$L). Peripheral smear showed a few atypical lymphocytes and no blast cells. Hemoglobin level was 12.9 g/dL, and platelet count was $358 \times 10^3/\mu$L. Blood culture tests were negative, and liver function tests were within normal limits. A dermatologist was consulted for the skin lesions, and DRESS syndrome was diagnosed.

Carbamazepine was discontinued and substituted with levetiracetam. Treatment was initiated with homatropine, timolol, and topical steroids, along with intravenous mannitol (1 g/kg body weight). His symptoms improved dramatically after

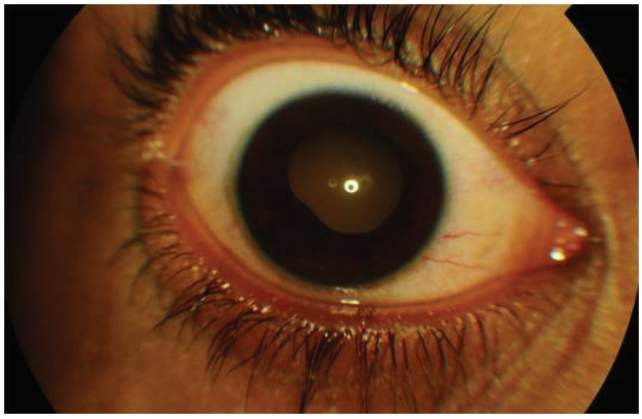

Figure 2. Anterior segment photograph of the right eye showing posterior synechiae.

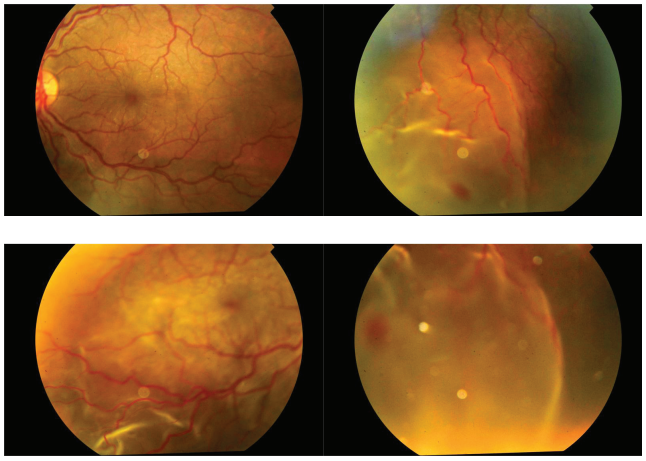

Figure 3. Fundus photograph of both eyes showing choroidal folds at the macula, retinal hemorrhages, and serous retinal detachment.

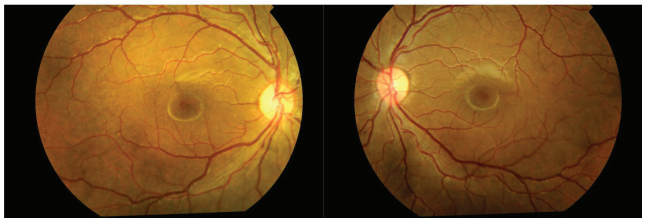

Figure 4. Fundus photograph at the three-week follow-up showing normal optic disc and macula.

two doses of intravenous dexamethasone (4 mg). Ocular examination on the third day revealed a clear cornea, deep anterior chamber with over three cells in both eyes, and posterior synechiae in the right eye [Figure 2]. Intraocular pressure in the right and left eyes was 6 and 5 mmHg, respectively. Fundus examination revealed choroidal folds in the macula and serous elevation of the retina along with scattered retinal hemorrhages [Figure 3].

Along with topical steroids and homatropine, oral prednisolone therapy was started (initial dose, 1 mg/kg body weight) and subsequently tapered. At the three-week follow-up, uveitis and retinal hemorrhages had resolved [Figure 4]. Unaided visual acuity was 20/20, and intraocular pressure was 16 mm Hg in both eyes.

DISCUSSION

Carbamazepine is not included among drugs causing uveitis or angle closure glaucoma. A literature search revealed one case of elevated intraocular pressure associated with carbamazepine in a patient with pseudoexfoliation glaucoma.[8]

Aromatic anticonvulsants, such as carbamazepine, phenytoin, and phenobarbitone, are the most common causes of DRESS; it usually occurs three weeks to three months after starting the drug therapy.[9] Although many children receive anticonvulsant therapy, DRESS is rare in childhood, with fewer cases reported in children compared to adults.[10] The exact pathogenesis of this syndrome is poorly understood. The implicated mechanisms include abnormalities in drug metabolism with accumulation of reactive metabolites, genetic predisposition of individuals to certain human leukocyte antigen (HLA) haplotypes, and interactions between herpes viruses and antiviral and drug-specific immune responses.[11]

Currently, there is no consensus on the best diagnostic criteria for DRESS syndrome. The original criteria were proposed by Bocquet et al.[1] Two separate scoring systems based on the diagnostic criteria have been developed by the Japanese Research Committee on Severe Cutaneous Adverse Reaction (J-SCAR) and the European Registry of Severe Cutaneous Adverse Reaction (RegiSCAR).[11, 12] The RegiSCAR, which outlines seven inclusion criteria, is the most widely used [Table 1].

Our patient fulfilled three of the four main criteria for the diagnosis of DRESS syndrome (as proposed by the European RegiSCAR), namely, acute rash, fever > 38°C, and abnormal eosinophil and lymphocyte counts. No internal organs were involved. This can be attributed to the timely discontinuation of carbamazepine and prompt initiation

Table 1. Diagnostic criteria for DRESS syndrome

Bocquet et al[1]	J-SCAR	RegiSCAR
All the three criteria are required	Typical DRESS: all the seven criteria are required Atypical DIHS: only the first five are required	Presence of more than three of the following criteria
1. Cutaneous drug eruption	1. Maculopapular rash developing three weeks after the treatment with the offending drug	1. Hospitalization
2. Hematologic abnormalities: Eosinophils $\geq 1.5 \times 10^9$/L and the presence of atypical lymphocytes	2. Prolonged clinical symptoms after discontinuing the causative drug	2. Acute rash
3. Systemic involvement: lymphadenopathy > 2 cm, hepatitis with transaminase levels twice the normal, interstitial nephritis, pneumonitis, and carditis	3. Fever > 38°C	3. Reaction suspected to be drug-related
	4. Hepatic abnormalities (ALT >100 U/L) or involvement of another organ	4. Fever > 38°C
	5. Leukocytosis, eosinophils $\geq 1.5 \times 10^9$/L, and the presence of atypical lymphocytes (> 5%)	5. Lymphadenopathy involving at least two sites
	6. Lymphadenopathy	6. Involvement of one internal organ (liver, kidney, or others)
	7. Reactivation of HHV-6	7. Hematologic abnormalities: lymphocyte count above or below normal limits, eosinophil count above laboratory limits, platelet count below laboratory limits.

ALT, Alanine transaminase; DIHS, drug-induced hypersensitivity syndrome; HHV, human herpes virus

of steroid therapy. Differential diagnosis in our patient includes viral infections, such as dengue, chikungunya, and hematological disorders, such as leukemia, anemia, and thrombocytopenia, all of which can present with retinal hemorrhages, serous retinal detachment, and uveitis.[13–15]

A clear temporal relationship between the administration of carbamazepine and onset of symptoms (three weeks), peripheral blood picture, an absence of findings in the clinical history and examination of the child suggestive of infection or neoplasia, and bilateral acute onset myopia with angle closure prompted us to suspect a drug-induced adverse reaction. The assessment of causality using the Naranjo Adverse Drug Reaction Probability Scale established a "probable" relationship (score of 6) with carbamazepine in the patient.[16]

Ocular involvement is a rare feature of DRESS syndrome and to the best of our knowledge, only five cases have been reported in literature. Uveitis (anterior, intermediate, and panuveitis) has been noted in all the cases. Reactivation of herpes viruses (human herpesvirus 6 and Epstein-Barr virus) were noted in two patients who had multi-organ involvement.[3–7]

We assume that the inflammation of the uveal tract and accumulation of exudate had resulted in uveal effusion. This led to the anterior displacement of the iris and lens diaphragm, eventually resulting in acute onset myopia, shallow anterior chamber, appositional angle closure, and elevation of intra ocular pressure in our patient. Cycloplegics promoted posterior rotation of the iris-lens diaphragm, and steroid therapy attenuated the allergic-type drug reaction, thereby stabilizing the blood-aqueous barrier and ensuring prompt recovery.

In contrast to other adverse drug reactions, dynamic changes in immune response have been reported in DRESS syndrome.[17] Hence, the uveal tract with its rich network of macrophages and

major histocompatibility complex (MHC) class II dendritic cells is most likely to be affected in patients with ocular involvement.

Ophthalmologists should be aware that hypersensitivity to anticonvulsants, such as carbamazepine, can present with bilateral uveitis and uveal effusion along with systemic symptoms. Given the delayed onset after the initiation of treatment with the offending drug, systemic symptoms, and potentially fatal multi-organ involvement, a high index of suspicion is necessary to prevent complications. Additionally, it is necessary to inform the patient about the adverse effects of carbamazepine before prescribing it.

Abstract

Purpose: Pneumatic retinopexy (PR) continues to remain an important technique in the management of rhegmatogenous retinal detachment (RRD). We describe the results of a novel surgical technique of PR with subretinal fluid (SRF) drainage in this retrospective, nonrandomized case series. **Subjects and Methods:** Medical records of patients with primary RRD who underwent PR with SRF drainage and had been followed up for 6 months or more were reviewed. The procedure involved transconjunctival cryotherapy followed by drainage of SRF using a 26G needle and intravitreal injection of perfluoropropane. Outcome data measured included final visual acuity, anatomical success with single surgical procedure, surgical complications, and need for subsequent procedures. **Results:** Out of the 12 patients, there were 7 males and 5 females. The 12 patients aged in range from 24 to 64 years (average - 43 ± 15.55 years). Average duration of follow-up was 10 ± 3.56 months (range: 6–14 months). Eleven eyes achieved anatomical reattachment of the retina with a single procedure (91.6%). Redetachment was noted in one patient who was successfully treated with pars plana vitrectomy and scleral buckle.The final anatomical success rate was 100%. Visual acuity improved in all the eyes treated, and no major complications related to SRF drainage were encountered. **Conclusion:** PR with needle-assisted SRF drainage is a safe and useful technique for selected cases of primary RRDs with good anatomical and functional outcomes.

Keywords: Pneumatic retinopexy, retinal detachment, subretinal fluid

Introduction

Pneumatic retinopexy (PR) is a minimally invasive surgical procedure useful in selected cases of primary rhegmatogenous retinal detachments (RRDs). Ever since its introduction by Hilton and Grizzard, PR has become a widely accepted alternative surgical technique to scleral buckle and pars plana vitrectomy for specific types of retinal detachments with comparable final anatomical results, less morbidity, and potential cost savings.[1-3] The procedure involves transconjunctival cryopexy or laser photocoagulation of retinal breaks along with intravitreal injection of gas and appropriate patient positioning.[4] Subretinal fluid (SRF) drainage is not usually performed in PR. The surface tension of the bubble closes the retinal break and prevents the bubble from passing into the subretinal space. With the retinal break closed, the retinal pigment epithelial pump removes the SRF. However, delayed resorption of SRF after PR has been reported by several authors.[5,6] Loculated pockets of SRF in the macula can delay visual recovery and may affect the final visual outcome.[7-9]

In this article, we present the results of a novel technique combining needle-assisted SRF drainage with PR for primary RRD. This approach combines the advantages of both PR and SRF drainage in conventional retinal reattachment procedures.

Subjects and Methods

This study was a retrospective, nonrandomized case analysis of patients with primary RRD who underwent PR with SRF drainage at a tertiary care center in South India. The medical records of these patients were reviewed. All patients had been followed up for a minimum duration of 6 months after the surgical procedure. Six months limit was chosen because the

risk of redetachment is reported to be highest within the first 6 months.[10]

The procedure was performed for new-onset primary RRD with breaks in the superior 8 o' clock hours (between 8 o' clock and 4'o clock) in patients older than 18 years of age after informed consent. The procedure was not performed in eyes with hazy media, glaucoma, proliferative vitreoretinopathy (PVR) Grade C, previous retinal surgery, or poor patient compliance. The Institutional review board approved the study protocol and the protocol complied with the tenets of the Declaration of Helsinki.

All patients had undergone complete ophthalmic evaluation including a detailed history, preoperative visual acuity, refraction, intraocular pressure measurement, and slit-lamp biomicroscopy. Indirect ophthalmoscopy with scleral indentation was performed to assess the number, size, and location of retinal breaks and macular status. Detailed retinal drawings had been drawn on standard retinal charts. All patients had undergone PR using the standard technique described below. Postoperatively, the patients had been followed at day 1, 1 week, 1 month, and 6 months. Wherever applicable, additional cryo/laser retinopexy was performed at the surgeon's discretion. New/missed peripheral breaks were treated by cryotherapy, while laser was performed for reopened breaks and persistent SRF. Additional procedures were performed around 1–2 weeks after the surgery.

Outcome data measured included final visual acuity, anatomical success with single surgical procedure, surgical complications, and need for subsequent procedures.

Technique

All procedures were performed under retrobulbar anesthesia. The retinal breaks were visualized and surrounded by transconjunctival cryotherapy. Localized conjunctival peritomy was performed in the quadrant where drainage was planned. After peritomy, one rectus muscle was bridled. The drainage site was marked with the help of bipolar cautery. The sclera was punctured with a ½-inch 26G needle, and the SRF was drained under the area of highest retinal elevation [Figure 1]. As the eye became quite soft after SRF drainage a pull on the bridled muscle helped in stabilizing the globe. This also helped in avoiding rotation of the eye and/or possible damage to the crystalline lens during the introduction of needle for gas injection. Around 0.6 cc of 100% perfluoropropane gas was injected via the superior pars plana 3–4 mm posterior to the limbus with the help of 26G needle in a brisk manner to achieve a single large bubble. With the injection site, uppermost and the needle vertical, moderately brisk injection of gas results in one single bubble at the needle tip. Conjunctiva was sutured with 8-0 vicryl. At the end of the procedure, indirect ophthalmoscopy was performed and perfusion of the optic nerve head was ensured in all patients. The patients were positioned such that the retinal breaks were uppermost to ensure tamponade by the injected gas bubble. Patients were asked to maintain the head position for 5–7 days.

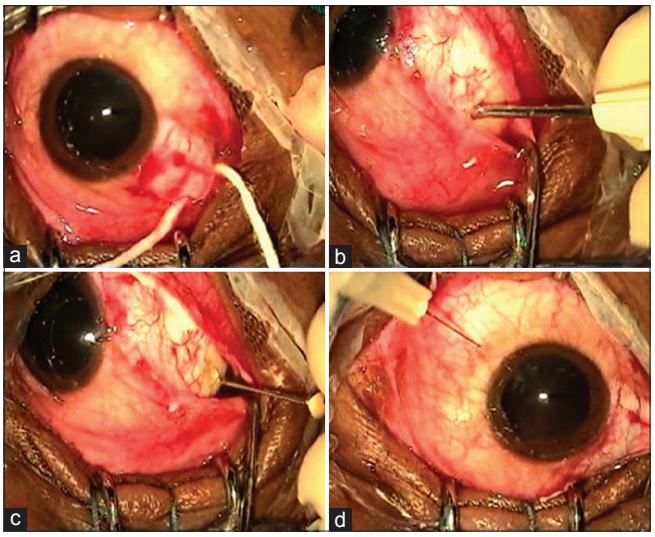

Figure 1: (a) Localized conjunctival peritomy with bridled rectus muscle, (b) subretinal fluid drainage site marked with cautery, (c) drainage of subretinal fluid with 26G needle, (d) intravitreal injection of gas via superior pars plana

Results

Out of the 12 patients, there were 7 males and 5 females. The 12 patients aged in range from 24 to 64 years (average - 43 ± 15.55 years). Average duration of follow-up was 10 ± 3.56 months (range - 6–14 months). None of the patients had phakic refraction >6 D. Nine had superior breaks (10:00–2:00) and three had temporal breaks (8:00–10:00). In patients with multiple breaks (5/12), all the breaks were clustered within the same quadrant. One patient (patient 12) had an additional inferior break in the attached retina. Table 1 shows the summary of patient data and Table 2 shows preoperative characteristics of the patients studied.

Out of the 12 eyes, 11 eyes achieved anatomical reattachment of the retina with a single procedure. Postoperative barrage LASER was done in five cases. Additional cryoretinopexy was done in one patient with peripheral new/missed break at follow-up. Resurgery was done in one patient (patient 11) who had severe vitreous condensation and a missed break. This patient underwent a scleral buckle along with pars plana vitrectomy and silicone oil infusion for persistent vitreoretinal traction.

Considering two Snellen lines of visual acuity change significant, vision improved in all the 12 patients studied. There were 10 patients with visual acuity of 20/200 or less preoperatively, while none of the patients had this acuity postoperatively [Table 3]. No major complications such as endophthalmitis, persistent elevated intraocular pressure, or cataract were encountered in our series. One patient had minimal choroidal hemorrhage at the drainage site in the inferotemporal periphery which resolved spontaneously. Patient 6 had inferior lattice with atrophic holes and a persistent shallow inferior RD postoperatively. She underwent additional laser retinopexy in the postoperative period and the detachment slowly settled.

Discussion

In this retrospective analysis, we found the rate of single surgery anatomical success after PR using the new technique to be 91.6%. This group included patients who received additional cryotherapy or laser in the postoperative period and maintained retinal reattachment throughout 6 months of follow-up. One patient who developed redetachment 1 month after surgery underwent additional reattachment procedure and had attached retina at the final follow-up visit. Hence, the final anatomical success rate was 100%.

Success rates following PR reported in the literature are found to vary in a wide range. Hilton and Tornambe reviewed the outcome of 1274 eyes in 26 published reports on PR performed between 1986 and 1989.[11] The average single operation success rate was found to be 80% (range: 53%–100%) and average final success rate was 98% (range: 92%–100%). A comprehensive review on the surgical outcome of 4138 eyes that underwent PR over a 21-year period (1986–2007) has reported a single operation success rate of 74.4% and the final success rate of 96.1%.[1] Few recent studies have reported lower rates of single operation success ranging from 59.5% to 69.6%.[12-14] This has been attributed to the wider inclusion criteria including RRDs that generally have lower PR success rates such as multiple breaks in multiple quadrants and retinal breaks in the inferior clock hours. Pseudophakia, large retinal break, and/or PVR are reported to be significant predictors of treatment failure.[14]

Cochrane Database Systematic Review 2015 comparing the relative efficacy of PR versus scleral buckle (with or without vitrectomy) for RRD found slightly less reattachment rate with PR (relative rate 0.89; 95% confidence interval: 0.77–1.02) and higher chances of recurrence (1.80; 95% confidence interval 1.0–3.24) but does not rule out no difference between the procedures.[15] Eyes in the scleral buckle group have been reported to be more susceptible to choroidal detachment and myopic shift than eyes in the PR group. However, the authors have concluded that there is the absence of sufficient high-quality evidence from randomized controlled trials comparing the risks and benefits of PR versus scleral buckle. The choice of procedure depends on the clinical judgment, patient preferences and the surgeon's skill, and experience with each procedure. In spite of reports of variable success rates, PR has been shown to be a very useful, cost-effective method of RD repair with the potential to significantly reduce health-care burden. This is of utmost importance for a developing nation like ours.[16]

Our high success rate can be attributed to the smaller sample size, meticulous preoperative examination, appropriate postoperative retinopexy, and the fact that most of our patients

had classic indications for PR such as retinal breaks in the superior retina and absence of significant PVR.

Literature search on PR with drainage of SRF revealed only one similar study by Gündüz and Günalp in 1994.[17] The authors have reported a series of thirty bullous retinal detachments treated with PR and SRF drainage using 25G diathermy needle. After 150°–180° limbal peritomy, drainage of SRF was performed under the area of highest retinal elevation first, and subsequently, cryotherapy and perfluoroethane injection were done. All the eyes were reattached after the first operation. In three (10%) eyes, new breaks with RD developed 2 weeks – 2 months after the initial procedure and were treated successfully with scleral buckling. The single operation success rate was 90% and eventual reattachment rate was 96.7%. Visual acuity improved in 80% of the eyes treated. They have concluded that anatomic and visual success rates after this procedure are comparable to conventional PR and that SRF drainage did not result in additional complications.

The authors have suggested that cryotherapy after drainage reduces risk of pigment epithelial dispersion into the vitreous and therefore lessens risk of PVR as well as avoids the need for steamroller technique. However, in our study, cryopexy was done before drainage of SRF. Adequate indentation of the sclera was achieved to produce enough cryopexy before SRF drainage in our series. In cases where the cryopexy was considered inadequate, it was repeated in the postoperative period. We observed no increased risk of PVR after this technique in our limited sample.

There are several advantages of PR with needle drainage of SRF over conventional PR. If bullous SRF extends almost to an attached macula, placement of bubble against the bullous detachment may push fluid into the macula and cause macular detachment. Steamroller technique has been suggested to prevent an iatrogenic detachment of macula, as well as iatrogenic detachment of an attached retinal break.[2] However, with drainage of SRF before gas injection, the steamroller technique can be avoided and the theoretical possibility of PVR secondary to movement of SRF into vitreous is prevented.

One of the major reasons for failure of conventional PR is the presence of peripheral or missed retinal breaks which lead to reaccumulation of SRF and persistent retinal detachment.[1] Drainage of SRF before gas injection allows better visualization of the peripheral fundus. This is useful in aphakic and pseudophakic eyes with multiple far peripheral breaks which have been reported to carry lower success rate after PR.[18,19] However, recent studies have noted similar anatomical outcome in phakic as well as pseudophakic eyes.[12,20] This has been attributed to an in-depth examination of the peripheral retina and treatment of breaks in all eyes, especially the nonphakic eyes.

A recent study comparing the outcome of PR as a primary procedure for RRD versus secondary procedure for recurrent RRD found a single operation success rate of 60% for primary intervention and 65.5% for secondary intervention.[21] Age and preoperative and postoperative visual acuity were found to have significant association with single operation success rate. Progression of PVR was found to be the most common cause of failure, followed by nonresolving SRF, reopening of the original break, and formation of new breaks. Although the technique described in this article looks little invasive compared to conventional PR, it hastens resolution of SRF, is highly cost-effective, and obviates the need for a major surgical procedure.

This procedure can also be selected intraoperatively when scleral buckling techniques are likely to be hazardous or likely to have significant postoperative complications such as eyes with marked scleral thinning or the need for a bulky scleral buckle beneath the superior rectus muscle.

The rates of delayed SRF resorption after PR have been reported to vary between 4% and 12%.[5,13,22] Although the SRF does get absorbed spontaneously over several months, persistent SRF can delay visual recovery and affect the final visual outcome. Drainage of SRF using a 26G needle as described in this article ensures rapid resolution of the detachment and visual recovery.

Patients with extensive lattice degeneration have been reported to be unsuitable for PR because of vitreoretinal adhesions and traction resulting in new breaks. However, in our study, six patients had lattice in the detached retina and three patients had lattice degeneration in the attached retina. Our results are consistent with the previous studies, in which lattice degeneration did not increase rate of surgical failure.[16,23]

Poor preoperative visual acuity has been reported to be associated with PR failure and poor final visual outcome by several authors and preoperative visual acuity has been suggested as one of the factors which predict visual recovery.[13,19] In contrast to these studies, worse initial visual acuity was not associated with adverse visual outcome in our series.

Our choice of long-acting perfluoropropane for intravitreal injection was based on its availability. The bubble expands slowly that allows for equilibration of intraocular pressure during the first few days following injection. Perfluoropropane also eliminated the need to reinject gas if a new break develops.

We did not encounter complications such as intraocular hemorrhage or vitreoretinal incarceration related to SRF drainage in our series. It has been argued that cryotherapy may cause vascular congestion of the choriocapillaris and that SRF drainage should not follow cryotherapy. However, we found that SRF drainage after cryotherapy was not associated with increased risk of intraocular hemorrhage or adverse visual outcome. Our observations are in line with other published studies.[24] The 26G needle used for SRF drainage results in a very narrow transscleral tract and therefore the risk of vitreoretinal incarceration is minimal. Furthermore, localized

conjunctival peritomy minimizes the conjunctival damage as compared to scleral buckling.

The limitations of our study include its limited sample size and retrospective design. Subgroup analysis could not be performed owing to the small sample size. Furthermore, we have not examined the relative efficacy of primary vitrectomy and/or scleral buckle versus PR with SRF drainage which would be useful, but beyond the scope of this article.

Conclusion

PR with needle-assisted drainage of SRF is a safe and useful technique for selected cases of primary RRD. Conjunctival damage is less and minimal additional instrumentation is required. This technique has many advantages over conventional PR and good anatomic and visual outcomes can be achieved with less morbidity.

Dry Eye Disease and Tear Dysfunction in Patients with Type 2 Diabetes: A Hospital-Based Study from South India

K Divya, N Dhivya, M Raaja Ganesh, D Sundar

Department of Ophthalmology, PSG Institute of Medical Sciences and Research, Coimbatore, Tamil Nadu, India

Abstract

Purpose: Diabetics are more prone to dry eye disease (DED) and tear film dysfunction. The aim of this study was to assess the frequency of DED and tear film abnormalities in patients with type 2 diabetes compared to healthy controls. **Materials and Methods:** This was a hospital-based prospective case-control study. One hundred patients with type 2 diabetes and 100 healthy controls were enrolled by consecutive sampling. All study participants completed the Ocular Surface Disease Index (OSDI) questionnaire to score dry eye symptoms. Tear film breakup time (TFBUT), ocular surface staining with fluorescein and Schirmer's test were performed, and results were analyzed. Student's *t*-test was applied for comparisons between groups. Correlation between variables was detected using Pearson's correlation coefficient. Statistical significance was set at $P < 0.05$. **Results:** Dry eye was encountered in 54 among the 100 diabetic patients studied. Age and sex of diabetic patients were not found to affect the dry eye status. Longer duration of diabetes was significantly associated with DED ($P = 0.03$). Significant differences in OSDI scores, TFBUT, fluorescein staining, and Schirmer's test values were observed between the study groups ($P < 0.001$). An increased level of glycosylated hemoglobin was significantly associated with abnormal tear function tests. **Conclusion:** Patients with longer duration of diabetes and poor glycemic control are more predisposed to have abnormalities of the tear film and DED. Apart from conventional therapies, optimal glycemic control should be an important consideration in the management of tear dysfunction in diabetic patients.

Keywords: *Diabetes, dry eye, tear film*

Introduction

The prevalence of diabetes mellitus (DM) has increased significantly in the past several decades and the disease continues to remain a global epidemic. Estimates suggest that 439 million people in the world are likely to have DM by 2030 and this increase in number of diabetics is predicted to be disproportionately more in developing countries.[1] The two major potentially blinding complications of diabetes, namely cataract and retinopathy, have been extensively researched in literature. Apart from these, people with diabetes are also prone for ocular surface disease that includes dry eye, persistent epithelial defects, decreased corneal sensation, and tear film dysfunction. Studies have shown an intimate, complex relationship between diabetes, dry eye, and ocular surface abnormalities.[2,3]

The reported prevalence rates of dry eye in diabetics have been found to vary widely between 27% and 54%.[4,5] A recent study from a cornea specialty clinic found the overall presence and the severity of dry eye to be similar in the diabetic and nondiabetic groups. However, significant differences were observed between groups with regard to individual diagnostic assessments.[6] Studies on changes in tear function parameters in diabetes have also shown conflicting results.[7,8] These can be attributed to major differences in the study characteristics of the population, methodologies, and wide array of diagnostic methods used for assessment. Limited data exist on the occurrence of dry eye and ocular surface disease among diabetics in the Indian population.[9]

This prospective study from India sought to study the frequency of dry eye disease (DED) and tear film changes in patients with type 2 diabetes compared to healthy controls.

Materials and Methods

This was a hospital-based cross-sectional study which included 100 patients

with type 2 DM. Consecutive patients attending the Ophthalmology Department of a tertiary care center in South India between June 2016 and 2017 were invited to participate. Exclusion criteria included the history of smoking, contact lens wear, past ocular surgery, intake of systemic medications such as antihistamines, tricyclic antidepressants, and other drugs known to cause dry eye. Patients with known ocular or systemic disease that might affect the ocular surface were also excluded from the study. One hundred individuals matched by age were enrolled as a control group. The controls were recruited from individuals attending the department of ophthalmology for routine eye examination and did not have any ocular or systemic disease other than refractive errors. The study protocol was approved by the Institutional Ethics Committee, and the study was conducted according to the principles of the Declaration of Helsinki. Informed consent was obtained from all participants.

For each participant, a detailed ocular and general medical history, including duration of diabetes, medications, and glycosylated hemoglobin (HbA1c) value within the past 3 months was obtained. All study participants completed the Ocular Surface Disease Index (OSDI; Allergan, Inc., Irvine, CA, USA) questionnaire to score dry eye symptoms. The OSDI consists of 12 questions based on symptoms within the past 1 week. The frequency of ocular subjective symptoms (soreness, blurred vision), difficulty with vision-related function (television, visual display unit, driving, and reading) and discomfort due to environmental triggers (low humidity, high wind) are assessed on a Likert scale. The scores range from 0 (least severe) to 100 (most severe).[10]

All participants underwent a general physical and comprehensive ophthalmic examination with slit lamp, including best-corrected visual acuity. Evaluation of the ocular surface and tear film was done by performing the following tests described below in a sequential manner.[11]

Tear film breakup time (TFBUT) was performed by applying a fluorescein strip (Fluostrip/India/Contacareophthalmics and diagnostics) moistening it with a drop of sterile saline, to the lower tarsal conjunctiva without the use of topical anesthesia. The participants were asked to blink several times and then cease blinking until instructed. The tear film was observed under slit lamp with cobalt blue filter. The time interval between the last blink to the appearance of the first random dry spot in the cornea was taken as the TFBUT. The average of three consecutive breakup times was calculated and recorded.

The ocular surface was evaluated by staining the cornea with fluorescein and Oxford grading scheme was used for the recording of staining severity. This scheme has five panels, labeled A to E, with staining represented by punctate dots that increase logarithmically between panels.[12] The appearance of staining on the exposed interpalpebral conjunctiva and cornea is compared with each panel, and the closest match gives the grade. Based on the number of dots seen a grade between 0 and 3 was given for staining on the cornea, nasal, and temporal conjunctiva. The individual scores were added giving a maximum possible total of 9 points. A score of 3 and above was considered to be abnormal.[13]

Schirmer's test was performed without topical anesthesia using standardized Whatman filter paper 41(Tearstrip/India/Contacareophthalmics and diagnostics). The strip was folded at the notch and placed at the junction of the middle and lateral thirds of the lower eyelids and left in place for 5 min. A value of <10 mm wetting in 5 min was considered abnormal.

Due to lack of consensus among the diagnostic criteria for dry eye described in different clinical studies we adopted the following criteria used by Alves *et al.*: OSDI score >20 and/or Schirmer test <10 mm or TFBUT <6 s and/or ocular surface staining score >3.[14] A diagnosis of DED was made if the participant had at least one positive test according to these criteria. In various clinical studies, authors have adopted different approaches for the diagnosis of dry eye on an *ad hoc* basis. Several studies have used the positivity of one or more of the tests (tear breakup time [TBUT] or Schirmer or OSDI) for the diagnosis of dry eye.[5,15,16] Since there is no uniform set of diagnostic criteria for DED, we considered a diagnosis of dry eye if the patient presented at least one positive test according to these preestablished criteria.

All measurements were performed by the same investigators on the same day under similar testing conditions. Clinical evaluations were done on both eyes, and the mean of the two eyes was used for analysis. To eliminate diurnal variation and possible diagnostic error, all tests were performed in the morning.

Statistical analysis

Statistical analysis was performed using the Statistical Package for the Social Sciences (SPSS Inc., Chicago, IL, USA) version 24. Descriptive statistics was presented as a mean ± standard deviation. The Shapiro–Wilk test was used to test the normality of data distribution. Student's *t*-test was applied for comparisons between two groups. Correlation between variables was detected using Pearson's correlation coefficient. Statistical significance was set at $P < 0.05$.

Results

The mean age of controls and diabetic patients was 54.7 ± 10.2 and 55.7 ± 9.5 years, respectively. There were 53 females among 100 controls and 45 females among 100 diabetics ($P = 0.25$). The baseline characteristics of the study participants are shown in Table 1. The mean duration of diabetes among diabetics with the dry

[Downloaded free from http://www.sjopthal.net on Monday, October 14, 2019, IP: 192.168.10.239]

eye was significantly higher compared to those without dry eye (P = 0.03).

Table 2 shows the comparison of OSDI, Schirmer test, fluorescein staining, and TFBUT between groups using the Student's *t*-test. Significant differences in OSDI scores, Schirmer test values, fluorescein staining, and TFBUT were observed between the study groups. OSDI Score was >20 in 32 participants (32%) in the diabetic group. Nineteen percent had OSDI scores between 12 and 20. In the diabetic group, 7 participants (7%) had Schirmer scores <10 mm and 30 (30%) had TBUT <10 s. Ocular surface staining score of >3 was encountered in 51% of the diabetic participants. None of the participants in the control group had abnormal OSDI, Schirmer test, fluorescein staining, or TFBUT.

We evaluated the relationship between HbA1c, duration of diabetes, and ocular surface parameters [Table 3]. The analysis showed significant positive correlation between the duration of diabetes and OSDI scores as well as fluorescein staining of the ocular surface. Although negative, the correlation between duration of diabetes and Schirmer/TFBUT was not statistically significant.

Table 1: Baseline characteristics of study participants

Characteristic	Controls	Diabetics without dry eye	Diabetics with dry eye
Number (%)	100	46	54
Age (years)	54.7±10.2	54.6±9.5	56.7±9.6
Females (%)	53 (53)	22 (47.8)	23 (42.6)
Duration of diabetes (years)	-	5.6±6.1	8.05±5.1*
HbA1c	5.3±0.3	8.5±2.2	9.4±2.3

*P=0.03. HbA1c: Glycosylated haemoglobin

Table 2: Comparison of ocular surface disease index scores, Schirmer test, fluorescein staining and tear film breakup time between groups

	Controls	Diabetics	*P*
OSDI	6.9±6.5	15.1±12.4	<0.001
Schirmer test	24.1±5.1	20.8±7.3	<0.001
Fluorescein staining	1.85±0.24	3.8±2.1	<0.001
TFBUT	16.7±3.6	12.6±4.5	<0.001

OSDI: Ocular surface disease index, TFBUT: Tear film breakup time

Table 3: Correlation coefficients between duration of diabetes, glycosylated haemoglobin and ocular surface parameters

Variable	Duration of diabetes (*P*)	HbA1c (*P*)
OSDI	0.342 (<0.001)	0.340 (<0.001)
Schirmer test	−0.07 (0.47)	−0.23 (0.01)
Fluorescein staining	0.3 (0.003)	0.3 (0.001)
TFBUT	−0.1 (0.27)	−0.21 (0.03)

HbA1c: Glycosylated haemoglobin, OSDI: Ocular surface disease index, TFBUT: Tear film breakup time

The HbA1c level was found to correlate positively with OSDI scores and ocular surface staining. HbA1c levels correlated negatively with Schirmer values and TFBUT.

Discussion

The purpose of this clinical study was to assess the frequency of DED and tear film abnormalities in people with diabetes and compare with that of healthy controls. The OSDI scores were higher, and tear film parameters were significantly altered in diabetic patients.

Out of the 100 diabetics studied, 54 were found to have dry eye. Mean age of diabetic individuals with and without dry eye were found to be similar (P = 0.262). Among the 100 patients with diabetes 45 (45%) were females, of which 23 (42.6%) had dry eye and 22 (47.8%) did not have evidence of dry eye (P = 0.600). Hence, there was no statistically significant association between dry eye and age or gender of the diabetic patients. The frequency of dry eye was significantly higher in patients with longer duration of diabetes.

Studies on dry eye in diabetics have revealed wide variation in the prevalence rates due to different diagnostic criteria as well as patient characteristics. Our observations are similar to that of Fuerst *et al*. who have noted a dry eye prevalence of 54% based on tear osmolarity.[16] Manaviat *et al*. performed Schirmer and TBUT tests and utilized the criterion of one positive test to diagnose dry eye. Out of the 199 participants studied, 108 (54.3%) were found to have dry eye.[5]

In contrast to these hospital-based studies, a community-based study from Shanghai has reported 17.5% prevalence of definitive DED.[17] Apart from methods used for diagnosis, several other factors such as age, gender, duration of diabetes, and metabolic control have also been reported to affect the prevalence of DED.[18,19]

Duration of diabetes was found to be significantly associated with dry eye in our study similar to observations of Manaviat *et al*.[5] Chronic hyperglycemia, diabetic neuropathy, decreased insulin levels, microvasculopathy, and systemic hyperosmotic disturbances in long-standing diabetes lead to dysfunction of the lacrimal functional unit as well as abnormal tear dynamics and DED.[20] However, some studies have found no correlation between DED and duration of diabetes.[4]

Diabetics in this study had significantly higher OSDI scores as compared to the control group. In contrast to our observations, Beckman found the mean OSDI scores to be higher in nondiabetic patients as compared to diabetic patients.[6] This could be attributed to the fact that the mean duration of diabetes in this study was much less (6.9 ± 5.7 years) compared to their study where the mean diabetic duration was 11.1 ± 9 years (range 1–41 years). Long-standing diabetes has been reported to

[Downloaded free from http://www.sjopthal.net on Monday, October 14, 2019, IP: 192.168.10.239]

be associated with reduced perception of dry eye symptoms due to impaired corneal sensation and therefore decreased OSDI scores.[16]

We found a significant positive correlation between OSDI scores and duration of diabetes in our study. One possibility for the observed positive correlation is that, as mentioned previously participants with shorter duration of diabetes have normal corneal sensation and therefore, will be aware of dry eye symptoms. Our findings are in agreement with the natural history of DED proposed by Bron *et al.* This model comprises three stages, namely initiation of DED, reflex compensation, and loss of compensatory response due to sensory nerve impairment.[21]

OSDI scores were found to correlate positively with HbA1c levels in our study. Our observations are in line with previous studies elsewhere, which have shown a positive correlation between OSDI scores and glycemic control.[22,23]

Although mean Schirmer test scores were in the normal range for both study groups, statistically significant differences were found between the Schirmer values in control and diabetic groups. Our observations are similar to that of Beckman and Yoon *et al*. who found the values of the Schirmer's test to be >10 mm in both diabetic and nondiabetic patients.[6,24] In contrast to these findings, the Schirmer values averaged 7.4 ± 0.38 mm in patients with diabetes versus 13.53 ± 0.50 mm in the controls in a series by Dogru *et al*.[7] Twenty eyes (22.7%) of the diabetic patients in their series had Schirmer test values <5 mm. In our study, only 3% had Schirmer scores <5 mm. Reduced Schirmer scores in people with diabetes compared with nondiabetic participants have been documented in several studies. Some studies have noted a reduction in basal tear secretion, whereas some authors have reported only the reflex tear secretion to be significantly reduced in diabetics.[8,19,25]

We found a significant negative correlation between Schirmer test scores and HbA1c levels. Our observations are in line with that of Ozdemir *et al*. who also found the Schirmer test and TBUT results to be worse in poorly controlled diabetics compared to those with good metabolic control. Kaiserman *et al*. have reported increasing consumption of ocular lubrication with increased mean annual levels of HbA1c.[18] Poor Schirmer test scores were not related to the duration of diabetes in our study which is in agreement with previous studies.[19]

Significant staining of the ocular surface with fluorescein was noted in diabetic patients in our study. Impaired corneal epithelial barrier function in diabetic patients has been reported by several studies and poor metabolic control, diabetic neuropathy, and advanced retinopathy have been found to correlate with epitheliopathy.[3,24] Ocular surface staining scores were found to correlate positively with duration of diabetes as well as HbA1c levels in this study. Accumulation of advanced glycation end products (AGE) on the basement membrane of the corneal epithelium has been shown to play a causative role in corneal epithelial disorders of diabetic patients.[26] Since HbA1c is a product of early stage glycation, it correlates well with AGE formation and hence impaired barrier function resulting in staining of the ocular surface.

Significant differences in TFBUT values were noted between diabetic and nondiabetic participants, and lower TFBUT scores were noted in patients with poor glycemic control. These results are comparable to that of Yoon *et al*. who had evaluated the tear film and ocular surface changes among diabetics from Korea.[24] Ma *et al*. have reported a significant inverse correlation between serum HbA1c levels and noninvasive TBUT in their study on 80 Chinese participants with type 2 diabetes.[23] These results suggest that poor glycemic control is associated with an unstable tearfilm and ocular surface disease in diabetic patients.

The study has few limitations. We had not performed tear film osmolarity assessment which is an objective test for the diagnosis and follow-up of DED. However, test combination of OSDI/Schirmer test/TFBUT has been shown to have an accuracy of 99.3% for the diagnosis of DED.[14] Sample size and conduct of the study at a single site are other potential limitations of the study. Further studies on large samples with the inclusion of tests such as corneal esthesiometry, tear osmolarity, and other markers of DED will provide valuable insight into the potential mechanisms and treatment options for diabetic DED.

Conclusion

There are limited data available in the literature about the frequency of dry eye and tear film dysfunction in diabetics from India. With the increasing prevalence of diabetes and its associated complications in India, there is need for more studies from this part of the world. Nearly half of the people with diabetes in this study had features consistent with DED. Patients with longer duration of diabetes and higher HbA1c levels are more predisposed to have abnormalities of tear film and DED. Examination of the ocular surface and testing for DED should be added to the routine screening of diabetes. Apart from conventional therapies such as lubricants, anti-inflammatory agents, and antioxidants optimal glycemic control should be an important consideration in the management of tear dysfunction in diabetic patients.

Acknowledgment

The authors are grateful and would like to acknowledge Dr.Suvetha.K, FAIMER fellow and Associate professor in community medicine, PSG Institute of Medical Sciences and Research, for statistical analysis and guidance in interpretation of results.

Evaluation of retrobulbar circulation in type 2 diabetic patients using color Doppler imaging

K Divya, Vikrant Kanagaraju[1], B Devanand[1], C Jeevamala, A Raghuram, D Sundar

Purpose: To investigate the retrobulbar circulatory parameters in type 2 diabetes mellitus patients with color Doppler imaging (CDI) and compare the results with nondiabetic controls. **Methods:** This prospective study included 50 type 2 diabetic patients and 50 age-matched controls. Seven field stereo fundus photography was used to diagnose and classify diabetic retinopathy (DR). Diabetic patients were further divided into two: Group 1, consisted of patients with no DR, mild and moderate non-proliferative DR (n = 36); Group 2, severe nonproliferative and proliferative DR (n = 14). CDI was performed using Philips iU22 xMATRIX ultrasound. The peak systolic velocity (PSV), end-diastolic velocity (EDV), resistivity index (RI) and pulsatile index (PI) of ophthalmic (OA), posterior ciliary artery (PCA), and central retinal artery (CRA) along with central retinal vein (CRV) were recorded. **Results:** RI in the ophthalmic artery was significantly higher in both DR groups than the control group (P = 0.000). Diabetic Group 1 had decreased blood flow velocity (PSV and EDV) in PCA compared to controls (P = 0.046 and P = 0.010, respectively). Group 2 DR had significantly reduced EDV and increased RI in CRA compared to Group 1 (P = 0.015). Binary logistic regression analysis revealed glycosylated hemoglobin and RI of OA to be independent risk factors of DR. **Conclusion:** Significant changes in resistivity index and flow velocities were observed in the retrobulbar vessels, especially in ophthalmic artery in diabetics compared to controls. CDI with results of increased resistance or decreased flow could be useful to predict individuals at higher risk for developing severe DR.

Quick Response Code:

Key words: Blood flow velocities, color Doppler ultrasonography, diabetes mellitus, retrobulbar

Ocular manifestations of diabetes are numerous and among them, diabetic retinopathy (DR) is a major clinical issue for ophthalmologists. DR is the most frequent cause of preventable blindness in working-age adults (20–74 years) and is therefore considered as a major public health issue.[1] Though treatable in appropriate stages, the prevention of retinal complications of diabetes and consequent visual impairment is vital to reduce the burden of DR. There is a felt need for better diagnostic modalities and surrogate markers in the evaluation and management of DR.

In spite of decades of research, the mechanisms behind the onset and progression of DR still remain unclear. From a hemodynamic point of view, evidence has shown that there is an early reduction in blood flow to retina before the onset of DR followed by a gradual increase as the retinopathy progresses.[2] Color Doppler imaging (CDI) is an established, safe, and noninvasive ultrasonic method useful for qualitatively and quantitatively assessing the blood flow velocities and indirect blood flow.[3] CDI has been suggested to be valuable in the diagnosis and management of several ocular diseases with altered hemodynamics such as glaucoma, retinal vascular diseases, ischemic optic neuropathy, and ocular ischemic syndrome.[4] An analysis of retrobulbar hemodynamics in diabetes using CDI can provide insight into the pathogenesis and prospective treatment for DR as well as predict those at higher risk of developing vision threatening DR. Several authors have evaluated the circulatory changes in diabetics using CDI and reported conflicting results. While few studies have reported a reduction in the retrobulbar blood flow velocities,[5-7] others have noted an increase[8] or no change.[9] Studies on the resistive index (RI) of orbital vessels which is a measure of peripheral vascular resistance have also shown significant discrepancies.[10,11] Factors such as demographic variables, duration of diabetes, methods of DR assessment, positions of CDI, and sample sizes account for the observed discrepancies. Moreover, most studies have not excluded patients with hypertension and those on medications affecting systemic blood flow which can influence the results. Studies on orbital hemodynamic alterations among type 2 diabetics from India are relatively few. The diabetic population in India is close to hitting the alarming mark of 69.9 million by 2025 and 80 million by 2030, denoting an expected increase of 266%. Hence, India is deemed as the world's capital of diabetes.[12] With increasing prevalence of diabetes and DR, it is important to know the hemodynamic alterations among diabetics from the Indian population.

The objective of this study was to evaluate the flow velocities and vascular resistance of orbital blood vessels using CDI in a pure cohort of type 2 diabetic patients from India and compare the results with healthy controls.

Methods

This prospective hospital-based study was carried out at a tertiary care institution from south India between March 2017 and April 2019. The study included consecutive patients of type 2 DM (as per definition of the American Diabetes Association) attending the ophthalmology outpatient clinic for the screening of retinopathy. Exclusion criteria were history of any ocular disease that might affect ocular blood flow such as glaucoma, nondiabetic retinal vascular occlusion, ocular inflammation, high myopia, previous ocular surgery, or panretinal photocoagulation. Patients with systemic hypertension, dyslipidemia, nephropathy, and cardiovascular diseases were excluded from the study. Pregnant and breastfeeding women were not included. Patients taking medications known to affect systemic hemodynamics such as Angiotensin-converting enzyme inhibitors, calcium channel blockers, and anti-migraine drugs were also excluded.

50 age-matched healthy subjects were enrolled as a control group. The control subjects were recruited from individuals attending the department of ophthalmology for a routine eye examination. They were not on any medication and did not have ocular or systemic disease. The study was conducted according to the principles of the Declaration of Helsinki and the study protocol was approved by the institutional ethics committee. Informed consent was obtained from all participants.

Information regarding age, gender, body mass index, duration of diabetes, antidiabetic medications, and blood pressure were obtained from all participants. Serum glycosylated hemoglobin (HbA1c) was determined from fasting venous blood sample.

All study participants underwent a comprehensive ophthalmic examination including dilated fundus with slit-lamp biomicroscope using a 90 diopter lens and indirect ophthalmoscopy. A 30° stereoscopic fundus photograph of 7 standard early treatment diabetic retinopathy study (ETDRS) fields was taken from both eyes of diabetic patients using a digital fundus camera (TRC-50 DX Mydriatic retinal camera; Topcon Medical Systems, Oakland, NJ).

The presence, as well as the severity of diabetic retinopathy, was determined by grading of color fundus photographs following the international clinical disease severity scale for diabetic retinopathy which is based on the findings of WESDR (Wisconsin Epidemiological Study of Diabetic Retinopathy) and ETDRS.[13] The diabetic patients were assigned to one of the following groups namely no retinopathy, mild nonproliferative diabetic retinopathy (NPDR), moderate NPDR, severe NPDR, and proliferative diabetic retinopathy (PDR). The

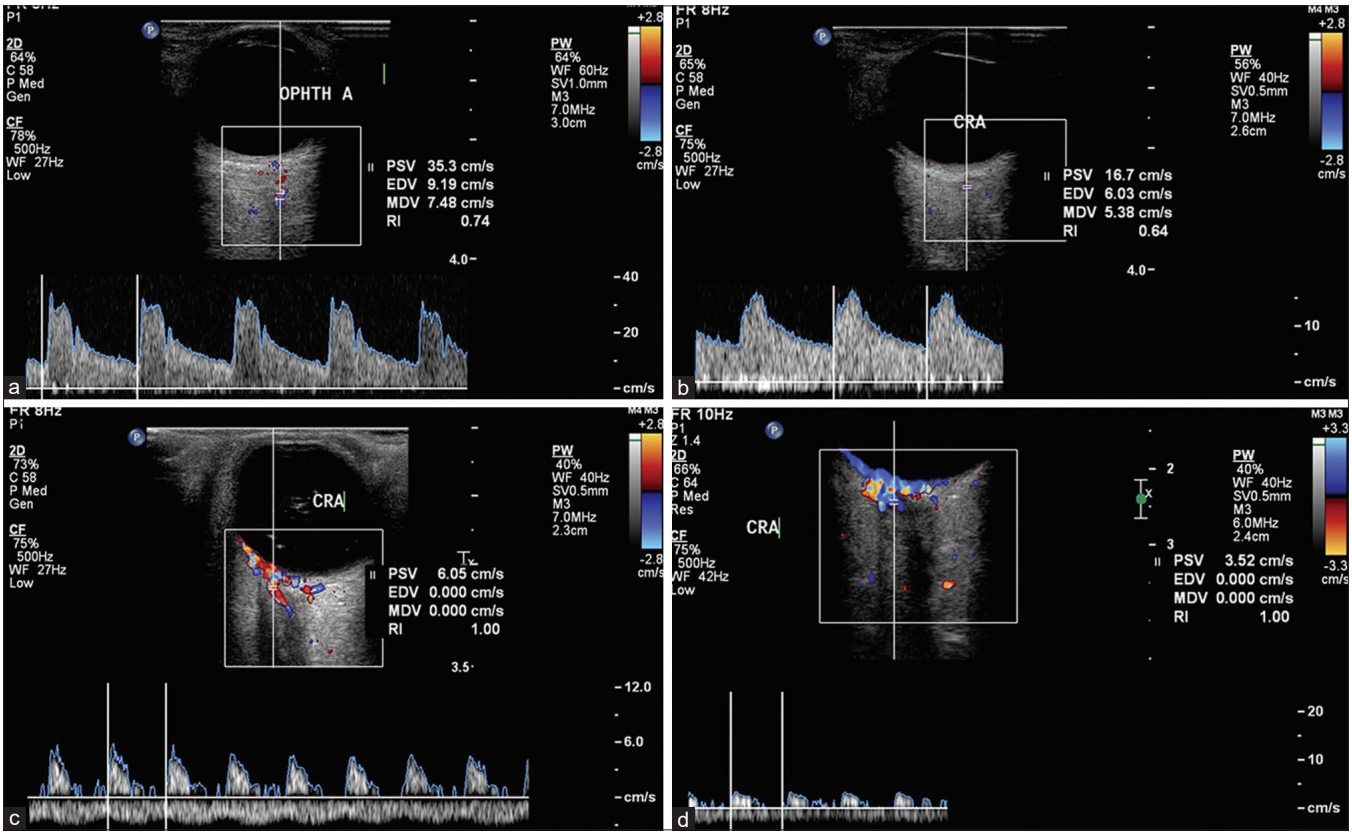

Figure 1: (a) Color Doppler image (CDI) showing normal color flow and spectral waveform in ophthalmic artery with preserved M wave pattern; (b) CDI showing normal color flow and spectral waveform in central retinal artery; (c) CDI showing low-velocity monophasic flow in central retinal artery in a patient with moderate NPDR; (d) CDI showing monophasic spectral waveform with absent diastolic flow in central retinal artery in a patient with severe NPDR

[Downloaded free from http://www.ijo.in on Thursday, June 4, 2020, IP: 192.168.10.239]

eye with worse retinopathy was included in the study. If both eyes had equal retinopathy, the right eye was assigned to the study.

Color Doppler sonography of the eye was performed for cases and controls by a masked expert Radiologist using a color Doppler unit and a 12 to 5 MHZ linear-array transducer (Philips iU22 xMATRIX ultrasound system). The patients were examined in the supine position and care was taken to avoid any undue pressure on the eye. Examiner's hand was rested on the orbital margin and sterile coupling gel was applied over closed eyelids. The Doppler signal was registered online after the cursor was positioned on the region of interest. To reduce errors in measurement of velocities, angle correction was applied to the pulsed Doppler recordings.

The peak systolic velocity (PSV) and end-diastolic velocity (EDV) readings were obtained from the ophthalmic artery (OA), central retinal artery (CRA), and the posterior ciliary artery (PCA). Since the velocity wave in a central retinal vein (CRV) is not in direct relation to the cardiac cycle its hemodynamic parameters were expressed as maximum (V max) and minimum (V min) blood velocity. Signals from the ophthalmic artery were obtained from the medial aspect of the eyeball, superior to the optic nerve. The central retinal artery and vein were located within the optic nerve, around 10 mm behind the eyeball. [Fig. 1] Signals from the temporal branch of the short posterior ciliary artery were located lateral to the optic nerve.

With the help of PSV and EDV, we calculated the vascular resistance expressed by the resistivity index and pulsatile index using Pourcelot's formula.

Resistive index (RI) = (PSV-EDV)/PSV; Pulsatile index (PI) = (PSV-EDV)/Vmean

Statistical analysis

For statistical analysis diabetic patients were further divided into two groups; Group 1 included patients with no retinopathy, mild NPDR, and moderate NPDR while Group 2 consisted of patients with severe NPDR and PDR.

Statistical analysis was performed using statistical package for social sciences (SPSS, SPSS Inc, Chicago, IL, USA) version 24. Data were expressed as mean ± standard deviation. The normality of data distribution was tested by the Kolmogorov-Smirnov test. One-way analysis of variance (ANOVA) with a *post hoc* Bonferroni was used for the analysis of normally distributed continuous data. Kruskal-Wallis analysis was used for analyzing non-normally distributed data. A comparison between hemodynamic parameters was calculated by ANOVA followed by Tukey-Kramer *post hoc* comparison. Pearson's coefficient was used to study the correlation between variables.

Table 1: Demographic and clinical characteristics of controls and diabetic subjects

Characteristic	Controls (*n*=50)	Group 1 (*n*=36)	Group 2 (*n*=14)	*P*
Age (years)	56.5±9.00	55.5±8.60	51.9±5.64	0.209

Binary logistic regression analysis was performed to determine independent risk factors for retinopathy. All tests for statistical significance were two-tailed and performed assuming a type I error probability of <0.05.

Results

Demographic and clinical parameters

The study included 52 males and 48 females. The age of patients ranged from 41 to 76 years. The duration of diabetes ranged from 6 months to 20 years. Among the diabetic patients, 29 were on oral hypoglycemic agents, 9 were on insulin, and 12 were on combination therapy. Group 1 (n = 36) consisted of 16 patients with no DR, 13 with mild NPDR, and 7 with moderate NPDR. Group 2 (n = 14) consisted of 6 patients with severe NPDR and 8 with PDR. There were no statistically significant differences in the age, body mass index and blood pressure between controls and diabetic groups. Glycosylated hemoglobin (HbA1c) levels were found to be significantly higher in Group 2 diabetic patients (P = 0.014). No significant difference was noted in the duration of diabetes among diabetic groups. The demographic and clinical characteristics of controls and diabetic subjects are presented in Table 1.

Hemodynamic parameters

Table 2 shows the hemodynamic parameters of retrobulbar blood vessels among controls and patient groups.

Ophthalmic artery

Significant differences were noted in the RI and PI values of the ophthalmic artery between controls and diabetic patients with various DR grades. OA flow velocities did not vary between groups.

Table 3: Pearson correlation coefficients between the duration of diabetes, HbA1c, and hemodynamic parameters

Variable	Duration of diabetes	HbA1c
OA PSV	0.021 (0.885)	-0.120 (0.407)
OA EDV	-0.141 (0.328)	-0.055 (0.706)
OA RI	0.314* (0.026)	0.097 (0.504)
OA PI	0.299* (0.035)	0.078 (0.588)
CRA PSV	-0.135 (0.349)	-0.269 (0.059)
CRA EDV	-0.464* (0.001)	-0.299*(0.035)
CRA RI	0.375* (0.007)	-0.046 (0.753)
CRA PI	0.487* (0.000)	0.131 (0.370)
PCA PSV	-0.052 (0.722)	0.170 (0.239)
PCA EDV	-0.234 (0.102)	0.196 (0.172)
PCA RI	0.332* (0.019)	-0.075 (0.606)
PCA PI	0.321*(0.023)	-0.085 (0.556)
CRV V max	0.134 (0.354)	0.128 (0.375)
CRV V min	-0.143 (0.322)	-0.058 (0.687)
CRV RI	0.390* (0.005)	0.172 (0.233)
CRV PI	0.415*(0.003)	0.210 (0.144)

Corresponding P values are shown in brackets. HbA1c=Glycosylated hemoglobin; OA=Ophthalmic artery; CRA=Central retinal artery; PCA=Posterior ciliary artery; CRV=Central retinal vein; PSV=Peak systolic velocity; EDV=End diastolic velocity; V max=maximum blood velocity; V min=minimum blood velocity; RI=Resistivity index; PI=Pulsatility index; *P<0.05

Central retinal artery and vein

The hemodynamic parameters of CRA were significantly different between controls, DR Group 1, and Group 2 whereas no such difference was seen in the CRV. *Post hoc* comparison revealed a significantly reduced PSV and EDV of CRA (P = 0.005 and 0.000, respectively) along with increased PI (P = 0.003) in DR group 2 compared to controls. Patients with group 2 DR also demonstrated a significant decrease of EDV and increased RI of CRA compared to group 1 (P = 0.015). PSV, EDV, and RI of CRA did not differ significantly between controls and DR group 1.

Posterior ciliary artery

The EDV and PI of PCA were found to vary significantly between controls and diabetic groups. Significant reduction in PSV and EDV of PCA was noted in DR group 1 compared to controls (P = 0.046 and P = 0.010, respectively after *post hoc* comparison).

Relation between duration of diabetes, HbA1c, and hemodynamic parameters

Duration of diabetes correlated positively with the resistive and pulsatile indices of all retrobulbar vessels studied namely ophthalmic artery, CRA, PCA, and CRV. HbA1c levels, as well as the duration of diabetes, were found to correlate negatively with EDV of CRA. No correlation was found between duration of diabetes and HbA1c levels (R = 0.183, P = 0.203). Table 3 shows the relationship between duration of diabetes, HbA1c levels, and hemodynamic parameters.

Binary logistic regression analysis revealed that HbA1c levels and RI of OA were independent risk factors of retinopathy.

Discussion

The main observations of our study are as follows: (1) RI in the ophthalmic artery was significantly higher in both DR groups than the control group and was an independent risk factor of retinopathy, (2) Patients with Group 1 DR had decreased blood flow velocity (PSV and EDV) in the posterior ciliary artery compared to control group, (3) Patients with Group 2 DR had significantly reduced EDV and increased RI in the CRA compared to Group 1, (4) Compared to the control group, patients with Group 2 DR had slower flow velocities and increased PI in CRA but RI values did not vary significantly.

Our finding of decreased EDV in the posterior ciliary artery in patients with Group 1 DR supports the hypothesis that choroidal blood flow is affected in the early stages of DR. Laser Doppler flowmetry has shown decreased choroidal blood flow in the foveal region in early DR.[14] Choroidal vascularity index (CVI) analysis by swept-source optical coherence tomography (OCT) has also shown reduced CVI in patients with mild/moderate NPDR.[15] Cao *et al.* have reported a 4 times more choriocapillary loss in diabetic eyes compared to non-diabetic eyes in histopathologic studies.[16] Ferrara *et al.* have demonstrated the loss of intermediate and large blood vessels in the Sattler's layer and Haller's layers in diabetic eyes in choroidal OCT.[17] Our observation of decreased EDV in the PCA suggests increased peripheral vascular resistance of the choroidal circulation in early DR and is in concordance with these studies. Dimitrova *et al.* reported decreased EDV and increased RI in PCA in patients

[Downloaded free from http://www.ijo.in on Thursday, June 4, 2020, IP: 192.168.10.239]

with background DR compared to controls in CDI of diabetic patients performed in sitting posture.[6] The authors have suggested that erect posture during CDI measurement is essential to appreciate significant alterations in posterior ciliary circulation. Supine posture has been suggested to increase EDV and decrease the RI.[18] As autoregulation and autonomic nervous responses are altered in diabetics, the correlation of change in circulatory parameters between normal individuals and diabetics associated with postural variation may not be expected to be equal. However, CDI was performed in supine posture in our patients. Our observations could be attributed to the shorter duration of diabetes in our patients than theirs.

RI in OA was higher in both DR groups compared with controls in our study. These findings are similar to those of previous studies.[5,19] Basturk *et al.* evaluated the association between the resistivity index of orbital arteries and DR in 91 types 2 diabetics with microalbuminuria using CDI. The authors have demonstrated increased RI values of all orbital arteries in patients with DR compared to those without DR and controls. RI value of ≥ 0.72 in OA indicated the presence of DR with 78.4% sensitivity and 70% specificity.[10] Our finding of increased RI in the OA in both DR groups can be attributed to the statistically nonsignificant reduction in EDV observed in diabetic subjects because of downstream vascular changes in the retina and choroid. We did not observe significant differences in CRA parameters between controls and DR Group 1. Hence, we believe that the OA hemodynamic parameters in our study probably represent alterations in choroidal blood flow. It has been suggested that of the total ocular blood supply from OA, less than 10% flows to the retina while the remainder is directed to choroid via the ciliary circulation due to the high metabolic demand of photoreceptors.[20] Moreover, the diastolic blood flow of PCA is higher than CRA since these vascular channels of choroid have low resistance.[21]

Table 4: Various published studies on ocular circulation in diabetic patients using color Doppler imaging

Study	Country	Sample size	Duration of diabetes (years)	Findings
Arai *et al.*, 1998[9]	Japan	74 Controls: 22 NDR: 27 DR: 25	NA	Significant increase in RI of CRA in patients with DR compared to those without DR and controls (P<0.01)
MacKinnon *et al.*, 2000[5]	Scotland	62 Controls: 17 NDR/BDR: 24 PPDR/PDR: 21	NDR/BDR: 10 PPDR/PDR: 12	Significant decrease in both PSV and EDV of CRA in the PPDR/PDR group compared to NDR/BDR and control group (P<0.05) while RI showed no significant change. RI of OA was increased in diabetics compared to controls.
Dimitrova *et al.* , 2001[6]	Japan	95 Controls: 22 NDR: 38 BDR: 35	NDR: 9.0±7.2 BDR: 18. 9±11.2	Significant decrease in EDV and increase in RI of PCA in BDR group compared to controls (P=0.01 and 0.0003, respectively)
Gracner *et al.*, 2004[8]	Slovenia	66 Controls: 22 NPDR: 22 SNPDR/PDR: 22	13.5±9.31	Significant increase in PSV of OA in the SNPDR/PDR group compared to controls. Significant increase in RI of PCA in SNPDR/PDR group compared to NPDR and controls
Sullu *et al.*, 2005[7]	Turkey	34 Controls: 20 PDR: 14	13.5±6.1	Decrease in mean EDV and increase in RI of both OA and CRA in PDR compared to controls (P<0.05)
Baydar *et al.*, 2007[11]	Australia	44 (65 eyes) Controls: 11 Diabetics: 33	4.94±3.90	The RI of CRA was significantly higher in the control group than in the NDR group. RI of OA was significantly higher in NDR than in the moderate NPDR group.
Basturk *et al.*, 2012[10]	Turkey	118 Controls: 27 NDR: 40 DR: 51	NDR: 6.87±4.37 DR: 8.23±2.55	Patients with DR had significantly higher mean RIs of OA, CRA and PCA compared to those without DR and controls (P<0.001)
Karami *et al.*, 2012[30]	Iran	123 Controls: 25 BDR: 74 PPDR: 24	BDR: 5.6±0.7 PPDR: 12.6±1.1	RI of OA and CRV were significantly higher in patients with DR compared to controls (P<0.005)
Our study	India	100 Controls: 50 NDR/mild/ moderate NPDR: 36 SNPDR/PDR: 14	NDR/mild/moderate NPDR: 8 SNPDR/PDR: 11	RI of OA was significantly increased in diabetics compared to controls. Significant decrease in both PSV and EDV of PCA in mild/ moderate NPDR compared to controls (P<0.05) Significantly reduced EDV and increased RI of CRA in SNPDR/PDR compared to mild/moderate NPDR group (P=0.015)

Khatri *et al.* assessed the correlation between RI of OA and topographic alterations of retinal pigment epithelium (RPE) on spectral-domain optical coherence tomography (SD-OCT).[22] In their study involving 75 patients with type 2 diabetes and 24 controls, a significant increase in OA RI was noted with the severity of DR ($F = 14.23$, $P < 0.001$). A positive correlation was noted between RI of OA and grades of RPE alterations on SD-OCT suggesting that decreased blood flow contributes to RPE dysfunction. Studies demonstrating early retinal damage in experimental diabetes have reported morphological changes in RPE and animal studies have also shown reduced choroidal blood flow in young diabetic animals suggesting that blood flow deficit could be an early pathological change in DR.[23,24] Although it is difficult to propose a causal association it can be postulated that changes in choroidal circulation (as reflected by increased RI of OA) lead to downregulation of antiangiogenic PEDF (pigment epithelial-derived factor) and upregulation of VEGF (vascular endothelial growth factor) thereby contributing to progression of DR. Differential expression and secretion of these growth factors derived from the retinal pigment epithelium have been suggested to lead to nonproliferative and proliferative DR.[25]

Patients with Group 2 DR had significantly reduced EDV in the CRA compared to Group 1 DR as well as healthy controls. Our observations are in line with previous studies.[5,6,8] These can be attributed to the increased peripheral vascular resistivity with the progression of DR. Pathological findings in DR such as capillary basement membrane thickening, retinal capillary leukostasis, loss of retinal capillaries, and altered blood rheology support this circulatory feature.[2,26,27]

Another observation of our study was that DR Group 2 had significantly reduced flow velocity in the CRA but an increase in RI was not statistically significant compared to the control group. This can be due to the concomitant decrease of both PSV and EDV in patients with Group 2 DR. Neudorfer *et al.* evaluated the long-term changes in the retrobulbar circulation of 138 eyes of diabetic subjects at a 10-year follow-up.[28] Patients were divided into four groups, namely, nondiabetic controls, diabetics without DR, nonproliferative DR, and proliferative DR. RI values of CRA and PCA had increased in the two no retinopathy groups and in the nonproliferative DR group, with a surprising nonsignificant decrease in the proliferative DR group. The authors have concluded that an increase of resistance in the retrobulbar blood vessels due to DR can decrease over time and may even be reversed. It has been suggested that the decrease in resistance reflects the beginning of an increase in retinal blood flow with the progression of DR due to the short-circuiting of the obstructed retinal capillary network.[28] This is supported by histopathologic studies, which have shown areas of capillary closure being traversed by preferential dilated anastomotic channels.[29]

Our finding of a positive correlation between duration of diabetes and RI of all retrobulbar vessels was similar to the observations of Karami *et al.*[30] We found negative correlation between EDV of CRA and duration of diabetes as well as HbA1c levels ($R = -0.464$, $P = 0.001$; $R = -0.299$, $P = 0.035$, respectively). Poor glycemic control (as reflected by increased HbA1c) and longer duration of diabetes can be associated with increased peripheral vascular resistance and thus reduced EDV in CRA. Our findings of HbA1c and RI of OA as independent risk factors of DR are similar to that of Basturk *et al.*[10]

Table 4 shows the various published studies on ocular circulation in diabetic patients using CDI.

Our study has several strengths. None of the diabetic patients had associated vascular diseases. Hypertension as well as antihypertensive medications significantly alter the resistive indices of blood vessels and therefore confound the results. We intentionally excluded these patients to study the influence of diabetes alone on ocular hemodynamics. A single masked, experienced radiologist performed all the Doppler examinations gently with the least pressure on the globe thus eliminating interobserver variability. The presence and severity of DR were graded based on seven field stereo fundus photography for accuracy.

To our knowledge, this study is the first of its kind in a pure cohort of diabetics from India.

There are a few limitations to our study. The sample size was small which accounts for the limited subgroup analysis. CDI provides information on blood flow velocity only and absolute volumetric blood flow cannot be quantified since it is not possible to study the diameter of retrobulbar vessels with CDI accurately. In spite of this limitation, blood velocity is probably a good indicator of blood flow within a given vessel.[31,32] Moreover, measurement of retinal blood flow is difficult and no accurate method to quantitatively assess perfusion is currently used clinically.

Conclusion

In conclusion, significant changes in the blood flow velocities and RI were observed in the retrobulbar vessels, especially in an ophthalmic artery in diabetics compared to controls. RI could be potentially useful for early diagnosis and follow-up of DR. CDI with results of increased resistance or decreased flow can be of help to identify diabetic individuals at higher risk for developing severe DR. This is especially useful in patients with opaque media where conventional methods are of little use.

Relationship between myopia and central corneal thickness – A hospital based study from South India

ABSTRACT

Background and Purpose: The prevalence of myopia has been increasing steadily, and studies on the relationship between myopia and central corneal thickness (CCT) have shown conflicting results. The purpose of this study was to investigate the relationship between myopia and CCT in a hospital based population from South India. **Materials and Methods:** This prospective, cross-sectional study was carried out from a tertiary care institution in South India between January 2017 and June 2018. One hundred and ninety-four myopic individuals between 11 and 40 years of age with spherical equivalent (SE) ranging from -0.5 to -6 Diopters after cycloplegic refraction were enrolled in the study. CCT was measured in both eyes of each patient using Tomey EM-3000 noncontact specular microscope (Tomey Corporation, Nagoya, Japan). The relation between CCT and myopia was analyzed using Pearson's correlation coefficient. Statistical significance was set at $P < 0.05$. **Results:** A total of 388 eyes were analyzed. 50% (n=97) of study participants were females. The mean age of the study participants was 25.47 ± 7.25 years (range: 12–40 years). The mean SE was -2.79±1.34 D (range: -0.5 to -6.0 D). The mean CCT was 540.53 ± 56.16 μm (range: 441–664 μm). No significant association was observed between CCT and age or gender of the study participants ($P = 0.706$ and 0.550, respectively). No correlation was observed between mean CCT and SE (Pearson, $r = 0.095$, $P = 0.062$). **Conclusion:** There was no correlation between CCT and degree of myopia. These data contribute to the ongoing discussion on the structural alterations in ocular coats and susceptibility to glaucoma in myopia.

Keywords: Central corneal thickness measurement, myopia, noncontact specular microscope, spherical equivalent

INTRODUCTION

Myopia, referred to as "short sight," is increasing in prevalence at an alarming rate and has emerged as a major cause for visual impairment globally. Estimates suggest that around 1.5 billion people or 22% of the present world population is myopic.[1] Apart from the ethnic and genetic factors, environmental and lifestyle changes have contributed significantly to the increasing prevalence of myopia. A recent meta-analysis on the prevalence of myopia in South-east Asia has shown an estimated pool prevalence of 4.9% (95% confidence interval [CI]: 1.6–8.1) in children and 32.9% (95% CI: 25.1–40.7) in adults.[2] The recent shift to younger age at the onset of myopia is even more worrisome considering its impact on the economic burden and quality of life.

With an increasing prevalence of myopia, there has also been a tremendous rise in the number of laser refractive procedures for the correction of myopia. Central corneal thickness (CCT) is a major factor determining the choice of refractive surgery for myopia, and a thin cornea is a recognized risk factor for corneal ectasia postrefractive surgery.[3] Corneal refractive surgery for myopia results in reduced corneal thickness and thereby leads to the underestimation of intraocular pressure.[4,5] This is relevant in the diagnosis and treatment of any glaucoma later in life,

since both myopia and reduced CCT are well-known risk factors for glaucoma.[6-8]

Studies evaluating the relationship between myopia and CCT have revealed conflicting results. While few studies have found a correlation between CCT and myopia,[9-11] some have reported no significant correlation.[12-15] This can be attributed to the differences in ethnicity, characteristics of the population studied as well as varied methods of the measurement of corneal thickness. Two population-based studies using ultrasonic pachymetry (UP) from India have reported thinner corneas in Indians than that of other populations.[12,16] Relatively fewer studies have evaluated CCT using noncontact specular microscopy, which is a noninvasive and accurate method with good reproducibility of CCT measurements.[17-19]

Given the increasing prevalence of myopia from India and conflicting evidence on the association between CCT and myopia, we attempted to study the relationship between myopia and CCT among patients attending the refraction clinic of a tertiary care institute using a noncontact specular microscope (NCSM).

MATERIALS AND METHODS

This prospective, hospital-based, cross-sectional study was carried out from a tertiary care institution in South India between January 2017 and June 2018. Individuals between 11 and 40 years of age who presented with visual impairment and found to have myopic refractive error (spherical equivalent [SE] more than −0.5 D) on cycloplegic refraction were included in the study. The exclusion criteria were myopia >−6 D, prior refractive or other ocular surgery, contact lens wear, trauma, corneal diseases, cataract, glaucoma, and ocular hypertension. Pregnant and lactating females and individuals with systemic diseases such as diabetes mellitus and collagen vascular disease were also excluded from the study. The study was performed according to the principles of the Declaration of Helsinki after prior approval from the Institutional Human Ethics Committee. Informed consent was obtained from all the participants.

All the study participants underwent a comprehensive ophthalmic examination, including slit-lamp biomicroscopy and fundus evaluation using +90 D lens and indirect ophthalmoscopy. Cycloplegia was achieved with three topical applications of 1% cyclopentolate at 15-min intervals. Cycloplegic refraction was performed 30–60 min after the first instillation of drug and spherical equivalent (SE, sphere + half-cylindrical component) was calculated.

CCT was measured by a single experienced ophthalmologist using Tomey EM-3000 NCSM (Tomey Corporation, Nagoya, Japan). The participants were instructed to fixate on the central target with chin and forehead positioned appropriately. Then, the participants were asked to blink completely once before measurements to spread an optically smooth tear film over the corneal surface. The measurements were taken using the auto-alignment and capture mode, thereby eliminating observer bias. Three consecutive valid measurements were taken, and the average of the three readings was used for the analysis. The CCT values were considered valid when the endothelial cells were focused clearly and bright corneal reflections were centered on the monitor. All measurements were performed in midday (between 12 and 4 PM) to eliminate diurnal variation.[20]

Statistical analysis

Statistical analysis was performed using the Statistical Package for the Social Sciences (SPSS, SPSS Inc., Chicago, LA, USA) software version 24. Descriptive statistics were presented as mean ± standard deviation. Discrete variables were presented as numbers (n) and percentages (%). Patients were classified into the following three groups according to SE: Group 1 included patients with SE -0.5 to <-2 D; Group 2 consisted of patients with SE -2 to < -4 D; and Group 3 individuals with SE -4 to < -6 D. The normality of CCT distribution was determined by the Shapiro–Wilk test. One-way analysis of variance followed by *post-hoc* Bonferroni was used for the analysis between the groups. The student's t-test was used to analyze the mean difference between two independent samples. Pearson's coefficient was used to study the correlation between variables. $P < 0.05$ was considered to be statistically significant.

RESULTS

This study included 388 eyes of 194 individuals with varying grades of myopia. 50% ($n = 97$) of the study participants were females. The mean age of the study participants was 25.47 ± 7.25 years (range: 12–40 years). The mean SE was − 2.79 ± 1.34 D (range: -0.5 to -6.0 D). The mean CCT was 540.53 ± 56.16 µm (range: 441–664 µm).

The CCT measurements were found to be nonnormally distributed. Figure 1 shows the distribution of CCT readings among the study participants. Figure 2 shows the distribution of SE among study participants.

Table 1 shows the association of gender of study participants with CCT. No significant differences were noted in the mean CCT between males and females ($P = 0.550$, Student's t-test).

[Downloaded free from http://www.kjophthal.com on Thursday, June 4, 2020, IP: 192.168.10.239]

Table 2 shows the association between mean CCT and age of study participants. No significant differences were noted in mean CCT values between various age groups ($P = 0.706$).

Table 3 shows the mean CCT values among the SE groups. Figure 3 shows the correlation between mean CCT and SE. No correlation was observed between mean CCT and SE (Pearson, $r = 0.095$, $P = 0.062$).

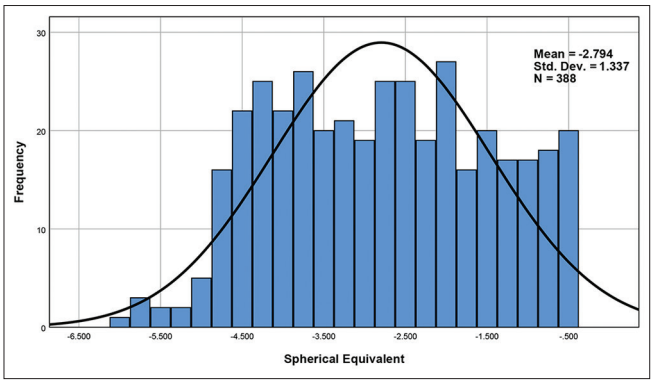

Figure 2: Distribution of spherical equivalent among the study participants

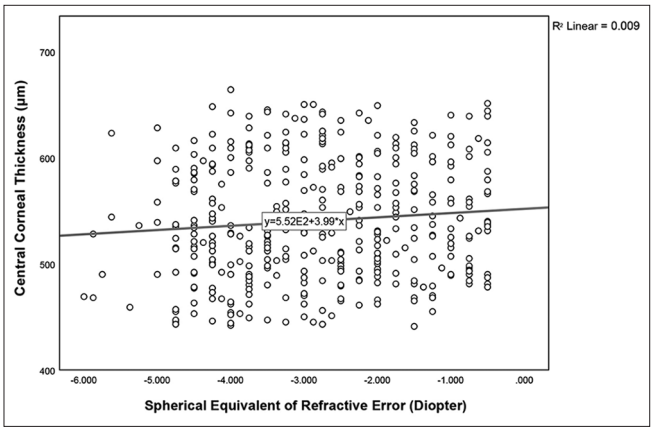

Figure 3: Scatter plot showing the correlation between mean central corneal thickness and spherical equivalent; no correlation was observed between mean central corneal thickness and spherical equivalent (Pearson, $r = 0.095$, $P = 0.062$)

DISCUSSION

In this hospital-based study from South India, we evaluated the CCT measurements of young myopic individuals with mild-to-moderate myopia using NCSM and found no correlation between mean CCT and degree of myopia.

Population-based studies from India using UP for CCT measurements have reported significantly thinner corneas among Indians compared to Africans (530 µm),[21] Nepalese (539 µm),[22] Caucasians (540 µm),[23] and Chinese (542 µm).[24] Nangia *et al*. evaluated the distribution of CCT among adults aged 30+ from rural Central India using UP. Mean CCT among 9370 eyes studied was 514 ± 33 µm (range: 290–696 µm). CCT was associated significantly with younger age, male gender, and lower corneal refractive power ($P < 0.001$). However, no statistically significant association was found between CCT and refractive error ($P = 0.54$).[12] Vijaya *et al*. evaluated 6754 adults aged 40+ from South India using UP and found the mean CCT to be 511.4 ± 33.5 µm.[16]

A hospital-based, prospective study involving 156 participants from South India, with a mean age of 29.27 years and mean refractive error of −3.10 D revealed a mean CCT value of 533.87 µm using UP. CCT had a positive correlation with axial length and negative correlation with SE, suggesting that axial

myopes tend to have thicker corneas.[10] Kunert *et al*. measured the CCT of 615 myopic patients of Indian origin (aged 18+) before laser *in situ* keratomileusis with UP as well as Orbscan scanning-slit topography/pachymetry.[25] Mean CCT reported was 519.92 ± 33.36 µm (range: 420–640 µm) using ultrasound method and 518.23 ± 31.03 µm (range: 428–607 µm) using Orbscan. No significant differences were noted in the CCT values measured using these two methods. Lower CCT readings were observed in individuals with myopia −0.5 to −4.9 D compared to those with myopia ranging from −5 to −9.9 D.

Mean CCT measurements obtained with EM-3000 (NCSM) in our study were 540.53 ± 56.16 µm (range: 441–664 µm). Módis *et al*. reported that the CCT values obtained using EM-3000 NCSM were higher than that found using ultrasound pachymetry ($P < 0.0001$).[26]

It would not be appropriate to compare our CCT measurements with other studies from India because we measured CCT using noncontact specular microscopy EM-3000 while others have utilized ultrasound pachymetry. The operating principles behind these two instruments are entirely different which explains the variation in measured values. While UP measurements depend on the reflection of ultrasonic sound waves from the anterior and posterior corneal surfaces, NCSM measurements rely on the reflection of light. CCT may be under or overestimated due to high inter-device variations, and studies have shown poor inter-device agreement among CCT measurements taken with different instruments.[27,28]

Although ultrasound pachymetry is the gold standard for CCT measurements, it is a contact method that needs topical anesthesia and user skill with regard to the placement of the probe. Furthermore, studies have reported alteration in corneal thickness values after the application of local anesthetic eye drops.[29,30] Unlike ultrasound pachymetry, NCSM is noninvasive and provides reproducible measurements of CCT.

There was no significant association between CCT and gender or age in our study. The role of gender on CCT has been reported to be variable, with few studies showing thicker CCT in males,[18,31] while others have reported no significant differences between males and females.[32] Few studies in patients older than 40 years of age have reported a negative association between CCT and age.[16,21,33]

The effect of refractive error on CCT has been analyzed by several investigators with contrasting results. Our study results demonstrate that CCT does not correlate with the myopia of different grades. Our observations are in agreement with the majority of studies elsewhere.[12-15] Chen *et al*. correlated the CCT measurements and degree of myopia among 528 Taiwanese adults enrolled for myopic laser refractive surgery.[13] No statistically significant association was found between CCT and refractive error ($P = 0.49$). The authors also studied the relation between CCT and myopia by intraindividual comparison in myopic anisometropia. The mean myopic anisometropia was 3.09 ± 1.06 D in their series, and the CCT in more myopic eye was not significantly different from the other less myopic eye. The authors have concluded that the cornea does not thin in the same way as the sclera in myopic eyes. Similarly, Fam *et al*. evaluated 714 consecutive Chinese patients with mean SE of − 5.3 D (range: −17.5 to −0.625).[15] No correlation was found between CCT and the degree of myopia ($r = -0.13$, $P = 0.719$). Ortiz *et al*. studied the relationship between CCT as well as mid-peripheral corneal thickness (PCT) in 175 myopic participants using Orbscan II.[34] Participants were divided into three groups, namely myopia <−6 D ($n = 76$), -6 to -12 D ($n = 72$), and more than −12 D ($n = 27$). No statistically significant differences were found in both CCT and PCT between the groups ($P > 0.05$).

A recent study comparing the thickness of preocular tear film, corneal layers (epithelium, Bowman layer, stroma and Descemet's membrane-endothelium complex in the central cornea), and anterior sclera using anterior segment spectral-domain optical coherence tomography found no statistically significant differences between emmetropia and those with moderate-to-high myopia ($P > 0.05$).[35]

However, few authors have found a significant correlation between CCT and myopic refractive error. Kadhim and Farhood evaluated CCT measurements of 418 eyes of 209 healthy individuals using UP.[9] The mean CCT was 543.95 ± 32.58 µm. CCT measurements significantly negatively correlated with age and myopes were noted to have significantly thinner corneas than emmetropic individuals ($P = 0.019$). Chang *et al*. evaluated a total of 216 participants, with a mean age of 22.2 years and mean refractive error of −4.17 D using UP.[36] A significant correlation was observed between CCT and SE ($r = 0.16$, $P = 0.021$). Corneas tended to be thinner in more myopic eyes. The authors have concluded that a decrease in corneal thickness is one among the changes in the anterior segment of the eye as myopia progresses. In contrast, Pedersen *et al*. measured CCT in 57 emmetropes and 48 high myopes using a high-precision Haag-Streit optical low coherence reflectometry pachymeter.[37] No statistically significant differences were noted between myopic participants and emmetropes (527.7 ± 35 µm versus

[Downloaded free from http://www.kjophthal.com on Thursday, June 4, 2020, IP: 192.168.10.239]

538.6 ± 32.1 μm), suggesting that the process by which myopia progresses does not influence the central cornea to a measurable degree.

The wide discrepancy in the observed results can be attributed to the varied age groups of patients, smaller sample sizes, nonelimination of contact lens wearers as well as the influence of diurnal variation, and use of pachymeters with variable reproducibility. The relatively new NCSM EM-3000 (Tomey, Japan) used in this study has been suggested to have high intraoperator repeatability in normal corneas.[27]

Our study has a few limitations. Observations are from a single-center, and axial length was not measured to differentiate axial myopia from other causes for myopia. However, we intentionally excluded patients older than 40 years to eliminate index myopia. To the best of our knowledge, this is the first study from India using NCSM to evaluate CCT measurements among myopic individuals.

CONCLUSION

In summary, we evaluated CCT measurements using noncontact specular microscopy in a cohort of young individuals with mild-to-moderate myopia. The mean CCT values did not correlate with myopic SE. Further studies with a larger sample size and different grades of myopia are needed to better understand the relation between myopia and CCT.

Evaluation of Resistive Index of Orbital Vessels Using Color Doppler Imaging in Patients with Type 2 Diabetes Mellitus

Vikrant Kanagaraju[1], K. Divya[2]*, M. Raajaganesh[2], B. Devanand[1]

[1]Department of Radiology, PSG Institute of Medical Sciences and Research, Coimbatore, Tamil Nadu, India, [2]Department of Ophthalmology, PSG Institute of Medical Sciences and Research, Coimbatore, Tamil Nadu, India

Abstract

Background: Resistive index (RI), derived from color Doppler imaging (CDI), is a marker of vascular resistance used widely in varied clinical settings. The aim of this study was to analyze the association between RIs of the orbital vessels in a pure cohort of type 2 diabetic patients with or without retinopathy using CDI. **Methods:** Fifty patients having type 2 diabetes and 50 age-matched controls were evaluated in this prospective study. Diabetic retinopathy (DR) was diagnosed based on seven-field stereo fundus photography and diabetic patients were divided into two. Patients with no DR ($n = 26$) were taken as Group 1, while patients with DR ($n = 24$) were taken as Group 2. CDI was performed and the RIs of the ophthalmic artery (OA), posterior ciliary artery (PCA), central retinal artery (CRA), and central retinal vein (CRV) were measured. **Results:** Significant differences were observed in the mean RI values of all orbital arteries between controls and patients with DR ($P < 0.05$). Comparison of RI values between controls and Group 1 showed no significant differences. Mean RI values of the PCA and CRA were found to be significantly higher in the patients in Group 2 than in Group 1 ($P = 0.03$ and $P < 0.001$, respectively). The duration of diabetes correlated with the mean RI of all the orbital vessels. RI of the CRA was a reliable predictive indicator for DR ($P = 0.001$). **Conclusion:** RIs of the orbital arteries are significantly higher in patients with DR. RI of the orbital vessels can be a potentially useful biomarker in the early diagnosis and follow-up of patients with DR.

Keywords: Color Doppler ultrasonography, diabetic retinopathy, vascular resistance

Introduction

Color Doppler imaging (CDI) is a convenient noninvasive method that gives information about the velocity of blood and vascular resistance at various sites of complex vasculature using simultaneous B mode ultrasound and Doppler images. The resistive index (RI), calculated from CDI, is a universally used measure of resistance to the arterial blood flow. In the recent past, RIs of the orbital arteries have been studied extensively to gain diagnostic and prognostic insight into a variety of clinical conditions, such as chronic obstructive pulmonary disease, hypertension, chronic kidney disease, and diabetes-related micro and macrovasculopathies.[1-5]

Usefulness of RI of the retrobulbar vessels in risk stratification and management of ophthalmic diseases such as diabetic retinopathy (DR), age-related macular degeneration, glaucoma, retinal vein occlusion, and thyroid-associated orbitopathy has been documented in the literature.[6,7]

Several studies have evaluated the RI of the retrobulbar vessels in diabetic patients with or without retinopathy and have shown inconsistent results. While few studies have shown significant correlation between RI of the orbital vessels and severity of DR,[8,9] few others suggest that the hemodynamic alterations observed in the orbital arteries reflect macrovascular changes and are not related to DR.[5,10] The observed inconsistencies can be attributed partly to the differences in sample sizes, patient characteristics, duration of diabetes, methods of assessment of DR, and probe positions used for color Doppler

measurement. Further, most of these studies included patients with comorbidities such as hypertension and coronary artery disease as well as those patients on cardiac or antihypertensive drugs, which might alter the vascular resistance.

The aim of this study was to analyze the association between RIs of the orbital vessels in a pure cohort of type 2 diabetic patients with or without retinopathy using CDI.

Materials and Methods

This prospective study was conducted between March 2017 and May 2019 from a tertiary care institution in South India. The institutional human ethical committee approval was obtained before the initiation of the study (IRB approval number: 16/325), and the principles of Declaration of Helsinki were adhered to. Informed, written consent was obtained from all the study participants. Fifty consecutive patients of type 2 diabetes (as per definition of the American Diabetes Association) were recruited for the study. Exclusion criteria were the presence of associated systemic hypertension, nephropathy, dyslipidemia, and cardiovascular diseases. Patients on medications known to affect systemic hemodynamics such as angiotensin-converting enzyme inhibitors, calcium channel blockers, and antimigraine drugs were excluded. Patients with a history of any ocular disease that might affect ocular blood flow such as retinal diseases, high myopia, glaucoma, previous ocular surgery, or panretinal photocoagulation were also excluded from the study. A control group of 50 age-matched subjects were included. None of the controls had any ocular or systemic disease.

Data regarding age, gender, body mass index (BMI), duration of diabetes and antidiabetic medications were obtained from all the study participants. Blood pressure and serum glycosylated hemoglobin (HbA1c) levels were determined.

All participants underwent a comprehensive eye examination and the presence/absence of retinopathy was diagnosed through dilated fundus examination and 30° stereoscopic fundus photograph of seven standard early treatment DR study fields using a digital fundus camera (TRC-50 DX Mydriatic Retinal Camera; Topcon Medical Systems, Oakland, NJ, USA). Diabetic patients were divided based on retinopathy into two groups. Group 1 contained patients with no DR; Group 2 included patients with DR. One eye (right eye, unless another ocular pathology was identified) was included from each study participant.

A masked expert radiologist performed CDI of the eye for all study participants using a color Doppler unit and a 12–5 MHZ linear-array transducer (Philips iU22 xMATRIX ultrasound system). The CDI was performed with patients lying in the supine position with a 30° head tilt and any undue pressure on the eye was avoided. Examiner's hand was rested on the orbital margin, and sterile coupling gel was applied over closed eyelids. Angle of the transducer was taken as 30°–60° during the examination. CDI was performed after exclusion of any other ocular or orbital pathologies by B mode, and optic nerve was considered as a reference for all further measurements. The velocity of blood flow in the ophthalmic artery (OA) was measured 20–30 mm behind the globe after crossing of the optic nerve in the nasal aspect. Blood flow velocity in the central retinal vein (CRV) and central retinal artery (CRA) was measured within the optic nerve around 5 mm behind the posterior margin of the eyeball. Blood flow velocity from the temporal branch of the short posterior ciliary artery (PCA) was determined approximately 5–10 mm posterior to the globe. The peak systolic velocity (PSV) and end diastolic velocity (EDV) measurements were taken for OA, CRA, PCA, and CRV. With the help of PSV and EDV, we calculated the vascular resistance based on the RI using Pourcelot's formula:

$$RI = (PSV - EDV)/PSV.$$

Statistical analysis

Statistical analysis was carried out using Statistical Package for the Social Sciences (SPSS, SPSS Inc., Chicago, IL, USA) Version 24. Data were reported as mean ± standard deviation. The normality of data distribution was assessed by Kolmogorov–Smirnov test. One-way analysis of variance with a *post hoc* Bonferroni was used for analysis of normally distributed continuous data. Kruskal–Wallis analysis was used for analyzing nonnormally distributed data. Bivariate analysis using Pearson's correlation coefficient was used to study the relationship of RIs with biochemical and demographic variables of patients with diabetes. Receiver operating characteristic (ROC) curve analysis was used to explore the predictive indicators of DR. A $P < 0.05$ (two-tailed) was considered statistically significant.

Results

The study consisted of 51 males and 49 females. The age of the participants ranged from 41 to 76 years. Duration of diabetes ranged between 6 months and 20 years. Among the diabetic patients studied, 26 had no DR and constituted Group 1. Group 2 consisted of 24 patients with DR. In Group 2, three patients had mild nonproliferative DR (NPDR) characterized by only few microaneurysms, seven had moderate NPDR (presence of more than just microaneurysms but less than severe NPDR), six had severe NPDR (presence of more than 20 intraretinal hemorrhages in each of four quadrants or definite venous beading in 2+ quadrants or prominent intraretinal microvascular abnormalities in 1+ quadrant), and eight had proliferative DR (presence of neovascularization of disc or elsewhere in the retina).

There were no statistically significant differences in the age, BMI, and blood pressure between controls and diabetic groups. Duration of diabetes and HbA1c levels were found to be significantly increased in Group 2 patients with DR ($P < 0.001$). Significant differences were observed in the RI values of all orbital arteries between controls and diabetic groups. Table 1 shows the demographic data and clinical attributes of controls and diabetic subjects.

[Downloaded free from http://www.jmuonline.org on Monday, June 28, 2021, IP: 10.232.74.27]

Subgroup analysis with *post hoc* comparison revealed significantly higher RI values in OA, PCA, and CRA in Group 2 compared to controls ($P < 0.001$, $P < 0.001$, and $P = 0.03$, respectively). Comparison of RI values between Group 1 and controls showed no significant differences. When diabetic Groups 1 and 2 were compared, statistically significant differences were observed in the mean RI values of CRA and PCA ($P < 0.001$ and $P = 0.03$, respectively).

In bivariate analysis, the mean RI values of all orbital vessels, namely OA, CRA, PCA, and CRV, had a significant correlation with the duration of diabetes ($R = 0.396$, $P < 0.001$; $R = 0.282$, $P = 0.005$; $R = 0.334$, $P = 0.001$; and $R = 0.290$, $P = 0.003$, respectively) [Figure 1]. In addition, the mean RI of the OA correlated significantly with HbA1c levels ($R = 0.321$, $P = 0.001$) [Figure 2].

ROC analysis showed that the RI of CRA was a definitive predictive indicator for DR. RI of the CRA ≥ 0.79 indicated the existence of DR with a sensitivity of 75% and a specificity of 73% (area under the curve = 0.780 [95% confidence interval: 0.650–0.909]) [Figure 3].

Discussion

DR, a common microvascular complication of diabetes, is one of the leading causes for preventable blindness in people of the working age.[11] There has been conflicting evidence on the ocular hemodynamics as to whether blood flow is increased or decreased in diabetics. Curtis *et al*. have proposed a hemodynamic framework which states that there is an initial reduction in the perfusion of retina before the onset of DR which later increases as DR progresses.[12]

The various hematological changes observed in diabetes such as increased aggregation of erythrocytes and platelets, increased blood viscosity, and reduced deformability of

Table 1: Demographic and clinical characteristics of controls and diabetic subjects

Characteristic	Controls ($n=50$)	Group 1 ($n=26$)	Group 2 ($n=24$)	*P*
Mean age (years)	56.58±8.81	54.85±8.52	54.42±7.84	0.52

erythrocytes contribute to increased peripheral vascular resistance.[13] RI, an indirect measure of vascular resistance, can be useful to identify individuals at higher risk for developing DR. Further, RI, being independent of Doppler angle, has been shown to be reliable and reproducible with least coefficient of variation.[14]

Our study results demonstrate that significant changes occur in the RIs of the orbital vessels in patients with diabetes. The orbital vascular resistance (as reflected by RI) was found to be significantly increased in patients with DR as compared to controls and those in Group 1. Our observations are in agreement with certain other published studies.[15,16]

We observed no significant differences in the mean RI values between controls and those without DR. Our findings are similar to that of Basturk *et al*., who evaluated the RI of the orbital arteries in type 2 diabetics with microalbuminuria. No significant differences were observed in the mean RIs of OA, CRA, and PCA between controls and no DR group.[9]

In contrast, Dimitrova *et al*. have noted higher RI in the PCA in patients with no DR than controls.[17] However, their study included patients with hypertension and longer duration of diabetes than ours. In patients with hypertension, the RI of the PCA is reported to be high and correlates with duration of hypertension.[18] Moreover, CDI was performed in erect posture, which might have influenced the results. Few other investigators have noted increased RI values in the OA and CRA in patients with diabetes but without DR compared to that of controls, suggesting that even before the appearance of overt DR, there is increased resistance to blood flow in the peripheral vascular bed.[19,20]

We found significantly greater RI in the PCA and CRA ($P = 0.03$ and $P < 0.001$, respectively) in patients with DR compared to those without DR. While the inner layers of the retina are perfused by the CRA, the choroidal vasculature (derived from PCA) is responsible for the nourishment of outer retina. The various pathological changes observed in DR, such as loss of pericytes, thickening of the capillary basement membrane, and vascular smooth muscle cells, lead to compromised arteriolar integrity and autoregulation of blood flow. Loss of capillaries is critical to the pathogenesis of progressive retinal ischemia in DR and is a ubiquitous retinal finding from histopathological specimens.[21] Dropout of capillaries could be responsible for the increased vascular resistance observed in the RI of CRA and PCA in patients with DR. Further, the RI of the CRA was found to be a reliable predictive indicator of DR in our study. In this context, our findings are partly in agreement with that of Krasnicki *et al*., who have noted significant differences in the RI of CRA in subjects with DR and concomitant coronary artery disease.[5] The CRA, one of the major feeding vessels of the retina, reflects the identified vascular changes that have been associated with DR more sensitively. It has been suggested that hemodynamics in OA, a medium-sized muscular artery with many branches, is unlikely to be influenced by isolated alterations in blood flow in one of the branches.[22]

However, with progression of DR, the RI of the OA can eventually increase due to ensuing vascular changes related to diabetes in both retinal and choroidal vasculature.

Our finding of positive correlation between RI of all orbital vessels and the duration of diabetes is in concordance with that of Karami *et al*.[23] With prolonged duration of diabetes, alterations in blood vessel diameter and perfusion pressure occur due to disturbed autoregulatory mechanisms, subsequently leading to changes in the resistance of all retrobulbar vessels. We identified a statistically significant correlation between RI of the OA and the levels of HbA1c ($P = 0.001$). Clermont *et al*. have demonstrated reduction in the blood flow to retina with increasing HbA1c in subjects with type 1 diabetes without DR.[24]

Nagaoka *et al*. evaluated subjects with type 2 diabetes for changes in the retinal circulatory parameters using laser Doppler velocimetry and found significantly higher HbA1c in patients with the least retinal blood flow quartile, suggesting that poor glycemic control is associated with lowering of the retinal blood flow.[25]

[Downloaded free from http://www.jmuonline.org on Monday, June 28, 2021, IP: 10.232.74.27]

Our study has several strengths. None of the patients had any associated vascular diseases such as hypertension. The presence of DR was assessed through seven-field stereo fundus photography for accuracy. A single experienced radiologist performed the CDI studies of the entire study participants, thereby eliminating interobserver variability. All examinations were performed with least pressure on the globe.

Limitations of our study include cross-sectional design and a small sample size. However, we intentionally excluded patients with other comorbid conditions to focus the effects of diabetes on retrobulbar circulation. Subgroup analysis of patients with different stages of retinopathy could not be performed because of limited sample size.

Conclusion

RIs of the orbital arteries are significantly higher in subjects with DR. RI of the orbital vessels can be a potentially useful biomarker in the early diagnosis and follow-up of patients with DR. This may be particularly helpful in patients with opacities in the ocular media.

Pseudotumor Cerebri Complicating Multisystem Inflammatory Syndrome in a Child

Karuppannasamy Divya[1], Chellappan Indumathi[2], Kanagaraju Vikrant[3], Sundaram Padmanaban[1]

[1]Department of Ophthalmology, PSG Institute of Medical Sciences and Research, Coimbatore, Tamil Nadu, India, [2]Department of Pediatrics, PSG Institute of Medical Sciences and Research, Coimbatore, Tamil Nadu, India, [3]Department of Radiology, PSG Institute of Medical Sciences and Research, Coimbatore, Tamil Nadu, India

Abstract

Purpose: To report a case of pseudotumor cerebri (PTC) in a child associated with multisystem inflammatory syndrome in children (MIS-C), associated with presumed coronavirus disease 2019.

Methods: A previously healthy 11-year-old female child presented with a 4-day history of fever, headache, vomiting, and loose stools. Laboratory investigations revealed neutrophilic leukocytosis, and markers of inflammation (C-reactive protein, ferritin, and interleukin-6) were significantly elevated. Pharyngeal swab for severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) by polymerase chain reaction was negative while anti-SARS-CoV-2 antibody was highly reactive. Ophthalmic evaluation for transient visual obscurations during hospital course revealed swelling of the optic disc in both eyes. Spectral-domain optical coherence tomography and ultrasonography confirmed the ophthalmoscopic findings. There was no neurologic deficit. Magnetic resonance imaging of the brain and magnetic resonance venogram revealed no structural lesion. The opening pressure of cerebrospinal fluid (CSF) was 336 mm of water, and CSF composition was normal.

Results: A diagnosis of PTC associated with MIS-C was made, and the child was treated with oral acetazolamide. Edema of the optic disc regressed following therapy, and the child is under follow-up.

Conclusions: PTC can occur in association with MIS-C. Clinicians need to be aware of this potential neuro-ophthalmic complication in MIS-C. Prompt diagnosis and treatment can prevent visual loss.

Introduction

Pseudotumor cerebri syndrome (PTCS) is a disorder characterized by increased intracranial pressure of unclear etiology that carries significant morbidity and limited therapeutic options. PTCS can be primary otherwise called idiopathic intracranial hypertension (IIH) or secondary, attributable to a number of medical conditions and drugs. This neurologic syndrome predominantly affects obese women of reproductive age group, and clinical features include symptoms and signs of raised intracranial pressure with normal cerebrospinal fluid (CSF) composition and no structural abnormality on brain imaging.[1] PTCS is relatively uncommon in children and is associated with variable risk factors and clinical presentation.[2] We report a case of PTCS in a child associated with multisystem inflammatory syndrome in children (MIS-C), temporally associated with coronavirus disease 2019 (COVID-19).

abdominal pain, and loose stools. There was associated lethargy but no history of seizures, altered sensorium, or respiratory symptoms. There were no sick contacts. At admission, the child had a temperature of 39°C, heart rate of 112 beats/min, and oxygen saturation of 100% on room air. Body mass index was 16 kg/m^2. Physical examination was unremarkable except for bilateral conjunctival congestion. Investigations revealed decreased hemoglobin, leukocytosis with neutrophilia, and elevated inflammatory markers including ferritin, interleukin-6 (IL-6), and C-reactive protein. Blood and urine cultures were negative, and liver function tests were found to be normal. Nasopharyngeal and oropharyngeal swabs for severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) by real-time polymerase chain reaction (RT-PCR) were negative. Serologic testing for SARS-CoV-2 antibodies by chemiluminescence immunoassay was highly reactive (observed titer – 212, ≥1 being labeled reactive) suggestive of SARS-CoV-2 infection. Table 1 shows the laboratory parameters. Echocardiogram was normal. On day 3 of admission, the child complained of transient obscurations of vision lasting for a few seconds associated with change in posture, and was referred for ophthalmic consultation.

On examination, uncorrected visual acuity was 20/20, and color vision was normal in both eyes. Anterior segment examination was unremarkable, and pupillary responses were normal. Extraocular movements were full. Fundus examination revealed optic disc swelling in both eyes [Figure 1a]. Neurologic examination was otherwise normal. Visual field evaluation by automated perimetry (Humphrey field analyzer) was found to be unreliable due to extensive fixation losses. Spectral-domain optical coherence tomography (OCT) showed increased thickness of peripapillary retinal nerve fiber layer (RNFL) in both eyes in all the four quadrants confirming edema of the optic disc [Figure 2a]. Magnetic resonance imaging of the brain and magnetic resonance venography (MRV) revealed normal ventricles, brain parenchyma, and venous sinuses. Transorbital ultrasound revealed bulging optic disc in both eyes. The optic nerve sheath diameter (ONSD) measurements obtained 3 mm posterior to the globe were found to be 5.6 mm in the right eye and 6 mm in the left eye [Figure 3a]. Lumbar puncture revealed a CSF opening pressure of 336 mm of water. CSF cultures were negative, and biochemistry was normal.

Since the child was hemodynamically stable and not hypoxic (SpO_2 100% on room air) at admission as well as during hospital course, she was managed with empiric broad-spectrum antibiotic therapy (intravenous ceftriaxone 2 g for 7 days) along with supportive care for fever (paracetamol) and loose stools (intravenous fluid replacement). As serial IL-6 and serum ferritin showed declining trend, the child was treated only with supportive measures. A diagnosis of pseudotumor cerebri (PTC) associated with MIS-C was made, and the child was started on oral acetazolamide 500 mg twice daily. By 4 weeks, headache and transient visual obscurations had subsided. Visual acuity remained 20/20, and fundus examination revealed resolving disc edema. The dose of oral acetazolamide was reduced to 250 mg thrice daily. At her last visit, 7 weeks since her initial presentation, she was found to have visual acuity of 20/20 and resolved disc edema in both eyes [Figure 1b]. Follow-up OCT revealed normalization of peripapillary RNFL thickness [Figure 2b]. The ONSD measurements were found to be 4 mm in both eyes at follow-up [Figure 3b]. The dose of acetazolamide has been tapered further, and she is under follow-up.

Table 1: Laboratory parameters of the patient and reference range

Parameter	Value	Reference range
Hemoglobin (g/dL)	10.5	11.5-15.5
White blood cell count (10^3/μL)	17	5-13
Neutrophil (%)	91.1	45-65
Lymphocyte (%)	7.5	32-52
Erythrocyte sedimentation rate (mm/h)	31	4-12
C-reactive protein (mg/dL)	39	<0.6
Serum ferritin (ng/mL)	352.4	7-140
IL-6 (pg/mL)	197.8	<7

Discussion

MIS-C, also called pediatric inflammatory multisystem syndrome temporally associated with SARS-CoV-2, is a life-threatening condition that can lead to multi-organ dysfunction and long-term sequelae. The clinical features of MIS-C include severe illness necessitating hospitalization, fever, and involvement of two or more organ systems, in combination with laboratory evidence of inflammation and laboratory or epidemiologic evidence of SARS-CoV-2 infection.[3] Our

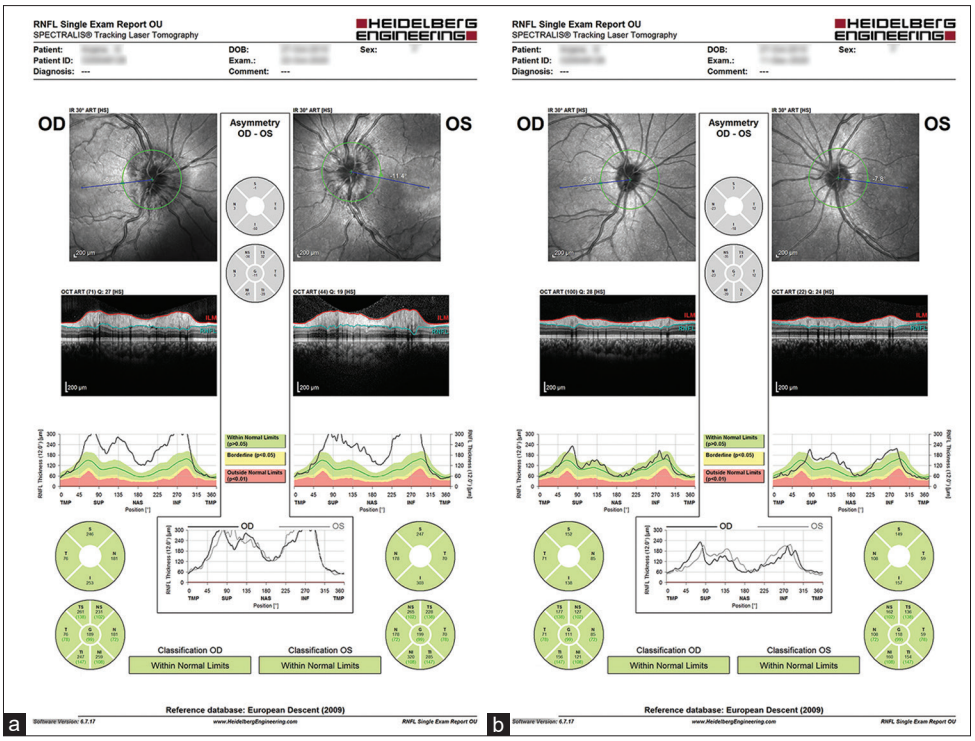

Figure 2: (a) Spectral-domain optical coherence tomography (SD-OCT) showing increased thickness of peripapillary retinal nerve fiber layer (RNFL) in both eyes. (b) SD-OCT both eyes at follow-up showing normalization of peripapillary RNFL thickness

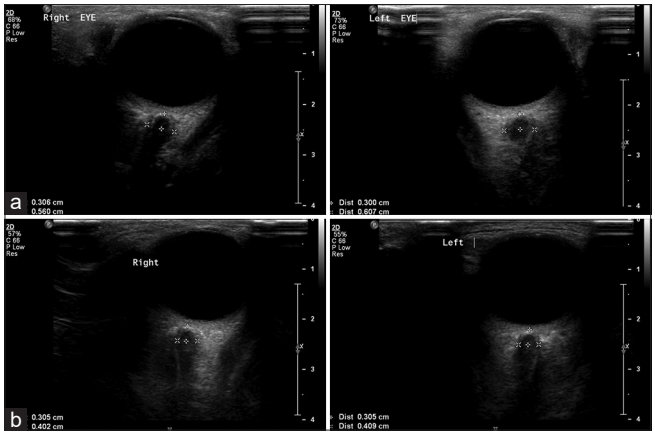

Figure 3: (a) Transorbital ultrasound showing increased optic nerve sheath diameter (ONSD) 3 mm posterior to inner scleral surface; 5.6 mm in the right eye and 6 mm in the left eye. (b) Transorbital ultrasound at follow-up showing normalization of ONSD; 4 mm in both eyes

patient was found to meet all the criteria specified in the Centers for Disease Control and Prevention and World Health Organization case definitions of MIS-C.[4,5]

The pathophysiology of MIS-C is unclear, and possible mechanisms include T-cell or antibody recognition of self-antigens resulting in autoantibodies, immune response against viral antigens expressed on infected cells and formation of immune complexes activating inflammation as well as viral superantigen sequences which activate host immune cells.[6] Dysregulated hyperinflammation is a critical event in the pathogenesis of MIS-C, and this condition is frequently associated with gastrointestinal symptoms and cardiovascular dysfunction.[7]

Although neurologic manifestations have been documented during acute phase of infection with SARS-CoV-2,[8,9] involvement of the central nervous system is uncommon in MIS-C. The neurologic features of MIS-C have been strongly suggested to represent a postinfectious immune response, and manifestations reported include headache, encephalopathy, and aseptic meningitis.[10]

We had not performed RT-PCR for SARS-CoV-2 on CSF since our patient showed evidence of previous infection with SARS-CoV-2 rather than current infection (pharyngeal swab was negative while antibodies to SARS-CoV-2 were present). Only one-third of cases of MIS-C have been reported to be positive by RT-PCR for SARS-CoV-2. The delayed presentation of MIS-C relative to the pandemic curve, a low proportion of cases who were SARS-CoV-2 positive by RT-PCR, and a high proportion who were antibody positive suggest that this inflammatory syndrome is not mediated by direct viral invasion but coincides with the development of acquired immune responses to SARS-CoV-2.[6] Previous studies have noted the absence of SARS-CoV-2 RNA in CSF analysis of COVID-19 patients with neurological symptoms suggesting that indirect mechanisms are responsible for neurologic manifestations in these patients.[11,12]

Although the symptoms of PTCS in children are similar to that of adults, the demographics vary, and children are reported to

have a higher incidence of secondary PTC. A distinct seasonal variation has been reported in the clinical presentation of IIH in prepubertal children, suggesting a possible association between IIH and concurrent infections in this age group.[13] Agraz *et al*. have noted a high incidence of atopy in their study cohort of children with PTC, suggesting that autoimmune component may play a role in pediatric population.[2]

To the best of our knowledge, four similar cases of PTCS associated with MIS-C (two case reports and a case series of two patients) have been reported in literature.[14-16] Although two patients had received therapy with doxycycline and steroids, the short course and recent initiation preclude the possibility of these medications contributing to increased intracranial pressure.

The mechanism behind the occurrence of PTCS in association with MIS-C is unclear. It has been postulated that increased intracranial pressure reflects systemic inflammation related to SARS-CoV-2 infection, resulting in central nervous system effects.[16] It is of interest to note that obesity, the most striking risk factor for PTCS, is associated with dysregulation of several inflammatory cytokines and aberrant glucocorticoid metabolism through manipulation of the enzyme 11-beta-hydroxysteroid dehydrogenase (11β-HSD).[17] 11β-HSD is a bidirectional enzyme that regulates prereceptor corticosteroid availability and glucocorticoid availability in the central nervous system that is one of the factors pivotal to intracranial pressure homeostasis. Among the two isoforms, 11β-HSD1 activates cortisol from cortisone while the isoform 11β-HSD2 inactivates cortisol. It is well established that several inflammatory cytokines such as tumor necrosis factor-α and ILs 1 and 6 are potent activators of 11β-HSD1.[18]

We speculate that PTC associated with MIS-C can be multifactorial, and one another possibility could be aberrant glucocorticoid metabolism as a result of cytokine storm and 11β-HSD1 activity. Increased 11β-HSD1 activity has been shown to influence the pathogenesis of PTC through manipulation of CSF dynamics at the level of choroidal plexus as well as arachnoidal granulations.[19] Further studies are warranted in this regard.

Few cases of isolated intracranial hypertension in association with active SARS-CoV-2 infection have been reported in adults. The proposed pathophysiologic mechanisms for intracranial hypertension include acute encephalitis, venous sinus thrombosis, intracranial venous congestion due to inflammation as a result of SARS-CoV-2 infection, and the associated coagulopathy as well as hyperviscosity state leading to impaired absorption of CSF.[20,21] The absence of clinical features such as altered sensorium/seizures and normal brain parenchyma evident on neuroimaging in our patient ruled out encephalitis. Normal MRV ruled out venous sinus thrombosis in our patient.

The other possible etiologies of swelling of optic disc in the setting of SARS-CoV-2 infection include optic neuritis, ischemic optic neuropathy, papillophlebitis, and retinal vein occlusion. The presence of normal visual acuity and color vision along with normal pupillary responses and the absence of associated retinal hemorrhages or venous tortuosity in our patient made us exclude these causes.

Prompt diagnosis and treatment of PTCS is essential since it can lead to irreversible visual loss. Although the pathophysiology remains unclear, clinicians should be aware of this potential complication with MIS-C. Fundus examination is valuable as part of a multidisciplinary approach toward management of MIS-C.

Declaration of patient consent

The authors certify that they have obtained all appropriate patient consent forms. In the form the patient(s) has/have given his/her/their consent for his/her/their images and other clinical information to be reported in the journal. The patients understand that their names and initials will not be published and due efforts will be made to conceal their identity, but anonymity cannot be guaranteed

Abstract:*Aim: To Analyse The Various Prognostic Factors Which Will Influence The Visual Outcome In Patients With Indirect Traumatic Optic Neuropathy. Design: Hospital Based Prospective Study. Materials And Methods: Patients More Than 20 Years Of Age, Admitted In Coimbatore Medical College Hospital With Head Injury And Diagnosed As Indirect Traumatic Optic Neuropathy Underwent Detailed Ophthalmic Evaluation Including Visual Acuity, Anterior Segment Examination, Colour Vision Testing, Visual Field Charting And Fundus Examination. Results And Conclusion: Visual Improvement Was Found To Be Good When Steroids Were Started Within 48 Hours Of Injury. It Was Also Observed That If Visual Improvement Did Not Occur Within 48 Hours Of Initiation Of Steroids, Further Visual Improvement Was Unlikely.An Initial Visual Acuity Of More Than Counting Fingers Was Associated With A Good Visual Prognosis.*
Key Words: Indirect Traumatic Optic Neuropathy, Initial Visual Acuity, Steroids

I. Introduction

Blindness Due To Trauma Is An Important Menace In The Industrialised World. Trauma Causes Various Manifestations In Eyes. It Can Be A Direct Mechanical Injury To The Eyes Or An Indirect Effect Due To The Transmission Of Forces Following Concussive Blow To Head Or Orbit. Optic Nerve Is An Important Structure Involved In Trauma And The Sequelae Of Optic Nerve Injury Is Severe As It Can Cause Permanent Visual Impairment[1]. Injury To The Optic Nerve Can Be Direct Or Indirect. Direct Injuries To The Optic Nerve Are Caused By Penetrating Trauma And Orbital Fractures.Indirect Injury, Being The More Common Type Is Due To The Transmission Of Force From The Blow To Head Or Orbit[1]. The Rise Of Road Traffic Accidents In The Industrialized World Has Led To An Increase In The Incidence Of Optic Nerve Injuries. There Have Been Various Studies Analysing The Causes Of Optic Nerve Injury And Most Of Them Have Concluded Motor Vehicle Accidents To Be The Most Common Cause Of Optic Nerve Injury[2,3]. The Initial Visual Acuity Is An Important Parameter To Be Assessed As It Influences The Improvement With Treatment. Results From Various Studies Show That The Improvement In Visual Acuity Following Treatment Was Better In Patients With An Initial Visual Acuity Of Perception Of Light Than In Patients With Visual Acuity Of No Perception Of Light.TheDiagnosis And Treatment Of Optic Nerve Injuries Can Be Challenging Especially In Unconscious Or Comatose Patients. Numerous Studies Have Been Published Comparing The Efficacy Of Various Modalities Of Management Of Optic Neuropathy I.E Conservative Management, Steroids Alone, Combination Of Steroids And Surgery, Surgery Alone. This Study Aims To Analyse The Prognostic Factors Influencing Visual Outcome In Patients With Indirect Traumatic Optic Neuropathy.

II. Materials And Methods

This Prospective Study Was Conducted In Patients More Than 20 Years Of Age, Admitted In Coimbatore Medical College Hospital With Head Injury And Diagnosed As Indirect Traumatic Optic Neuropathy During The Period Of August 2014-July 2015. A Total Of 50 Patients Were Included In The Study.
Study Design: HospitalBased Prospective Study

Study Location: Coimbatore Medical College Hospital, Coimbatore, Tamil Nadu, India, Which Is A Tertiary Care Centre And Regional Referral Centre.
Study Duration: August 2014 – July 2015
Sample Size: 50
Sample Selection: Patients To Be Included In The Study Were Selected Among Those Admitted In Trauma Ward With Head Injury. Ophthalmic Examination Was Done And Those Patients Diagnosed As Indirect Traumatic Optic Neuropathy Were Selected For The Study, Based On Inclusion And Exclusion Criteria.

Inclusion Criteria:
1. Patients With Head Injury
2. Age More Than 20 Years
3. Normal Anterior Segment Anatomy
4. Diagnosis Of Indirect Traumatic Optic Neuropathy

Exclusion Criteria:
1. Penetrating Eye Injury And Globe Rupture
2. Blunt Trauma To The Globe
3. Patients With Optic Canal Fracture
4. Past History Of Eye Diseases, Surgery
5. History Of Loss Of Consciousness For More Than 72 Hours
6. History Of Diabetes Mellitus, Hypertension, Cardiac Disorders, Neurological Disorders
7. Patients Not Willing For Regular Follow Up
8. Comatose Patients

III. Procedure Methodology:

After Getting Informed Consent From The Patients In Their Own Language, Detailed History Was Elicited From The Patients Or Their Relatives In Case Of Comatose Patients, Using A Questionnaire Which Included Characteristics Such As Age And Sex Of The Patient; Time And Cause Of Injury; Loss Of Consciousness And Its Duration If Present, With Associated Seizures, ENT Bleed; Immediate Amaurosis Following Injury; Previous Eye Disorders, Refractive Error Or Surgery; Previous Head Injury Or Neurological Disorders; Past History Of Diabetes Mellitus, Systemic Hypertension, Any Other Systemic Disorders.

General Examination Of The Patient Was Done Including Assessment Of Cardiovascular Status And Respiratory Status, BP Measurement, Detailed Neurological Evaluation. Injuries Over The Forehead And Temple Were Noted.

Detailed Ophthalmic Examination Was Done Which Included Uncorrected And Best Corrected Visual Acuity In Both Eyes, Anterior Segment Examination Using Slit Lamp, Detailed Pupillary Examination, Extraocular Movements, Detailed Fundus Examination Using Direct And Indirect Ophthalmoscope, Colour Vision Testing Using Ishihara Chart, And Visual Field Assessment Using Automated Perimetry Or Confrontation Method.

Investigations Done Included Blood Investigations Such As Blood Count, Blood Sugar And Renal Function Tests; Electrocardiogram; X Ray Orbit; CT, MRI Scan Of The Orbit.

After Detailed Evaluation, Patients With Indirect Traumatic Optic Neuropathy Were Started On Treatment With High Dose On Injection IV Methyl Prednisolone, After Ruling Out Contraindications For The Same, And With The Consent Of Neurosurgeon.

The Treatment Regimen Of Steroids Is As Follows:

Injection Methyl Prednisolone 1gm IV OD X 3 Days Followed By Tab. Prednisolone 1mg/Kg/Day Per Oral X 11days. After 11 Days, The Steroids Were Tapered And Stopped.

The Patients Were Monitored By Testing Visual Acuity Using Snellen's Visual Acuity Chart At 24, 48 And 72 Hours After Starting High Dose Methyl Prednisolone Therapy. Patients Were Examined Daily During The First Week With Recording Of Visual Acuity. The Patients Were Followed Up Weekly During The First Month And Monthly Once For Three Months. During Follow Up, Visual Acuity, Anterior Segment Examination, Pupillary Assessment, Fundus Examination Was Done Along With Colour Vision And Visual Field Charting.

Improvement In Best Corrected Visual Acuity By One Line After Treatment, From The Baseline Visual Acuity Was Considered As Improvement In Vision.

Statistical Analysis:

At The End Of The Study Period, The Data Were Subjected To Statistical Analysis. The Differences In Quantitative Variables Between Groups Were Assessed By Unpaired Test. Comparison Between Groups Was

Made By Non-Parametric Mann Whitney Test. A Chi-Square Test Was Used To Assess Differences In Categoric Variables Between Groups.

III. Results

Age Wise Distribution Of The 50 Patients Showed That Majority Of Patients Were In The 20 – 40 Years Age Group, With 30% In 20 – 30 Years Age Group And 24 Patients (48%) Were In 31 – 40 Years Age Group. Patients In 41 – 50 Years Age Group Constituted 14% Of Total Cases, Whereas Only 4 Patients (8%) Were More Than 50 Years Of Age. The Mean Age Of Patients Studied Was 35 Years With Minimum Age Of 20 Years And Maximum Age Of 58 Years.

Table 1: Age Wise Distribution

Age Group	Number Of Patients	Percentage
20 – 30	15	30%
31 – 40	24	48%
41 – 50	7	14%
>50 Years	4	8%
Total	**50**	**100%**

Sex Distribution Showed All Patients In The Study To Be Males, With No Female Patients Being Diagnosed With Indirect Traumatic Optic Neuropathy During The Study Period.

Table 2: Sex Distribution

Gender	Number Of Patients	Percentage
Male	50	100%
Female	0	0%
Total	**50**	**100%**

There Was An Evidence Of Injury Over Forehead In 92% Patients. Among Them Abrasion Was The Most Common Constituting 48% Of The Total. Laceration Was Seen In 16 (32%) Patients And 8% Patients Had No Injury.

Table3: Injury Over Forehead

Injury	Number Of Patients	Percentage
Abrasion	24	48%
Laceration	16	32%
Contusion	6	12%
No Injury	4	8%
Total	**50**	**100%**

Best Corrected Visual Acuity Of Patients Was Assessed Using Snellen's Chart Immediately Following Injury. It Was Found That BCVA Was <6/60 In 38 (76%) Patients. In 17 (34%) Patients, Vision Was In The Range Of 6/60 – CFCF, Whereas 12 (24%) Patients Had Vision Of Hand Movements To Perception Of Light. 9 (18%) Out Of 50 Patients Had No Perception Of Light. Only 4(8%) Patients Had Vision Of 6/36, Whereas 8 (16%) Had Visual Acuity Of 6/60. No Patients Had Visual Acuity Better Than 6/36.

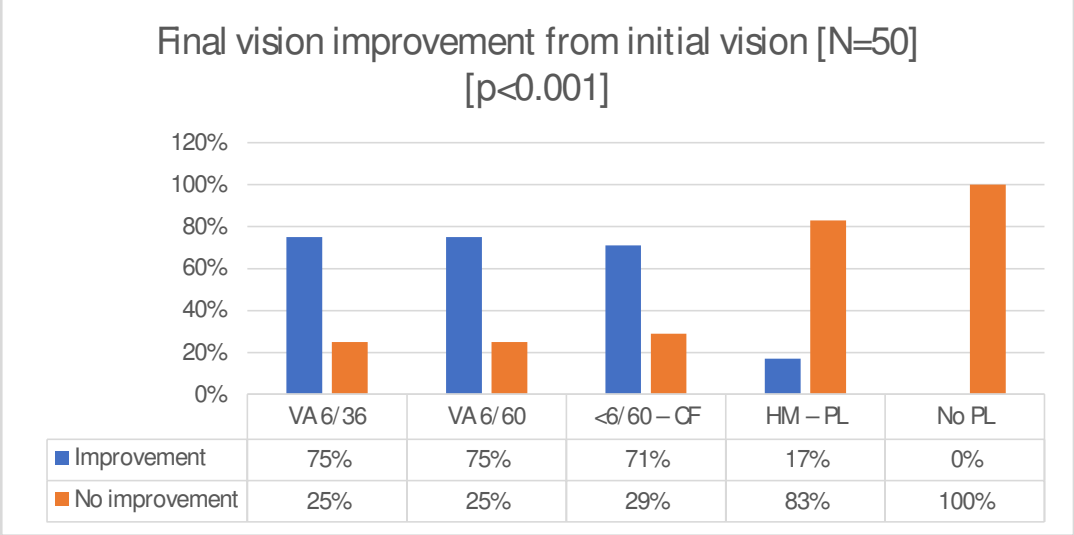
Table 4:BCVA At Presentation

Vision	Number Of Patients	Percentage
6/36	4	8%
6/60	8	16%
<6/60 – CFCF	17	34%
HM – PL	12	24%
No PL	9	18%
Total	**50**	**100%**

All Patients Diagnosed As Indirect Traumatic Optic Neuropathy Were Started On Steroids After Ruling Out Contraindications For The Same. Steroids Were Started In 8(16%) Patients Within A Period Of 12 Hours. In 18(36%) Patients It Was Started Between 12 – 24 Hours Whereas In 15 (30%) Patients It Was Started Between 25 – 48 Hours. Due To Delay In Admission, Steroids Could Be Started Between 49 – 72 Hours In 5(10%) And After 72 Hours In 4 (8%).

Table 5: Interval Between Injury And Starting Treatment

Duration	Number Of Patients	Percentage
<12 Hours	8	16%
12-24 Hours	18	36%



25-48 Hours	15	30%
49-72 Hours	5	10%
>72 Hours	4	8%
Total	**50**	**100%**

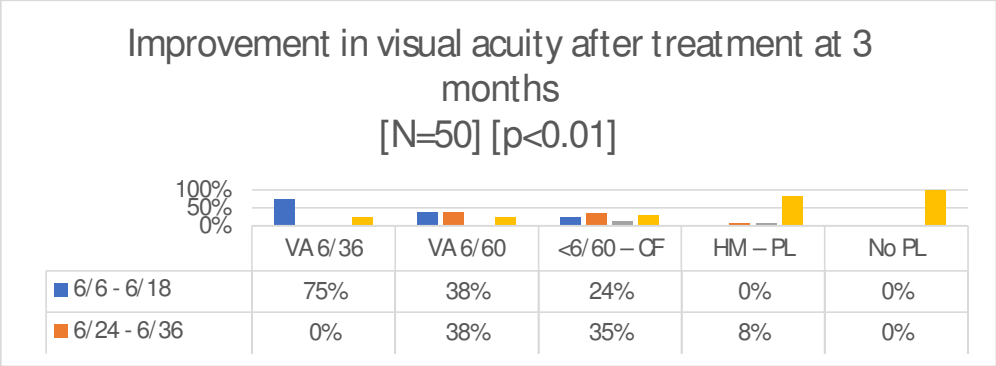
Analysis Of Improvement Of Visual Acuity In Patients In Our Study Showed That There Was No Visual Improvement In Patients Who Presented With Immediate Amaurosis Following Injury With No Perception Of Light. Only 2 Among The 12 Patients With Slightly Better Vision Ranging From HM To PL Showed Improvement In Vision Which Is Only 17% Of Patients In This Group. Among Patients With Initial BCVA Of 6/36 And 6/60 There Was Improvement In 75% Of Patients In Each Of These Two Group Of Patients. In The Group Of Patients With Initial BCVA Of 6/60 – CF There Was Improvement In 12 Among 17 Patients. There Was Significant Statistical Analysis Between Initial Visual Acuity And Visual Improvement At 3 Months With P Value Less Than 0.001.

Table6: Association Of Final Visual Improvement (At 3 Months Follow Up) With Initial BCVA

	Visual Acuity At Three Months			
Initial Vision	**Improvement**	**No Improvement**	**Total**	**Percentage**
6/36	3 (75%)	1 (25%)	4	8%
6/60	6 (75%)	2 (25%)	8	16%
<6/60 – CF	12 (71%)	5 (29%)	17	34%
HM – PL	2 (17%)	10 (83%)	12	24%
No PL	0 (0%)	9 (100%)	9	18%
Total	**23**	**27**	**50**	**100%**

Figure1:

Visual Improvement At 3 Months In All Patients Were Compared With Initial Visual Acuity. It Showed That Patients With Initial BCVA Of 6/36 And 6/60 Had Good Improvement Of BCVA Compared With Patients With Initial BCVA Of Less Than 6/60. All Patients With Initial BCVA Of 6/36 Who Improved With Therapy Showed Final BCVA Of 6/6 – 6/18. Final BCVA Improved To 6/6 – 6/36 In All Patients Who Had Initial BCVA Of 6/60 And Showed Improvement With Treatment. Among The 12 Patients Who Had Initial BCVA Ranging From HM – PL There Was Visual Improvement In Only Two Patients In Which One Showed Final BCVA Of 6/36 And The Other Patient Showed 6/60.



There Was No Visual Improvement In All Patients Without Initial Perception Of Light. The Analysis Showed Very Strong Statistical Correlation Between Baseline Visual Acuity And Final BCVA Achieved At 3 Months With P Value Less Than 0.001.

Table 7: Association Of Final BCVA With Initial Vision

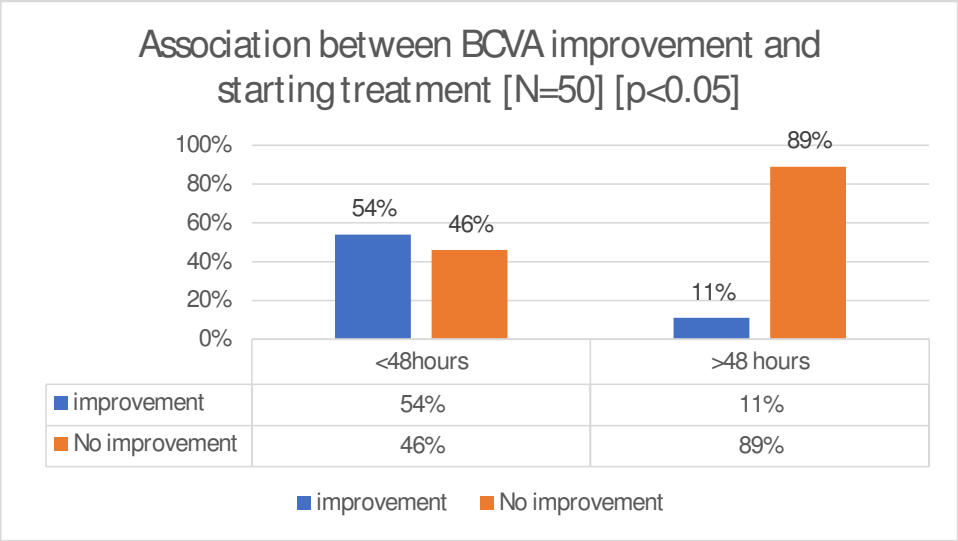
	Visual Acuity At Three Months Follow Up					
Initial Vision	**6/6 – 6/18**	**6/24 – 6/36**	**6/60**	**No Improvement**	**Total**	**Percentage**
VA 6/36	3 (75%)	0	0	1 (25%)	4	8%
VA 6/60	3 (38%)	3 (38%)	0	2 (25%)	8	16%
<6/60 – CF	4 (24%)	6 (35%)	2 (12%)	5 (29%)	17	34%

HM – PL	0	1 (8%)	1 (8%)	10 (83%)	12	24%
No PL	0	0	0	9 (100%)	9	18%
Total	**10**	**10**	**3**	**27**	**50**	**100%**

Figure2:

Patients With Indirect Traumatic Optic Neuropathy Were Treatedwith Full Course Of High Dose Steroids As Per Our Treatment Regimen.PatientsWere Regularly Followed Up And Best Corrected Visual Acuity Was Assessed Regularly. Improvement Of One Line In Snellen's Chart Wasconsidered As Improvement In Visual Acuity. According To That Criteria23 Patients Showed Improvement In BCVA At 3 Months, Constituting46% Of Study Population. But There Was No Visual Improvement In 27(57%) Of Patients In Spite Of Steroid Treatment**.**

Table 8: Improvement Of BCVA With Steroid Treatment



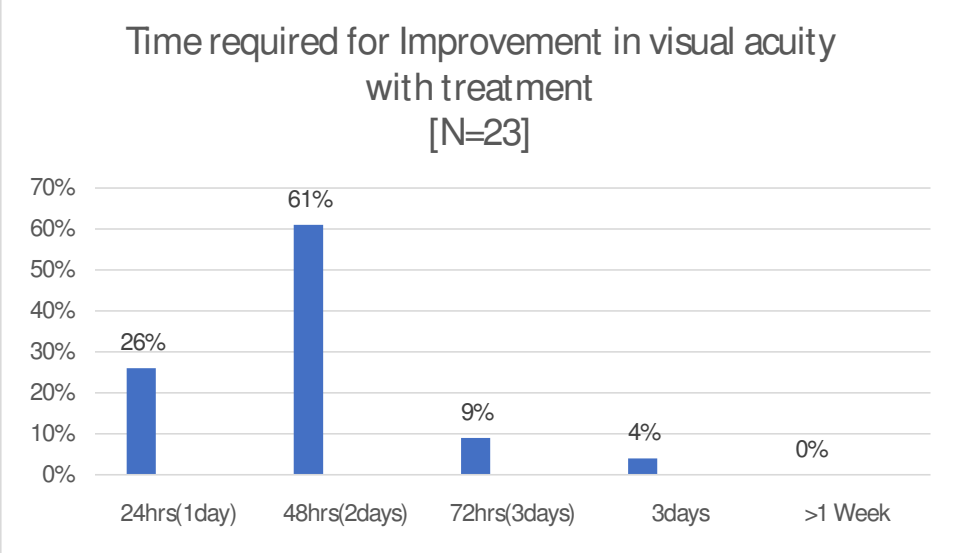
Status	**Number Of Patients**	**Percentage**
Improvement	23	46%
No Improvement	27	54%
Total	**50**	**100%**

There Was A Strong Statistical Association Between Improvement Of Visual Acuity At 3months And Duration Of Starting Steroid Treatment After Injury With P Value Of Less Than 0.05. Among The 41 Patients In Whom Steroid Treatment Was Started Before 48hours, There Was Improvement In 22 Patients Which Account For 54%. But Among The 9 Patients In Whom Steroids Was Started After 48hours There Was Improvement In Only 1 Patient.

Table 9: Association Between Final BCVA Improvement And Duration Of Starting Treatment

	Visual Acuity			
Duration	**Improvement**	**No Improvement**	**TOTAL**	**Percentage**
<48 Hrs	22	19	41	82%
>48 Hrs	1	8	9	18%
TOTAL	**23**	**27**	**50**	**100%**

Figure3:



Visual Acuity Improvement Was Assessed Every 24 Hours Following Initiation Of Steroid Treatment In All Patients. Analysis Showed That 6 Among The 23 Patients (26%) Showed Improvement Within First 24 Hours. Majority Of Patients (71%) Among Those With Improved Vision Showed Improvement On The Second Day Of Starting Treatment. Only 2 Patients Showed Improvement On The 3rd Day, While There Was Improvement In Vision In Only One Patient From 3 To 7 Days. Those Patients Who Did Not Show Improvement Of Vision In The First Week Of Starting Treatment Never Showed Improvement After First Week. The Chi Square Test Of This Analysis Showed A P Value Of More Than 0.05 Which Was Statistically Significant.

Table 10: Time Required For Initial BCVA Improvement After Initiation Of Treatment

Duration	**No. Of Patients**	**Percentage**	**Cumulative (%)**
24hrs(1day)	6	26%	26%
48hrs(2days)	14	61%	87%
72hrs(3days)	2	9%	96%
3days	1	4%	100%
>1 Week	0	0%	0%
Total	**23**	**100%**	

Figure 4:

IV. Discussion

Indirect Traumatic Optic Neuropathy Is Due To Closed Head Trauma Which Results In Transmission Of Forces From Forehead To The Optic Nerve In The Optic Canal Or In The Intracranial Portion Of The Optic Nerve. It Causes Severe Visual Morbidity In The Form Of Vision Loss, Field Defects, Colour Vision Defects.

The Diagnosis Of Indirect Traumatic Optic Neuropathy Is Based On The Clinical Finding Of Reduced Visual Acuity With Relative Afferent Pupillary Defect. The Diagnosis Is Mainly Clinical. The Role Of Imaging Is To Rule Out Causes Of Direct Injury To The Optic Nerve Such As Optic Canal Fracture Or Avulsion Of The Optic Nerve.

Treatment Options Of Traumatic Optic Neuropathy Include Conservative Management, Medical Management With High Or Mega Dose Steroids And Surgery. Various Studies Have Shown Variable Results With Different Treatment Options.

A Hospital Based Prospective Study Was Conducted To Analyse The Various Prognostic Factors Affecting The Final Visual Outcome In Patients With Indirect Traumatic Optic Neuropathy. Demographic Profile Showed That All The Patients In Our Study Were Males And The Most Of The Patients Belonged To The Second And Third Decade Of Life. Among The 50 Patients Studied, 78% Belonged To The Age Group Of 20 – 40 Years. Mean Age Of The Patients In Our Study Was 38. This Was Consistent With Other Studies Which Showed A Similar Age And Sex Distribution[4,5]. There Was A Slight Preponderance In The Involvement Of Right Eye, Which Accounted For 56% Of Cases With No Bilateral Involvement.

The Most Common Cause Of Indirect Traumatic Optic Neuropathy In Our Study Was Motor Vehicle Accidents Which Constituted 92% Of Patients. Among Motor Vehicle Accidents, Two-Wheeler Accidents Were The Most Common Constituting 84%. These Findings Were Consistent With The Studies Done By MatsuzakiEt Al[6] And Lee Et Al[5].

Best Corrected Visual Acuity Of All Patients Was Evaluated Following Injury. 76% Of Patients Had BCVA Less Than 6/60 While Only 8% Patients Had BCVA Of 6/36 And 16% Had BCVA Of 6/60. This Observation Was Similar To Other Studies[1].

High Dose Steroid Therapy Was Started In All Patients After Ruling Out Contraindications For The Same. In Conscious Patients, Steroid Therapy Was Started Soon As Possible Following Admission. In 16% Of Patients It Was Started Within 12 Hours. The Delay In Starting Steroid Therapy In Other Patients Was Either Due To Delay In Admission Or Delay In Recovery Of Consciousness. In 8% Of Patients, Steroid Was Started After 72 Hours. All Patients Were Followed Up Daily During The First Week And Periodically Thereafter.

Assessment Of BCVA At 3 Months Showed Visual Improvement In 46% Patients Who Were Started On Steroids. Improvement Of One Line Of Vision In Snellen's Chart Was Considered As Improvement In Visual Acuity. A Study By FujitamiEt Al[7], Levin Et Al[8], And International Optic Nerve Trauma Study[5]also Showed Improvement In Visual Acuity In 44%, 52% And 52% Patients Respectively.

There Was No Statistically Significant Association Between The Age Of The Patient And Final Improvement In Visual Acuity (P=0.563). This Implies That Age Does Not Influence The Final Visual Outcome. This Inference Was Similar To The Study By Wang Et Al[9].

There Was Found To Be No Statistical Significance Between Loss Of Consciousness Following Injury And Improvement In Visual Acuity. Studies Have Shown That Irrespective Of Level Of Consciousness, Patients Showed Improvement In Vision.

The Timing Of Initiation Of Steroids Following Injury Had An Influence On The Visual Outcome In Patients With Indirect Traumatic Optic Neuropathy. Among The 41 Patients Who Were Started On Steroids Within 48 Hours Of Injury, There Was Improvement In BCVA In 54% Of Them As Against 11% Who Were Started On Steroids After 48 Hours On Injury. The Association Between Time Of Initiation Of Steroids And Final Visual Improvement As Statistically Significant With P Value Less Than 0.05. These Results Were Consistent With Studies Done By SteiffEt Al[10] And MaurielloEt Al[11]. This Shows The Importance Of Starting Steroids As Soon As Possible And Possibly Within 48 Hours Of Injury.

Among The 23 Patients Who Improved With Steroids, 20 (40%) Of Them Improved Within 48 Hours Of Starting Steroid Treatment. After 48 Hours There Was Improvement In Only 6% And No Patients Showed Improvement After One Week Of Starting Steroids. There Was A Statistically Significant Association Of Poor Visual Improvement After 48 Hours Of Starting Steroid Therapy ($P<0.05$)[12]. This Result Suggests That Patients With No Improvement Within 48 Hours Of Starting Treatment Need Not Be Treated With Further Steroids. Surgical Decompression Can Also Be Considered In Patients With Indirect Traumatic Optic Neuropathy Who Do Not Show Improvement With Medical Management Within 48 Hours Of Initiation.

There Was A Strong Statistical Association Between Immediate Amaurosis Following Trauma And Absence Of Final Visual Improvement ($P<0.001$)[12]. It Was Also Evident That Patients With Initial Good Vision Had Better Final Visual Recovery Than In Patients With Poor Initial Visual Acuity. The Correlation Of Final Vision Achieved With Initial Visual Acuity Was Highly Statistically Significant ($P<0.001$)[4]. This Result Showed That There Will Be No Improvement In Visual Acuity In Patients With Initial Vision Of No Perception Of Light And The Visual Acuity Improvement Will Be Very Poor In Patients With Initial Vision Of Less Than

Counting Fingers. This Implies That There Is Not Much Use In Treating Patients With Very Poor Initial Vision With High Dose Steroids.

V. Conclusion

ThusitIs Concluded That Indirect Traumatic Optic Neuropathy Has A Better Visual Outcome When Treated With High Dose Systemic Steroid Therapy. Visual Outcome Was Better When The Treatment Was Initiated Within 48 Hours Of Injury. If Response To Treatment Was Not Apparent Within 48 Hours Of Starting Treatment, Improvement Is Unlikely To Occur. An Initial Visual Acuity Of More Than Counting Fingers Was Associated With A Better Visual Prognosis.

Abstract

Aim: To study and analyse the epidemiology of pterygium in a tertiary care centre. **Design:** Cross sectional observational study. **Materials and methods:** The patients more than 20 years of age, with true pterygium attending the outpatient clinic of Department of Ophthalmology of Coimbatore Medical College Hospital were included in the study. Data collection was done using a structured questionnaire which comprises of socio-demographic characteristics including age, sex, occupation and detailed history. The exact hours of sun exposure per day and the years of sun exposure were noted as well as any other ocular or systemic co morbid conditions like diabetes and hypertension. A complete ocular examination was done and recording of the uncorrected and best corrected visual acuity along with the degree of astigmatism was done with the help of automated keratometry. Tear film was assessed with Schirmer's test and tear film break-up time. **Results and conclusion:** Middle aged to elderly people were found to be more affected due to their prolonged exposure to inciting agents in the environment. There was no significant gender predilection, if the environmental factors are the same. Sunlight exposure was found to be a significant risk factor and dry eye played a contributory role. No co relation was found between development of pterygium and systemic diseases like diabetes and hypertension.

Key Word: true pterygium, sunlight, dry eye, astigmatism.

INTRODUCTION

Pterygium is one of the common ocular conditions found in middle aged and elderly individuals. It is a benign, degenerative and proliferative condition of conjunctiva and subconjunctival tissue, with potential to cause visual disturbances[10] It can be easily diagnosed and staged by clinical examination. The most important factor related to the development of pterygium is thought to be sunlight exposure[2,5]. Other contributing factors include dry eyes, smoking, prolonged outdoor activities, low socioeconomic status and high altitude[7]. Major complication is the obscuration of visual axis if it grows into the centre of the cornea. The development of irregular astigmatism due to flattening of the cornea in the horizontal meridian is another cause of decrease in vision[9]. Proper understanding of the epidemiology and risk factors of this condition is essential for planning appropriate measures to prevent its occurrence and thereby reducing the physical and financial burden to the society. This study aims to identify the risk factors of pterygium and specific associations and correlations if any.

MATERIALS AND METHODS

This cross-sectional observational study was done in patients more than 20 years of age, with true pterygium presenting to the outpatient clinic of Department of Ophthalmology, Coimbatore Medical College Hospital

How to cite this article: Thaialnayaki Vellaichamy, Padmanaban S, Swetha K. An analytical study on the epidemiology of pterygium in a tertiary care centre. *MedPulse International Journal of Ophthalmology*. May 2019; 10(2): 25-30.

during the period of one year. A total of 104 patients were included in the study.

Criteria for patient selection were as follows:

Inclusion criteria

- People of age group >20 years
- True pterygium
- Patients with other comorbid conditions like diabetes and hypertension
- Patients with known dry eye syndrome

Exclusion criteria

- Pediatric patients
- Patients with fundus pathology
- Glaucoma patient
- Pseudopterygium
- Injuries of eye
- Suspected ocular surface squamous neoplasia
- The patients who had asymmetrical pterygium in both eyes

METHODOLOGY

After getting informed consent, data collection was done using a structured questionnaire which comprises of socio-demographic characteristics including age, sex, occupation and detailed history. The exact hours of sun exposure per day and the years of sun exposure were noted as well as any other ocular or systemic co morbid conditions like diabetes and hypertension. Patients were grouped into outdoor and indoor workers according to the nature of their occupation. They were categorized as rural and urban population depending on their hometown. Previous history of trauma, smoking habits and alcohol intake were also documented. For the purpose of analysis, the patients coming from areas which were higher than 1000 meters from the sea level were considered as high altitude and less than 1000 considered as low altitude. During symptoms assessment, care was taken to find out if patient had any dry eye symptoms like irritation and burning sensation. A complete ocular examination was done and recording of the uncorrected and best corrected visual acuity along with the degree of astigmatism was done with the help of automated keratometry. Astigmatism was recorded as with the rule, against the rule or oblique astigmatism. For the purpose of analysis pterygium was considered in one eye of bilateral cases. The asymmetric bilateral cases were excluded from the study. Detailed slit lamp examination to find the stage and measurement of the pterygium was done. It was classified as stage I- restricted to limbus, stage 2- marginally invade the cornea, stage 3- between limbus and pupillary margin and stage 4- central to the pupillary margin. Pterygium was classified as regressing, intermediate or fleshy pterygium according to Tan *et al* classification [11] according to the visibility of episcleral vessels. The recording of the position of pterygium was also done as nasal, temporal or double pterygium as well as whether the pterygium was unilateral or bilateral. The tear film assessment was done with the help of Schirmer's test and tear film break up time (TBUT). Data analysis was performed using statistical software package SPSS version 22.0. Both descriptive and inferential statistics were used. The comparison of continuous variable across different subgroups was done using ONE WAY ANOVA. The comparison of categorical and ordinal variables across different subgroups were done using chi square test. Correlation analysis was done by estimating Pearson estimation co-efficient. P value of less than 0.05 was considered significant.

RESULTS

Age of the patients ranged from 27 years to 78 years. The mean age of the study population is 51.5 years, the standard deviation being 13.5 years (Table 1). Majority of the patients belonged to the age group of 46- 55 (n=28, 26.92%). None of the patients were below 25 years of age. Females were more in the study group (n=70, 67%) (Table 2).Majority of patients were engaged in outdoor works (n=82, 9%) (Table 3).Most of the subjects were from low altitude areas (n=73, 70%) (Table 4).Pterygium was unilateral in 54 patients and bilateral in 50 (Table 5).In 43.27% of patients, pterygium was of the regressive type, which was the most common. The next common type was intermediate followed by fleshy type (Table 6). Mean sun exposure hours was 5.7 hours per day (SD.2.7hours), Mean years of sun exposure was 27.7 years (SD 11.7) (Table 8).The patients engaged in indoor working had less than 4 hours of sun xposure per day and those working outdoor had 4-9 hours of exposure per day.77.9 % (n=81) had significant sun exposure per day (>4 hours).63.5% (n=66) were exposed to long duration of sunlight for more than 20 years. Duration of sun exposure is not significantly different across types (Kruskal Wallis test, $P = 0.087$). But it is close to the significance (Table 9). Years of sun exposure is significantly higher in the fleshy type in comparison to regressive ($p<0.01$) and intermediate types ($P<0.01$) (One-way ANOVA overall, $P = 0.0008$) (Table 10) Proportion of the patients with dry eyes as a risk factor was not significantly different across the various types (Chi square test for trend $P = 0.79$) (Table 11 and Table 12) More number of patients were found to have with the rule astigmatism (Table 13).

DISCUSSION

Our study included 104 subjects who were diagnosed to have true pterygium in either or both of the eyes. The mean age of the patients in our study was 51.5 years with a standard deviation of 13.5 years, which is comparable to previous studies. Youngest patient was 27 years and the oldest 78 years. 15 patients (14.42%) were in the age group 26-35, 22 (21.15%) in the age group 36-45, 28(26.92%) in the age group 46-55, 21(20.19%) in the age group 56-65 and 18 (17.31%) in the age group >65 years, in our study. Majority of the patients presented in the age group of 45 to 55 years (n=28, 26.92%) Females were predominant in our population (n=70, 67%). Most of the previous studies have shown an increased incidence of pterygium in males, as men were commonly involved in outdoor works.[2] Our study population consisted of the people coming from low socioeconomic conditions who were ladies involved in outdoor occupation. This may account for the increased number of female pterygium cases in our study. The association of UV light with occurrence of pterygium is well documented in previous studies.[3,4,5]. Mean sun exposed hours were 5.7 hours per day with a standard deviation of 2.7 hours and mean year of sun exposure was 27.7 years with a standard deviation of 11.7 years. The average daily duration of sun exposure was not significantly different across types of pterygium (p=0.087). However, the years of sun exposure (p=0.008) and cumulative hours of sun exposure (p=0.002) were significantly higher in the fleshy type. Most of the patients in our study were from the rural area (n=74, 70.2%). Rural area and low socioeconomic status are associated with more amount of outdoor work and more UV exposure. These people will have low level of education and may not be aware of the harmful effects of the UV light and thus don't adopt protective measures such as hats and glasses [6] It is well documented that people living in high altitude have higher chance developing pterygium because of the higher UV light

exposure along with dry eye.[7,8] In our study no significant association between high altitude and pterygium were found probably because of the low sample size. We could not find any significant association between diabetes (p=0.52) and hypertension (p=0.75) with the type of the pterygium, in our study. No such correlation was documented in other studies also. The diabetic patients have more chance of developing tear film instability thereby making the eye more vulnerable to UV damage. Dry eye was found to be present in 19 patients (18.27%). Even though dry eye may be a risk factor for pterygium, statistical correlation could not be established in our study due to the small sample size (p=0.79). Out of 104 patients 77 patients (74.04%) had astigmatism among which maximum were having with the rule astigmatism (n=40, 38.46%). This is in accordance with the other studies[9].

CONCLUSION

The objective of our study was to document the demography and clinical assessment of pterygium and to identify risk factors or associations, if any. The following conclusions were made. Middle aged to elderly people are more affected due to their prolonged exposure to inciting agents in the environment. There is no significant gender predilection, if the environmental factors are the same. UV exposure was a significant risk factor in the development of pterygium. Patients working outdoors should be counselled about the importance of wearing protective eye gears. It should be emphasized that such protective measures can not only delay the onset but also the progression of pterygium to some extent. Adequate management of asymptomatic dry eye is mandatory especially in patients working outdoors, as it can play a contributory role and hence the importance of dry eye evaluation in all cases of pterygium. Though co morbid conditions like hypertension and diabetes do not play any role in the initiation and progression of pterygium, they can still contribute further to the visual morbidity. Proper understanding of the epidemiology and risk factors of this condition is essential for planning appropriate measures to prevent its occurrence and thereby reduce the physical and financial burden to the society.

Abstract:

Aim: To report cases of sight threatening ophthalmic complications observed during dengue epidemic in 2017 at a tertiary health center in Tamil Nadu.

Settings and Design: Tertiary Care Referral Center in Tamil Nadu. Prospective, single institution, Observational case-series.

Methods: Five patients with dengue fever with grave ophthalmic complications seen in fever intensive care ward in our center during the period of dengue epidemic in 2017 were included.

Results: Out of 3338 dengue positive cases reported in our center from June-2017 to December-2017, five cases presented with grave eye findings with loss of vision / loss of the eye in due course.All presented with a short history of fever with thrombocytopenia, with ocular manifestations namely 1.Retro-bulbar hemorrhage with hyphema-ended with globe luxation, 2.Suprachoroidal hemorrhage with globe rupture, 3.Endogenous Endophthalmitis with ring abscess going for Panophthalmitis, 4.Premacular hemorrhage resolved with some improvement in vision after hyaloidotomy, 5.Massive suprachoroidal hemorrhage.

Conclusion: Dengue hemorrhagic fever itself is a dreadful and sometimes fatal disease, in which we encountered few patients with very rare and severe ocular manifestations during the dengue epidemic in our hospital in 2017.Some of these complications have not been reported so far.

Keywords: Dengue epidemic,dengue eye complications, dengue fever, globe rupture, luxated globe, thrombocytopenia.

INTRODUCTION

Dengue fever is a mosquito-borne tropical disease caused by the dengue virus[1]. It is an RNA virus of the family Flaviviridae, genus Flavivirus. The virus has four different types, where infection with one type usually gives lifelong immunity to that type, but a short-term immunity to the other types. Subsequently infection with a different type increases the risk of severe complications. Dengue is spread by the bite of several fresh water breeding species of mosquito of the Aedes type, principally A. Aegypti [1].

Dengue fever usually presents with an acute onset of fever associated with malaise, rhinitis, sore throat and cough, headache, muscle ache, retro-bulbar pain, joint pain, abdominal discomfort and rash[1,3]. Other clinical features of dengue are bleeding manifestations attributed to thrombocytopenia. Dengue fever is confirmed with laboratory tests based on the duration of presentation; polymerase chain reaction

(PCR) is the frequently used test during the early phase of the infection, when fever is within 5 days. If fever exceeds 5 days, the preferred tests are dengue IgM and IgG tests [2].

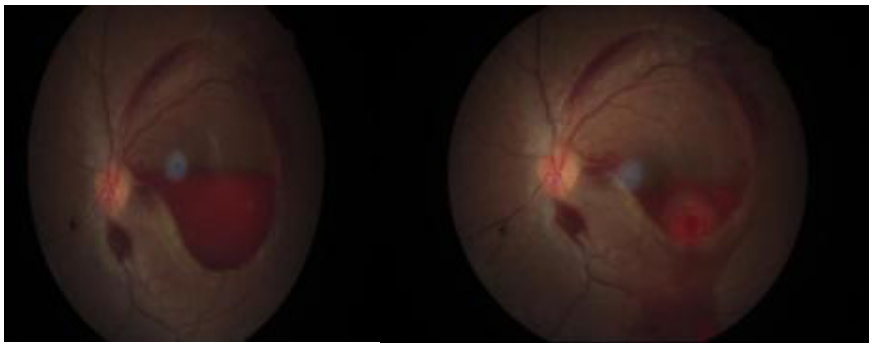
Dengue is a self-limiting infection. But sequential infections with other serotypes may increase the risk of serious systemic disease, such as dengue hemorrhagic fever or dengue shock syndrome, which are life-threatening[3,4]. Herein we report few grave ocular manifestations associated with dengue infection. The precise pathophysiologic mechanism of dengue ocular complications is not yet well understood[5]; however, many studies have alluded to the possibility of an immune-mediated process as a likely mechanism[6].

Materials and methods

This study is a prospective review of five consecutive sight threatening ocular complications observed during the dengue epidemic period, June-2017 to December-2017 in a tertiary institute in Tamil nadu. Out of 5652 blood samples collected from patients with fever with thrombocytopenia, 3338 were diagnosed with dengue infection by dengue IgM ELISA and NS1 antigen tests. Among them five patients presented with serious ocular manifestations which are reported here.

Case 2.1: Retrobulbar hemorrhage with globe luxation:A 23 years old male presented with fever with cough and loose stools for 5 days and was found to have thrombocytopenia. His dengue IgM was positive. He developed pain Left eye on 6th day, with severe deterioration of vision. On examination patient's general condition was found to be very poor and ocular examination showed vision in Right eye-6/6, Left eye-no perception of light. Right eye-anterior and posterior segment were normal, Left eye was proptosed and the globe luxated outside the palpebral aperture, lids were edematous and retracted,hemorrhagic chemosis present with dry and lustreless cornea. Further details not visualized due to hyphema in anterior chamber. All extraocular movements were restricted [Fig.1]. Intra-ocular pressure in left eye was digitally elevated. Day-by-day his symptoms worsened. MRI brain and orbit was reported as vitreous hemorrhage and subretinal hemorrhage and retinal detachment with Retrobulbar hemorrhage and temporal fossa hematoma [Fig.2].

Figures 1 and 2: Patient with luxated globe Left eye with temporal fossa hematoma.



Case 2.2: Suprachoroidal hemorrhage with globe rupture:A 75 years old female patient with history of fever for 2 days with thrombocytopenia was admitted in fever intensive care ward. Dengue NS1Ag

was positive. Patient had complaints of defective vision and pain in Left eye. On examination of Left eye vision was perception of light, mild lid edema, chemosis, mild shallow anterior chamber, pupil-3 mm, sluggishly reacting to light with hazy fundus view. Intra-ocular tension raised digitally [Fig.3]. Next day patient's vision in Left eye further deteriorated to no perception of light and anterior chamber was very shallow.Clinically diagnosed as suprachoroidal hemorrhage, which was confirmed by B-scan. During the early hours of next morning,patient had excruciating pain with excessive bleeding from the Left eye. Immediate examination revealed rupture of the globe Left eye [Fig.4).

Figures 3 and 4:(3) Left eye with chemosis on day 1 (4) Left eye globe rupture at the limbus {white arrow} with prolapse of uveal tissue and vitreous on day 2.

Case 2.3: Sub-hyaloid premacular hemorrhage: A 23 years old male presented with fever for 10 days with thrombocytopenia and dengue IgM was positive. Patient developed painless defective vision in both eyes over the last 5 days. On examination,vision in Right eye was 6/36, Left eye was 3/60 with mild conjunctival congestion, anterior chamber was mild shallow with 3 mm pupil, reacting to light. Fundus of both eye showed sub-hyaloid premacular hemorrhage [Fig.5]. Nd:Yag laser hyaloidotomy was performed in each eye[Fig.6]. Later patient's vision improved to 6/9 in each eye.

Figures 5 and 6:(5) Left eye premacular subhyaloid hemorrhage (6) Left eye hemorrhage draining after hyaloidotomy.

www.ijbamr.com P ISSN: 2250-284X , E ISSN : 2250-2858

Case 2.4: Endogenous Endophthalmitis: A 25 years old male admitted in fever ward with complaints of fever for 6 days with thrombocytopenia. Dengue IgM was positive. Patient developed painful loss of vision in Left eye with history of vomiting. On examination patient was toxic, vision in Left eye was no projection of light, mild lid edema with hemorrhagic chemosis and ring abscess in the cornea with keratic precipitates over back of the cornea, anterior chamber showing flare and cells and other details could not be made out [Fig.7]. Extra-ocular movements were painful and restricted. B-scan Left eye revealed thickening of sclero-choroidoretinal complex and few echoes in the vitreous cavity suggestive of Endogenous Endophthalmitis going to Panophthalmitis [Fig.8]. Grave visual prognosis was explained to the patient and patient was lost for further follow-up.

Figures 7 and 8: (7) Left eye with hemorrhagic chemosis with corneal ring abscess (8) B-scan of Left eye showing sclero-choroidoretinal complex thickening with echoes in vitreous.

Case 2.5 : Massive suprachoroidal hemorrhage : A 23 years old male referred from secondary center as fever for 5 days with thrombocytopenia admitted in intensive care unit. Dengue NS1Ag was positive. Patient's general condition was very poor. On examination patient was unconscious. Right eye showed mild hazy cornea and shallow anterior chamber with relative affarent pupillary defect and intra-ocular pressure was raised (27.3 mmHg by Schiotz tonometer) [Fig.9]. Left eye anterior segment was normal with fundus showing a Roth spot. When we reviewed the case 6 hours later, Right eye showed worsening of all signs viz. lid edema with ecchymosis, hemorrhagic chemosis, cornea became very hazy with Descemet's folds, more shallowing of anterior chamber and pupil now 3 mm and non-reacting to light [Fig.10]. A clinical diagnosis of massive suprachoroidal hemorrhage was made. CT-Brain showed right intracerebral hemorrhage with fronto-parietal edema. Patient deteriorated and declared dead after 1 hour the same day.

Figures 9 and 10: (9) Right eye with mild hazy cornea and shallow anterior chamber (10) Right eye with hemorrhagic chemosis.

Results

Out of five patients observed 4 were male and 1 was a female patient. Left eye alone was affected in 3 patients and both eyes were affected in 2 patients with left eye affected more than right eye. All had a short history of fever with thrombocytopenia, ranging from 3 to 10 days duration and got treated in fever intensive care unit specifically created for treatment of fever cases during the dengue epidemic. The diagnosis of dengue fever was confirmed by dengue IgM and NS1Ag. Predominant eye symptom was defective vision with or without eye pain presented after 5 days of onset of dengue hemorrhagic fever. All five Ophthalmic manifestations were sight threatening. These ocular presentations often correspond to the nadir of thrombocytopenia. Two patients developed suprachoroidal hemorrhage,resulted with rupture globe in the one who survived the course of the disease. One patient developed Retrobulbar hemorrhage with luxated globe. Another patient developed Endogenous Endophthalmitis going to Panophthalmitis. The last patient had premacular subhyaloid hemorrhage which was intervened at right time and the vision was restored.

Discussion

Dengue fever is endemic in tropical countries which is classified by WHO as neglected tropical disease (NTDs)[7]. It can manifest as simple **dengue fever** which is self-limiting and recovers in two-seven days. In a small proportion of cases, due to subsequent infection by other subtypes, the disease develops into a life-threatening **dengue hemorrhagic fever** with low blood platelets levels with bleeding manifestations and blood plasma leakage or into **dengue shock syndrome** where dangerously low blood pressure occurs[4]. The infection typically affects young immunocompetent adults, who often present at the nadir of thrombocytopenia with a myriad of ocular complications relate to dengue infection like sub-conjunctival hemorrhage, uveitis, shallow anterior chamber due to choroidal effusion or angle closure glaucoma, intra-retinal hemorrhages, dengue-related maculopathy, optic neuropathy, vitreous hemorrhage, vascular occlusions[8]. Endogenous Endophthalmitis[9] and Panophthalmitis[10,11]rarely documented. The mechanism behind dengue infection and ocular involvement is unknown, but related to an immune-mediated process and possibly associated with dengue serotyping. Till now the prognosis for the Ophthalmic complications in documented literature is reported to be good with resolution of ocular signs and improved visual acuity in most patients without treatment following dengue infection[5] with

www.ijbamr.com P ISSN: 2250-284X , E ISSN : 2250-2858

occasional reports of Endogenous Endophthalmitis[5,9]. So the authors here propose to create awareness regarding the possibility of few rare sight threatening complications in patients with dengue fever with thrombocytopenia.

Conclusion

Physician are aware that dengue fever with thrombocytopenia may be fatal in some patients and the risk is explained to the patient and the attendant. Rarely as shown in few of the above instances there may be loss of vision or the eye.In some cases visual recovery may occur. Ophthalmologist and physician should be aware and vigilant towards the patient with dengue-related ophthalmic symptoms as a small proportion of patients of dengue fever with thrombocytopenia may have poor visual outcome refractory to the treatment, the possibility of which should be informed to the patient and their attendant during the course of the treatment. Moreover the study also highlights occurence of globe luxation and ruptured globe in dengue fever and thrombocytopenia which have not been documented so far for the best of our knowledge.

Acknowledgements

We would like to thank Dr.R.Manohari, Associate professor and incharge of fever intensive care unit, Department of Medicine, Coimbatore Medical College , Coimbatore, Tamil Nadu, for her co-operation and guidance. Also we are very thankful to Dr.N.Mythily, Professor and Head of the Department, Department of Microbiology, Coimbatore Medical College, Coimbatore, Tamil Nadu, for providing dengue statistics.

Abstract

Currently, an estimated 347 million people in the world have diabetes, making it one of the most common non-communicable medical conditions worldwide. India, considered as the "diabetes capital" of the world, is home to 74 million diabetics with a prevalence of ~8.7% among the adult population. Ocular manifestations of diabetes and its complications are well known over year's. In recent years, attention has been drawn to ocular surface disorders, especially dry eye in diabetic patients. Our purpose was to correlate the dry eye and diabetic retinopathy with duration of diabetes and blood urea and serum creatinine level. Ours was a hospital based cross sectional study done from August 2013 to July 2014. Thorough fundus examination was done using indirect ophthalmoscopy, tear film and ocular surface were evaluated using Schirmer test and tear film break-up time (TBUT) and renal parameters analysed in our hospital lab. Out of 150 patients studied 61.3% of patients had diabetes of 1 to 5 years duration. 35.3% of diabetic patients had dry eye symptoms. 75% of them had poor glycemic control. 72 of them had some degrees of diabetic retinopathy with altered renal parameters. P value of the above correlation was significant. Dry eye is the most common problem encountered in patients with diabetes mellitus. Hence, all the diabetic patients should be evaluated and screened at the earliest for retinopathy changes and presence of ocular surface disorders and treated accordingly. Early treatment would prevent complications associated with ocular surface disorders and diabetic retinopathy. They should be emphasized upon on need for regular follow up and maintaining a good glycemic control.

Key Word: diabetes mellitus, dry eye, diabetic retinopathy

INTRODUCTION

Diabetes mellitus is a metabolic disorder characterized by chronic hyperglycemia associated with disturbances of carbohydrate, protein and fat metabolism due to absolute or relative deficiency in insulin action and or secretion. Diabetes is the leading cause of blindness in twenty to seventy four year age group[1]. Exact etiology of diabetic retinopathy is not known. It is believed that exposure to hyperglycemia over an extended period results in specific changes in retinal capillaries such as loss of pericytes and thickening of the basement membrane resulting in occlusion of capillaries and non-perfusion of retina and decompensation in retinal barrier function. The prevalence of diabetic retinopathy increases with the duration of diabetes and age of the patient. Dry eye is the most common problem encountered in patients with diabetes mellitus[3]. The exact mechanism for cause of dry eye in diabetes is not known[2]. Autonomic dysfunction plays a role in causing dry eye. Aldose reductase enzyme which converts glucose to sorbitol also plays a role[4]. Jin *et al* found that diabetes mellitus type 2 patients are prone to develop dysfunction of tear film. Cousen *et al* studied

How to cite this article: P Mohanapriya, S Padmanaban, Suguna. The prevalence of dry eye and diabetic retinopathy in diabetes mellitus ...

production of tears and sensation of cornea in diabetes. In addition to dry eye, tear film instability, metaplasia of conjunctiva, decreased goblet cells, decreased sensation of cornea and decreased tear film lipid layer are encountered in diabetes[5].Chronic hyperglycemia impairs inflammatory process and invasion of lids by bacteria leads on to blepharitis in diabetes patients[6]. This is cause for evaporative dry eye. The etio-pathological factors for dry eye in diabetic patients includes autonomic neuropathy, chronic hyperglycemia, insulin deficiency and chronic inflammation. Autonomic neuropathy is the key result of hyperglycemia in diabetes[7].Nerve signal pathways are damaged in autonomic neuropathy. Microvascular abnormalities and high blood sugar damage the corneal nerves and block the nerve feedback mechanism that controls secretion of tears. So lacrimal gland does not secrete tears[7]. Benetis-Del-Castillo *et al* studied relation between innervation of cornea with confocal microscopy and corneal sensations using noncontact esthesiometry in dry eye patients with diabetes[8]. Dogru stated that diabetes mellitus patients with autonomic neuropathy and uncontrolled diabetes patients exhibit abnormal Schirmer and TBUT test[9]. In diabetic patients, Schirmer test exhibits lower than normal values[10]. 55% of patients with diabetes had dry eyes symptoms and signs[11]. The Beaver Dam eye study suggested that twenty percent of diabetes mellitus patients aged between forty three and eighty six years diagnosed to have dry eyes[12]. Kaiserman and associates have told that good control of blood sugar is important for the control and prevention of dry eye syndrome among diabetic patients. Nepp and associates stated that severity of dry eye correlates with diabetic retinopathy severity[13]. In diabetes goblet cell density is reduced in patients with neuropathy[14].Schultz *et al* reported forty seven to sixty four percentage of diabetic patients having corneal abnormalities as epithelial defects, delayed healing of epithelium, corneal ulcer and kerato conjunctivitis sicca[15]. Increased duration influence the occurrence of DR and its severity was due to prolonged exposure to hyperglycemia. Duration of diabetes is an independent risk factor. Ten percent of the newly diagnosed diabetes shows DR, suggesting that these patients were not diagnosed earlier. The duration of diabetes is an important predictor of DR and its severity[16].

AIMS AND OBJECTIVES

To correlate the dry eye and diabetic retinopathy with duration of diabetes and blood urea and serum creatinine level and to evaluate the risk factors attributed to dry eye and diabetic retinopathy in diabetes mellitus patients and also to study the prevalence of dry eye and diabetic retinopathy in diabetes mellitus patients.

MATERIALS AND METHODS

It is a hospital based cross sectional study. This study was done in the period between August 2013 to July 2014. The study was done on all diabetic patients attending ophthalmology outpatient clinic. Before commencing the study Ethics committee approval was obtained from the Coimbatore medical college and government hospital. Diabetic patients attending outpatient clinic were screened for dry eye and diabetic retinopathy after obtaining consent. Detailed history was obtained including name, age, sex, presenting symptoms, duration and associated systemic disease and type of diabetes. The blood investigations such as fasting and post prandial blood sugar, urea, creatinine level were done. All patients of either sex in all age groups diagnosed to have diabetes mellitus of any duration were included. Patients with known ocular surface disorder, contact lenses usage, history of ocular surgeries in past and patients on local or systemic medications which cause dry eye are excluded. Detailed ophthalmic examination was done including best corrected visual acuity using Snellen chart and anterior segment examination using slit lamp. Symptoms of the dry eye such as redness, burning sensation, grittiness were evaluated using the questionnaire given to the patients. Condition of lid, meibomian gland and corneal surface were noted. Tear film evaluation was done by Schirmer test and tear film break up time. Intra ocular pressure measurement done using applanation tonometer. Detailed fundus examination was done and Diabetic retinopathy graded according to ETDRS criteria.

OBSERVATION AND RESULTS

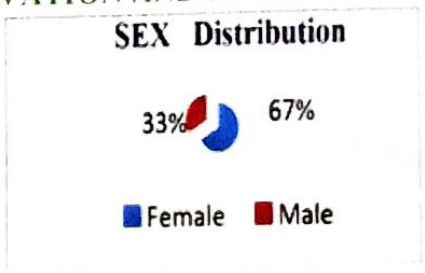

Figure 1: Sex Distribution

Among 150 patients studied, 100 patients were females and 50 patients were males.

Table 1: Duration Range

Duration	Frequency	Percent
Less than 1 year	6	4.0
1 to 5 years	92	61.3
6 to 10 years	38	25.3
11 to 20 years	14	9.3

Table 1 shows, patients diagnosed with diabetes less than 1 year duration were 4 %. Majority of population were between 1 to 5 years duration i.e., 61.3 %

Table 2: prevalence of dry eye symptoms

Dry eye Symptoms	No of patients	Percent
Absent	97	64.7
Present	53	35.3
Total	150	100.0

Table 2 shows 64.7% had no dry eye symptoms. 35.3% had dry eye symptoms.

Table 3 A and 3 B: fasting and post prandial blood sugar range

FBS(3A)	Frequency	Percent
FBS < 110	38	25.3
FBS >110	112	74.7
Total	150	100.0

PPBS (3B)	Frequency	Percent
Up to 160	37	24.7
Above 160	113	75.3
Total	150	100.0

Table 3A shows 25.3% of patients had FBS less than 110mg dl. 74.7% had FBS more than 110mg dl. Table 3B shows 37 patients had PPBS less than 160 mg dl. 113 patients had PPBS more than 160 mg dl.

Table 4A and 4B: Blood Urea And Serum Creatinine Rang

Urea(4A)	Frequency	Percent
Upto 40	127	84.7
>40	23	15.3
Total	150	100.0

Creatinine(4B)	Frequency	Percent
Upto 1	133	88.7
> 1	17	11.3
Total	150	100.0

Table 4A shows 127 patients had urea level less than 40 mg dl. 23 patients had urea level more than 40 mg. Table 4B shows 133 patients had Creatinine level less than 1 mg dl.17 patients had Creatinine more than 1 mg/dl.

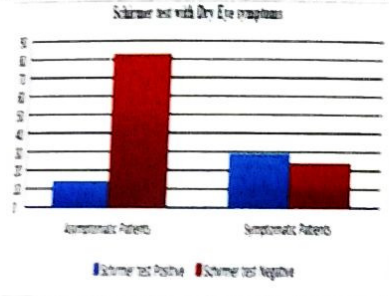

Figure 2: Schirmer Test

Among 150 patients. 43 patients were Schirmer test positive. 107 patients were negative for Schirmer test. Figure 2 shows Among 53 symptom positive patients, 29 of them Schirmer test positive and 24 of them Schirmer test negative.

Table 5: Schirmer Test and Duration Of Diabetes

Schirmer test	Less than 1 year	1 to 5 years	6 to 10 years	11 to 20 years
Positive	0	10	22	11
Negative	6	82	16	3

Table 5 shows among 43 Schirmer test positive patients, 10 patients had 1 to 5 years of diabetes. 22 of them were 6 to 10 years of diabetes. 11 of them were 10 to 20 years of diabetes. The P value of above comparison was significant.

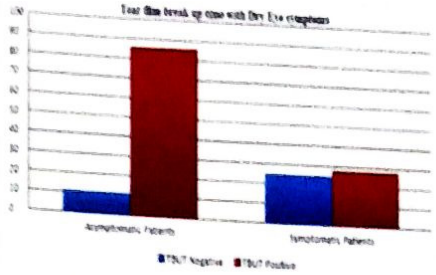

Figure 3: Tear Film Breakup Time

Among 53 dry eye symptom positive patients, Only 25 of them were TBUT positive in symptomatic patients. 28 of them TBUT test negative. The p value of the below chart is < 0.01.

Table 6: Tbut And Duration Of Diabetes Mellitus

Duration	Less than 1 year	1 to 5 years	6 to 10 years	11 to 20 years
positive	0	5	20	11
negative	6	87	18	3

Table 6 shows among 36 TBUT test positive patients, 5 of them were in 1 to 5 years duration of diabetes.20 of the were in 6 to 10 years duration and 11 of them were in 11 to 20 years duration of diabetes

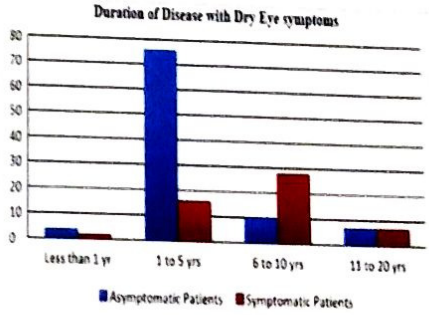

Figure 4: Duration Range and Dry Eye

Among 53 dry eye symptom positive patients.2 of them had diabetes of less than 1 year duration,.16 of them of 1 to 5 years duration, 28 of them of 5 to 10 years duration and 7 of them of 10 to 20 years duration. The p value of the above chart is < 0.01which is highly significant.

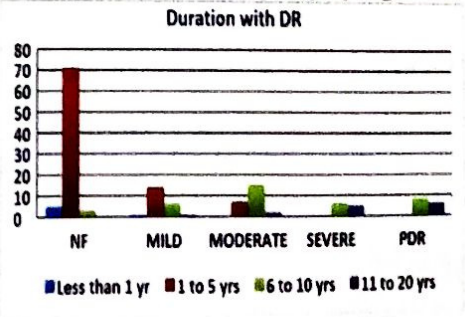

Figure 5: Duration Range And DR

92 patients were in 1 to 5 years duration. Among 92 patients,71 of them had normal fundus, 14 of them mild NPDR and 7 of them had moderate NPDR. The p value of the above chart is significant

Table 7: Schirmer Test And Dr

Schirmers Test	Normal Fundus	Mild NPDR	Moderate NPDR	Severe NPDR	PDR
Positive	3	8	14	7	11
Negative	76	14	10	4	3

The p value of the above table is <0.01, significant. 43 patients are Schirmers test positive. Among 43 patients 3 of them normal fundus, 8 of them mild NPDR, 14 of them moderate NPDR, 7 of them severe NPDR, 11 of them had PDR.

Table 8: Tbut And Dr

Tbut	Normal Fundus	Mild NPDR	Moderate NPDR	Severe NPDR	PDR
Positive	0	4	12	7	13
Negative	79	18	12	4	1

The p value of above table is <0.01 which is significant. 36patients were TBUT positive. Among 36 patients ,4 patients had mild NPDR, 12 patients had moderate NPDR, 7 patients had severe NPDR and 13 of them had PDR

Table 9: Fbs Range With Dr

FBS	Normal Fundus	Mild NPDR	Moderate NPDR	Severe NPDR	PDR
Upto 110	29	3	4	0	2
Above 110	50	19	20	11	12

The p value of the above table is <0.01. significant.112patients had FBS more than 110 mg/dl. Among 112 patients 50 of them had normal fundus , 19 of them had mild NPDR, 20 of them had moderate NPDR, 11 of them had severe NPDR and 12 0f them had PDR

Table 10: Ppbs Range With Dr

PPBS	NORMAL FUNDUS	MILD NPDR	MODERATE NPDR	SEVERE NPDR	PDR
upto 160	33	1	2	1	0
above 160	46	21	22	10	14

The p value of the above table is <0.01, significant.113 patients had PPBS more than 160 mg/dl.46 of them had normal fundus, 21 of them had mild NPDR, 22 of them moderate NPDR, 10 of them had severe NPDR and 14 of them had PD

Table 11: Dry Eye and Sex Predilection

dry eye symptoms	female	male
Negative	58	39
Positive	42	11

The p value of table no. 11 is <0.01, significant. Among 53 symptomatic patients 42 were females.

DISCUSSION

In this study 150 patients with type 2 diabetes mellitus were examined for dry eye and diabetic retinopathy manifestations and above manifestations are correlated with age, duration, control of diabetes and urea, creatinine level. Among 150 patients ,100 patients were females and 50 were males. 61.3% of patients diabetes of between 1 to 5 years duration.35.3% of diabetic patients had dry eye symptoms. Our study showed that 75% of them were not in good glycemic control. Binder A *et al* study showed that 55% of patients with diabetes had dry eye signs and symptoms at least at some of the time. Among 53 symptomatic patients, 29 were Schirmer test positive and 24 of them were Schirmer negative. 14 of the asymptomatic patients showed Schirmer test positive. Schirmer test is useful screening test for diagnosing hyposecretion, but not for an adequate determination of tear production. Its sensitivity is between 10% and 30%. Among symptom positive patients (53), TBUT is positive in 25 patients. The p value of above comparison is significant. Mannavit published prevalence of dry eye in diabetic patients utilising either Schirmers test or TBUT. In our study 42 females are dry eye symptom positive and only 11 males are symptom positive. p value is significant. Prevalence of dry eye is higher among advancing age, female sex, poor glycemic control, patients with diabetic retinopathy and high urea, creatinine level. In our study higher grades of diabetic retinopathy is associated with higher incidence of dry eye symptoms and the p value of the test is significant. Among 150 patients,23 patients had urea level more than 40 mg/dl. In 23 patients only 2 of them had normal fundus. 1 patient had mild NPDR. 7 of them had moderate NPDR. 5 of them had severe NPDR. 8 of them had PDR.P value of the above test is significant. With regard to serum Creatinine level, 17 of them had more than 1mg/dl. Only one patient had normal fundus. Remaining patients with elevated creatinine level had some degree of DR. p value of the above correlation is significant. 38 patients among 150 patients had fasting blood sugar less than 110mg/dl. Remaining patients(112) had more than 110 mg/dl. 50 patients had normal fundus in more than 110 FBS group. 72 of them had some degrees of diabetic retinopathy. Microvascular complications develop in nearly all patients with type 1 diabetes and in more than 77% of those with type 2 diabetes who survives for over 20 years with the disease. Vision threatening retinopathy is rare in type 1 diabetes in the first 3 to 5 years of diabetes or before puberty. After 2 decades nearly all patients with type 1 DM develop retinopathy. 21% of type 2 diabetes patients have retinopathy at the time of first diagnosis of diabetes. UKPDS demonstrated that improved blood glucose control reduced the risk of developing retinopathy, nephropathy and possibly reducing neuropathy. Moss and associates also reported a high incidence of dry eye

among females 16 .7% compared to males 11.4%, but in our study p value of gender correlation with diabetic retinopathy is not significant.

CONCLUSION

Dry eyes are more prevalent in diabetic individuals. The ocular surface disease in diabetic individuals was confirmed by Schirmer test and tear film breakup time. Early detection of dry eye and diabetic retinopathy prevents vision threatening complications like formation of corneal opacity, diabetic macular edema, tractional retinal detachment and vitreous haemorrhage. Dry eye syndrome is a definite entity, that occurs in diabetic patients, more so, when the duration of diabetes is longer, poor glycemic control, high urea, creatinine level are associated with DR, irrespective of severity. Hence it is mandatory to look for ocular surface abnormality in diabetic patients, as it can interfere with vision further. Schirmer test and TBUT test are easy to perform and easily available. They can be routinely done in all diabetic patients, in order to diagnose dry eye in early stage, so that prompt treatment can be initiated. As dry eye symptoms and DR have a correlation, it is important to rule out DR in symptomatic dry eye patients and vice versa. Since poor glycemic control and elevated urea, Creatinine levels have been associated with increased incidence of dry eye, it is important to look for the same, even in asymptomatic patients with altered biochemical parameters. Apart from ophthalmoscopy, Schirmer test and TBUT should be compulsorily done in all diabetic patients.

Congenital capillary hemangioma arising from palpebral conjunctiva of a neonate

S Padmanaban, P Sumathi, Prayagi Kandoth, R P Dharmendra[1]

Capillary hemangioma is the most common benign vascular eyelid tumor in childhood. The periocular lesion appears within the first few weeks after birth and usually has superficial or deep components. Primary conjunctival capillary hemangiomas are rarely reported. We present the case of a 2-day-old child with a pedunculated capillary hemangioma arising from superior palpebral conjunctiva. A complete surgical excision was performed under general anesthesia, and the child was asymptomatic at follow-up of two months.

Key words: Congenital capillary hemangioma, conjunctival capillary hemangioma, management, pedunculated capillary hemangioma

Manuscript received: 23.06.17; Revision accepted: 25.09.17

Capillary hemangioma is the most common benign vascular eyelid tumor in childhood.[1] It is present in 1%–4% of all births[2] and is more common in premature infants and often following chorionic villus sampling.[3] It is usually a cutaneous, subcutaneous, or deep orbital lesion and commonly presents a few weeks after birth. The usual clinical course of infantile cutaneous or subcutaneous hemangiomas includes an initial engorgement (age 6–12 months) followed by regression

(age 1–7 years). It usually regresses spontaneously and hence is kept under close observation. Active intervention is performed only if the lesion is very extensive and causes amblyopia, mechanical ptosis, exposure keratopathy, or optic neuropathy. Treatment modalities for cutaneous or subcutaneous hemangiomas include topical[4] and oral beta blockers,[5-8] local and oral steroids,[9,10] surgical excision, immunotherapy,[11] laser photocoagulation with pulsed dye laser,[3] and embolization.[12] Although conjunctiva may be involved as a part of capillary hemangioma of the lid, isolated conjunctival lesion is rare and its congenital presence is rarer. In a series of 1463 cases of conjunctival tumors studied, only 10 were capillary hemangiomas, forming 16% of conjunctival vascular tumors, only 1% of all conjunctival tumors.[13] Usually, hemangiomas of conjunctiva are small and require only observation. Chang and Estes, in a recent paper, report usage of topical timolol in the management of small bulbar conjunctival hemangioma.[14] Oral propranolol was also recently reported to be in use in the treatment of a case of bilateral sessile infantile hemangioma of posterior lamella of upper lid by Syed Ali Raza Rizvi *et al*., with clearing of visual axis within 12 weeks of treatment.

We report a case of capillary hemangioma in a newborn, which could be treated completely by surgical excision due to its unique pedunculated morphology. Such a case of congenital pedunculated conjunctival capillary hemangioma has not been reported so far to the best of our knowledge.

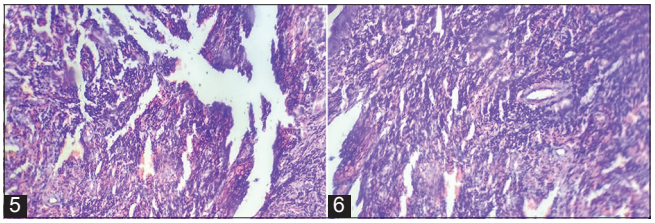
Case Report

A 2-day-old female baby presented to our pediatric surgery department with a red mass arising from left upper eyelid since birth [Fig. 1]. In the antenatal history elicited, mother was found to be a primipara who had regular antenatal checkups, with no history of any invasive interventions, and the baby was born out of full-term normal vaginal delivery with no perinatal complications.

On examination, the right eye appeared to be normal. Examination of the left eye showed a red, pedunculated, highly vascular, nontender mass of 2.5 cm × 1.5 cm arising from the palpebral conjunctiva of upper lid. The mass had a flattened stalk with terminal lobulations, at the tip of which, there was dried up mixture of blood and discharge. On upper eyelid eversion, the base of peduncle was found to be at 4 mm from lid margin. The lesion appeared to cause mechanical ptosis and covered the visual axis. The eyelid opening appeared inadequate [Fig. 2]. There was minor bleeding from the surface of the swelling on manipulation. The rest of the conjunctiva was normal except for mild congestion. The cornea of the left eye was clear. There was no evidence of similar cutaneous lesions on the rest of the body.

A provisional diagnosis of capillary hemangioma was made. There was also the possibility of pyogenic granuloma and rare possibility of rhabdomyosarcoma. Complete hemogram of the baby showed normal hemoglobin (17.3 g%), white blood cell (11,000/μL), and platelet (2.5 lakhs/μL) levels. Ultrasonogram (USG) showed high-internal reflectivity with irregular acoustic structures suggestive of capillary hemangioma. USG of cranium and abdomen were done to rule out internal hemangiomas but were found to be normal.

Taking into consideration the pedunculated nature, unsightly appearance, possibility of developing amblyopia due to the central location and also to obtain a histopathological diagnosis (to rule out any other tumor), surgical removal was finalized as the treatment. On postnatal day 6, the baby was prepared for general anesthesia. Under anesthesia, detailed examination of the conjunctiva of both eyes was done to rule out deeper lesions and bilaterality. Excision of the mass was done with bipolar electrocautery device by a team consisting of ophthalmologist and pediatric surgeon. It was cut close to tarsal plate, and adequate hemostasis was obtained [Fig. 3].



On the 1st postoperative day, the eye was quiet with adequate eyelid opening, clear cornea, and normal fundus [Fig. 4]. On follow-up visits, there was no conjunctival scarring and cornea appeared clear. Multiple sections studied showed a cellular neoplasm composed of plump endothelial cells with well-canalized and poorly canalized vessels, confirming the diagnosis of cellular infantile hemangioma [Figs. 5 and 6]. The

baby was followed up for 2 months postsurgery and showed no deformities and had adequate lid movements.

Discussion

Capillary hemangioma is common in eyelids but uncommon in the conjunctiva. These are benign vascular tumors which consist of endothelial cell proliferation. It usually presents a few weeks after birth, sometimes at birth, grows for several months, and later regresses spontaneously over years. These occur singly or as part of syndromes (PHACES). Capillary hemangiomas of conjunctiva are rare, and mostly, the lesions are small, demanding only close watch. Usually, cutaneous and orbital hemangiomas are treated with oral steroids or propranolol. Recently, cases of effective management of small conjunctival hemangiomas with topical timolol have been reported. The current literature also shows management of sessile palpebral conjunctival capillary hemangiomas with oral beta blockers. In our case, the baby was brought to us with a red, lobulated mass with stalk present since birth and arising exclusively from the upper eyelid conjunctiva. In order to prevent amblyopia,the lesion was surgically excised,which was possible due to its pedunculated nature.

Conclusion

Conjunctival capillary hemangioma of pedunculated nature has not been reported in literature so far to the best of our knowledge.

Acknowledgment

We would like to thank Dr. G Rajamani, Professor and Head of the Department, Department of Paediatric surgery, Coimbatore Medical College Hospital, Coimbatore, for the technical aid.

Declaration of patient consent

The authors certify that they have obtained all appropriate patient consent forms. In the form the patient(s) has/have given his/her/their consent for his/her/their images and other clinical information to be reported in the journal. The patients understand that their names and initials will not be published and due efforts will be made to conceal their identity, but anonymity cannot be guaranteed.

Pseudotumor Cerebri Complicating Multisystem Inflammatory Syndrome in a Child

Karuppannasamy Divya[1], Chellappan Indumathi[2], Kanagaraju Vikrant[3], Sundaram Padmanaban[1]

[1]Department of Ophthalmology, PSG Institute of Medical Sciences and Research, Coimbatore, Tamil Nadu, India, [2]Department of Pediatrics, PSG Institute of Medical Sciences and Research, Coimbatore, Tamil Nadu, India, [3]Department of Radiology, PSG Institute of Medical Sciences and Research, Coimbatore, Tamil Nadu, India

Abstract

Purpose: To report a case of pseudotumor cerebri (PTC) in a child associated with multisystem inflammatory syndrome in children (MIS-C), associated with presumed coronavirus disease 2019.

Methods: A previously healthy 11-year-old female child presented with a 4-day history of fever, headache, vomiting, and loose stools. Laboratory investigations revealed neutrophilic leukocytosis, and markers of inflammation (C-reactive protein, ferritin, and interleukin-6) were significantly elevated. Pharyngeal swab for severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) by polymerase chain reaction was negative while anti-SARS-CoV-2 antibody was highly reactive. Ophthalmic evaluation for transient visual obscurations during hospital course revealed swelling of the optic disc in both eyes. Spectral-domain optical coherence tomography and ultrasonography confirmed the ophthalmoscopic findings. There was no neurologic deficit. Magnetic resonance imaging of the brain and magnetic resonance venogram revealed no structural lesion. The opening pressure of cerebrospinal fluid (CSF) was 336 mm of water, and CSF composition was normal.

Results: A diagnosis of PTC associated with MIS-C was made, and the child was treated with oral acetazolamide. Edema of the optic disc regressed following therapy, and the child is under follow-up.

Conclusions: PTC can occur in association with MIS-C. Clinicians need to be aware of this potential neuro-ophthalmic complication in MIS-C. Prompt diagnosis and treatment can prevent visual loss.

Introduction

Pseudotumor cerebri syndrome (PTCS) is a disorder characterized by increased intracranial pressure of unclear etiology that carries significant morbidity and limited therapeutic options. PTCS can be primary otherwise called idiopathic intracranial hypertension (IIH) or secondary, attributable to a number of medical conditions and drugs. This neurologic syndrome predominantly affects obese women of reproductive age group, and clinical features include symptoms and signs of raised intracranial pressure with normal cerebrospinal fluid (CSF) composition and no structural abnormality on brain imaging.[1] PTCS is relatively uncommon in children and is associated with variable risk factors and clinical presentation.[2] We report a case of PTCS in a child associated with multisystem inflammatory syndrome in children (MIS-C), temporally associated with coronavirus disease 2019 (COVID-19).

abdominal pain, and loose stools. There was associated lethargy but no history of seizures, altered sensorium, or respiratory symptoms. There were no sick contacts. At admission, the child had a temperature of 39°C, heart rate of 112 beats/min, and oxygen saturation of 100% on room air. Body mass index was 16 kg/m^2. Physical examination was unremarkable except for bilateral conjunctival congestion. Investigations revealed decreased hemoglobin, leukocytosis with neutrophilia, and elevated inflammatory markers including ferritin, interleukin-6 (IL-6), and C-reactive protein. Blood and urine cultures were negative, and liver function tests were found to be normal. Nasopharyngeal and oropharyngeal swabs for severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) by real-time polymerase chain reaction (RT-PCR) were negative. Serologic testing for SARS-CoV-2 antibodies by chemiluminescence immunoassay was highly reactive (observed titer – 212, ≥1 being labeled reactive) suggestive of SARS-CoV-2 infection. Table 1 shows the laboratory parameters. Echocardiogram was normal. On day 3 of admission, the child complained of transient obscurations of vision lasting for a few seconds associated with change in posture, and was referred for ophthalmic consultation.

On examination, uncorrected visual acuity was 20/20, and color vision was normal in both eyes. Anterior segment examination was unremarkable, and pupillary responses were normal. Extraocular movements were full. Fundus examination revealed optic disc swelling in both eyes [Figure 1a]. Neurologic examination was otherwise normal. Visual field evaluation by automated perimetry (Humphrey field analyzer) was found to be unreliable due to extensive fixation losses. Spectral-domain optical coherence tomography (OCT) showed increased thickness of peripapillary retinal nerve fiber layer (RNFL) in both eyes in all the four quadrants confirming edema of the optic disc [Figure 2a]. Magnetic resonance imaging of the brain and magnetic resonance venography (MRV) revealed normal ventricles, brain parenchyma, and venous sinuses. Transorbital ultrasound revealed bulging optic disc in both eyes. The optic nerve sheath diameter (ONSD) measurements obtained 3 mm posterior to the globe were found to be 5.6 mm in the right eye and 6 mm in the left eye [Figure 3a]. Lumbar puncture revealed a CSF opening pressure of 336 mm of water. CSF cultures were negative, and biochemistry was normal.

Since the child was hemodynamically stable and not hypoxic (SpO_2 100% on room air) at admission as well as during hospital course, she was managed with empiric broad-spectrum antibiotic therapy (intravenous ceftriaxone 2 g for 7 days) along with supportive care for fever (paracetamol) and loose stools (intravenous fluid replacement). As serial IL-6 and serum ferritin showed declining trend, the child was treated only with supportive measures. A diagnosis of pseudotumor cerebri (PTC) associated with MIS-C was made, and the child was started on oral acetazolamide 500 mg twice daily. By 4 weeks, headache and transient visual obscurations had subsided. Visual acuity remained 20/20, and fundus examination revealed resolving disc edema. The dose of oral acetazolamide was reduced to 250 mg thrice daily. At her last visit, 7 weeks since her initial presentation, she was found to have visual acuity of 20/20 and resolved disc edema in both eyes [Figure 1b]. Follow-up OCT revealed normalization of peripapillary RNFL thickness [Figure 2b]. The ONSD measurements were found to be 4 mm in both eyes at follow-up [Figure 3b]. The dose of acetazolamide has been tapered further, and she is under follow-up.

Table 1: Laboratory parameters of the patient and reference range

Parameter	Value	Reference range
Hemoglobin (g/dL)	10.5	11.5-15.5
White blood cell count (10^3/μL)	17	5-13
Neutrophil (%)	91.1	45-65
Lymphocyte (%)	7.5	32-52
Erythrocyte sedimentation rate (mm/h)	31	4-12
C-reactive protein (mg/dL)	39	<0.6
Serum ferritin (ng/mL)	352.4	7-140
IL-6 (pg/mL)	197.8	<7
NT-proBNP (pg/mL)	1163	<125
D-dimer (mg/L FEU)	1.48	<0.5
Anti-SARS-CoV-2 titer	212	<1

IL-6: Interleukin-6, NT-proBNP: N-terminal-pro-brain natriuretic peptide, Anti-SARS-CoV-2: Antibody against severe acute respiratory syndrome coronavirus 2

Discussion

MIS-C, also called pediatric inflammatory multisystem syndrome temporally associated with SARS-CoV-2, is a life-threatening condition that can lead to multi-organ dysfunction and long-term sequelae. The clinical features of MIS-C include severe illness necessitating hospitalization, fever, and involvement of two or more organ systems, in combination with laboratory evidence of inflammation and laboratory or epidemiologic evidence of SARS-CoV-2 infection.[3] Our

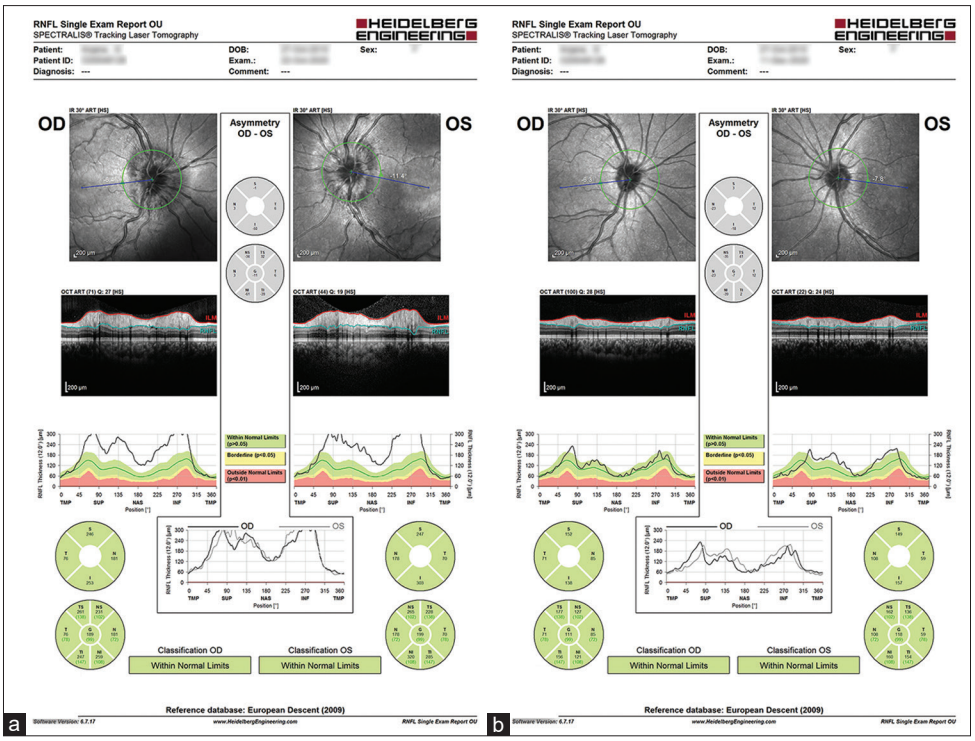

Figure 2: (a) Spectral-domain optical coherence tomography (SD-OCT) showing increased thickness of peripapillary retinal nerve fiber layer (RNFL) in both eyes. (b) SD-OCT both eyes at follow-up showing normalization of peripapillary RNFL thickness

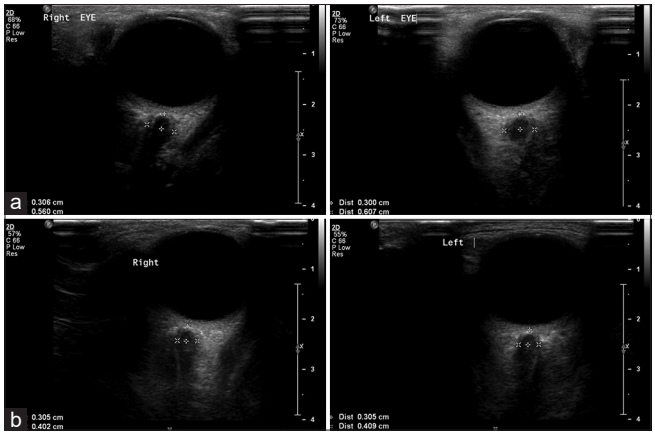

Figure 3: (a) Transorbital ultrasound showing increased optic nerve sheath diameter (ONSD) 3 mm posterior to inner scleral surface; 5.6 mm in the right eye and 6 mm in the left eye. (b) Transorbital ultrasound at follow-up showing normalization of ONSD; 4 mm in both eyes

patient was found to meet all the criteria specified in the Centers for Disease Control and Prevention and World Health Organization case definitions of MIS-C.[4,5]

The pathophysiology of MIS-C is unclear, and possible mechanisms include T-cell or antibody recognition of self-antigens resulting in autoantibodies, immune response against viral antigens expressed on infected cells and formation of immune complexes activating inflammation as well as viral superantigen sequences which activate host immune cells.[6] Dysregulated hyperinflammation is a critical event in the pathogenesis of MIS-C, and this condition is frequently associated with gastrointestinal symptoms and cardiovascular dysfunction.[7]

Although neurologic manifestations have been documented during acute phase of infection with SARS-CoV-2,[8,9] involvement of the central nervous system is uncommon in MIS-C. The neurologic features of MIS-C have been strongly suggested to represent a postinfectious immune response, and manifestations reported include headache, encephalopathy, and aseptic meningitis.[10]

We had not performed RT-PCR for SARS-CoV-2 on CSF since our patient showed evidence of previous infection with SARS-CoV-2 rather than current infection (pharyngeal swab was negative while antibodies to SARS-CoV-2 were present). Only one-third of cases of MIS-C have been reported to be positive by RT-PCR for SARS-CoV-2. The delayed presentation of MIS-C relative to the pandemic curve, a low proportion of cases who were SARS-CoV-2 positive by RT-PCR, and a high proportion who were antibody positive suggest that this inflammatory syndrome is not mediated by direct viral invasion but coincides with the development of acquired immune responses to SARS-CoV-2.[6] Previous studies have noted the absence of SARS-CoV-2 RNA in CSF analysis of COVID-19 patients with neurological symptoms suggesting that indirect mechanisms are responsible for neurologic manifestations in these patients.[11,12]

Although the symptoms of PTCS in children are similar to that of adults, the demographics vary, and children are reported to

have a higher incidence of secondary PTC. A distinct seasonal variation has been reported in the clinical presentation of IIH in prepubertal children, suggesting a possible association between IIH and concurrent infections in this age group.[13] Agraz *et al*. have noted a high incidence of atopy in their study cohort of children with PTC, suggesting that autoimmune component may play a role in pediatric population.[2]

To the best of our knowledge, four similar cases of PTCS associated with MIS-C (two case reports and a case series of two patients) have been reported in literature.[14-16] Although two patients had received therapy with doxycycline and steroids, the short course and recent initiation preclude the possibility of these medications contributing to increased intracranial pressure.

The mechanism behind the occurrence of PTCS in association with MIS-C is unclear. It has been postulated that increased intracranial pressure reflects systemic inflammation related to SARS-CoV-2 infection, resulting in central nervous system effects.[16] It is of interest to note that obesity, the most striking risk factor for PTCS, is associated with dysregulation of several inflammatory cytokines and aberrant glucocorticoid metabolism through manipulation of the enzyme 11-beta-hydroxysteroid dehydrogenase (11β-HSD).[17] 11β-HSD is a bidirectional enzyme that regulates prereceptor corticosteroid availability and glucocorticoid availability in the central nervous system that is one of the factors pivotal to intracranial pressure homeostasis. Among the two isoforms, 11β-HSD1 activates cortisol from cortisone while the isoform 11β-HSD2 inactivates cortisol. It is well established that several inflammatory cytokines such as tumor necrosis factor-α and ILs 1 and 6 are potent activators of 11β-HSD1.[18]

We speculate that PTC associated with MIS-C can be multifactorial, and one another possibility could be aberrant glucocorticoid metabolism as a result of cytokine storm and 11β-HSD1 activity. Increased 11β-HSD1 activity has been shown to influence the pathogenesis of PTC through manipulation of CSF dynamics at the level of choroidal plexus as well as arachnoidal granulations.[19] Further studies are warranted in this regard.

Few cases of isolated intracranial hypertension in association with active SARS-CoV-2 infection have been reported in adults. The proposed pathophysiologic mechanisms for intracranial hypertension include acute encephalitis, venous sinus thrombosis, intracranial venous congestion due to inflammation as a result of SARS-CoV-2 infection, and the associated coagulopathy as well as hyperviscosity state leading to impaired absorption of CSF.[20,21] The absence of clinical features such as altered sensorium/seizures and normal brain parenchyma evident on neuroimaging in our patient ruled out encephalitis. Normal MRV ruled out venous sinus thrombosis in our patient.

The other possible etiologies of swelling of optic disc in the setting of SARS-CoV-2 infection include optic neuritis, ischemic optic neuropathy, papillophlebitis, and retinal vein occlusion. The presence of normal visual acuity and color vision along with normal pupillary responses and the absence of associated retinal hemorrhages or venous tortuosity in our patient made us exclude these causes.

Prompt diagnosis and treatment of PTCS is essential since it can lead to irreversible visual loss. Although the pathophysiology remains unclear, clinicians should be aware of this potential complication with MIS-C. Fundus examination is valuable as part of a multidisciplinary approach toward management of MIS-C.

Inverse Association between Serum Bilirubin Levels and Retinopathy in Patients with Type 2 Diabetes Mellitus.

DIVYA KARUPPANNASAMY[1], RAGHURAM VENKATESAN[2], LEKHA THANKAPPAN[3], RAGHURAM ANDAVAR[4], SUNDAR DEVISUNDARAM[5]

ABSTRACT

Introduction: Oxidative stress plays a central role in the pathogenesis of Diabetic Retinopathy (DR) and serum bilirubin has been shown to have antioxidant properties.

Aim: To investigate the association between serum bilirubin concentration and DR in patients with Type 2 diabetes Mellitus (DM).

Materials and Methods: This was a hospital based, cross-sectional study where in 86 patients with Type 2 DM and 30 controls were recruited. The study was conducted at a tertiary care centre in South India between January 2014 and December 2014. The presence and the severity of DR were determined by fundus examination and grading of colour fundus photographs using the international clinical disease severity scale for diabetic retinopathy. Serum total, direct and indirect bilirubin levels were determined in all subjects and the association between bilirubin levels and severity of DR was studied.

Results: Among the 86 diabetics, 24 had no retinopathy and 62 had diabetic retinopathy of varying grades. The mean total bilirubin level among diabetic subjects (0.52±0.17) and controls (0.51±0.19) were found to be similar. The mean total as well as direct bilirubin levels were found to be lower in patients with retinopathy as compared to no retinopathy group ($p \leq 0.001$). The severity of DR was inversely proportional to the serum bilirubin levels ($p=0.010$). Serum total bilirubin was found to have a negative association with glycosylated haemoglobin and served as an independent determinant of diabetic retinopathy even after adjusting for risk factors known to be associated with DR ($p=0.001$).

Conclusion: Low serum bilirubin levels are significantly associated with increased risk of diabetic retinopathy independent of classic risk factors. Serum bilirubin can serve as a useful biomarker in identifying patients at risk for developing proliferative diabetic retinopathy.

INTRODUCTION

Diabetes Mellitus (DM) has assumed the proportions of a global epidemic and the number of diabetics in the world today is 415 million. This number is being projected to increase to 642 million by 2040 [1]. India leads the world in terms of its diabetic population and estimates have revealed that there are 62.4 million people with diabetes, and 77.2 million with prediabetes in India [2]. It is predicted that by 2030, DM may affect up to 79.4 million in India [3]. Due to these sheer numbers, the socioeconomic burden as a result of diabetes in India is among the highest in the world [4].

Along with this rapidly increasing disease, there is an increase in the associated microvascular complication DR, which is said to affect more than 93 million people worldwide [5]. Almost all patients with Type 1 DM and over 60% of the patients with Type 2 DM will develop DR in 20 years. DR is the most frequent cause of preventable blindness in middle aged population and therefore,represents a major public health issue [6].

Oxidative stress is considered to be one of the key factors in the pathogenesis of DR [7]. The retina is especially more susceptible to oxidative damage because of its high energy demands and exposure to light [8]. Various mechanisms contributing to the pathogenesis of DR such as inflammation, polyol pathway, accumulation of Advanced Glycation End Products (AGEs), flux of hexosamine Pathway and Protein Kinase C (PKC) activation are associated with overproduction of Reactive Oxygen Species (ROS) by the mitochondria [9].

Although, bilirubin has long been considered as a toxic waste product of heme catabolism, its role as a potential endogenous anti-oxidant under physiological conditions is being increasingly recognized [10]. Apart from its ability to scavenge over produced ROS, bilirubin is also said to have anti inflammatory effects [11]. Based on these physiological effects of bilirubin, several population-based studies have reported a negative association between serum bilirubin concentrations and the risk of diabetes [12], coronary artery disease [13], chronic kidney disease [14], peripheral arterial disease [15] and diabetic peripheral neuropathy [16].

Few studies in literature have shown, the association between serum bilirubin and DR [17-20]. Apart from age, gender, smoking and intake of drugs serum bilirubin concentrations are also affected by factors such as altitude and ethnicity and these are likely to influence the biological effects of bilirubin on human body.

Considering the potential role of oxidative stress in the pathogenesis of DR and the antioxidant and cytoprotective effects of bilirubin, this cross-sectional study aimed to evaluate the association between serum bilirubin and severity of retinopathy in patients with Type 2 DM from South India.

MATERIALS AND METHODS

This was a hospital-based cross-sectional study which included patients with Type 2 DM who were referred to the Ophthalmology Department of a tertiary care centre in South India between January 2014 and December 2014 for screening of DR. Exclusion criteria included history of chronic alcohol intake, smoking, intake of hepatotoxic medications within past six months, preexisting hepatobiliary abnormalities or chronic liver disease. Patients with preexisting ocular diseases like glaucoma, high myopia, previous ocular surgery or photocoagulation were excluded from the study. Patients with hypertension (>160/90 mmHg), anaemia or other systemic diseases like nephropathy which can accelerate the progression of DR were also excluded from the study. The study protocol was approved by the Institutional Ethics Committee and this study was conducted according to the principles of the Declaration of Helsinki. Informed consent was obtained from all participants.

Information on age, gender, duration of diabetes, blood pressure and body mass index was obtained from all participants.

All participants underwent a complete ocular examination including fundus examination with slit lamp biomicroscope using a 90 diopter lens after dilatation of pupils using 1% tropicamide eyedrops. This was followed by 30 degree colour stereoscopic fundus photography of 7 standard Early Treatment Diabetic Retinopathy Study (ETDRS) fields using a digital fundus camera (TRC-50 DX Mydriatic retinal camera; Topcon Medical Systems, Oakland, NJ).The severity of DR was determined by grading of colour fundus photographs following the international clinical disease severity scale for diabetic retinopathy which is based upon the findings of WESDR (Wisconsin Epidemiological Study of Diabetic Retinopathy) and ETDRS [21].

The diabetic patients were assigned to one of the following groups based on presence and severity of retinopathy.

1. Diabetic patients with no retinopathy.
2. Mild Non-Proliferative Diabetic Retinopathy (NPDR)
3. Moderate NPDR.
4. Severe NPDR and
5. Proliferative Diabetic Retinopathy (PDR)

The eye with worse retinopathy was chosen for inclusion in the study examinations. If both eyes had equal retinopathy, the right eye was assigned to the study.

Fasting venous blood samples were collected for the determination of serum total, direct and indirect bilirubin, blood glucose and Glycosylated Haemoglobin (HbA1c). The normal range of total serum bilirubin levels used in the study was 0.2 to 1.2 mg/dl.

STATISTICAL ANALYSIS

Statistical analysis was performed using SPSS version 19. The baseline characteristics of patients were presented as mean±standard deviation and n (%). Data on the patient's clinical characteristics were compared using One-way Analysis of Variance (ANOVA) as well as an independent sample Student's t-test. The serum bilirubin levels were divided into quartiles and Chi-square test was used to see the comparison between the proportions. Multiple logistic regression analysis was performed to assess independent associations between the presence of key risk factors of DR including the statistically significant factors in univariate analysis. All tests for statistical significance were two-tailed, and performed assuming a Type I error probability of <0.05.

RESULTS

A total of 116 subjects were included in the study out of whom 86 were patients with Type 2 diabetes and 30 were controls.

The mean total bilirubin level among diabetic subjects (0.52±0.17) and controls (0.51±0.19) were found to be similar. The direct bilirubin level was found to be higher in diabetics (0.29±0.13) as compared to controls (0.18±0.06, p=0.000). The indirect bilirubin level was lower in diabetics (0.23±0.07) as compared to healthy controls (0.33±0.13, p=0.000).

[Table/Fig-1] shows the clinical characteristics of the study population.

The mean duration of diabetes and HbA1c were significantly higher among patients with DR compared to those without retinopathy (p<0.001). We compared the serum total, direct and indirect bilirubin levels for diabetics without retinopathy (n=24) and those with DR (n=62). The total bilirubin was 0.65±0.16 in patients with no retinopathy and 0.47±0.16 in patients with DR. The mean total as well as direct bilirubin levels were found to be lower in patients with retinopathy as compared to no retinopathy group (p=0.000). There was no statistically significant difference in the levels of indirect bilirubin among both groups (p=0.100).

Characteristic	Controls (n=30)	Diabetics with no retinopathy (n=24)	Diabetics with retinopathy (n=62)
Age (yr)	52.97±8.95	57.63±10.54	57.29±8.5
Females, no. (%)	18 (60%)	9 (37.5%)	23 (37.1%)

[Table/Fig-4]: Scatter diagram showing negative association between serum total bilirubin and HbA1c (glycosylated haemoglobin) in diabetics.
TOT BR-Total bilirubin; HBA1C-glycosylated haemoglobin

Of the 62 diabetic patients with retinopathy, 15 patients had mild NPDR, 22 had moderate NPDR and 9 had severe NPDR. PDR was noted in 16 patients. We divided the study participants into quartiles on the basis of serum total bilirubin concentration (quartile 1=<0.40 mg/dl, quartile 2= 0.41-0.50 mg/dl, quartile 3= 0.51-0.60 mg/dl, quartile 4=>0.61 mg/dl).

[Table/Fig-2] shows the correlation between serum total bilirubin and severity of DR.

The percentage of DR in persons with lowest bilirubin quartile was 36.04%, compared with the percentage of 19.8%, 8.1% and 8.1% respectively in the second, third and fourth quartiles. Thus, the proportion of patients with DR was significantly higher in quartile 1 with lower levels of bilirubin as compared to the other three quartiles [Table/Fig-2]. The severity of DR was inversely proportional to the serum bilirubin levels (p=0.010) and none of the patients in the last quartile (>0.61) had proliferative retinopathy.

On multiple logistic regression analysis the duration of diabetes, HbA1c and total serum bilirubin were found to be independently associated with DR [Table/Fig-3]

Also, serum total bilirubin in diabetic subjects was found to have negative association with HbA1c [Table/Fig-4].

DISCUSSION

In the present, study serum bilirubin concentration correlated negatively with the severity of retinopathy in patients with Type 2 DM. Multiple regression analysis also revealed serum total bilirubin as an independent risk factor associated with diabetic retinopathy.

Bilirubin is generated when the enzyme Heme Oxygenase (HO) catalyzes the degradation of heme. This leads to the formation of biliverdin which is converted to bilirubin by biliverdin reductase. In the hepatocytes, unconjugated (lipid-soluble) bilirubin is conjugated by uridine diphosphate glucuronyl transferase (UDP-GT) to a water soluble form for excretion. Total bilirubin is the sum of unconjugated (indirect) and conjugated (direct) bilirubin and generally ranges from 0.2 to 1.2 mg/dl in healthy individuals.

Ever since the description of beneficial role of bilirubin as a physiologic antioxidant, several clinical studies evaluating, the possible associations between serum bilirubin and the risk of diabetes (and its complications) have been published [22-24].

In this observational study, we noted that Type 2 diabetics with retinopathy had significantly lower serum bilirubin concentrations than those without retinopathy. Our observations are in line with epidemiologic and hospital based studies elsewhere which have suggested an inverse relation between serum total bilirubin and DR [17-20]. There has been only one study on the association between serum bilirubin and DR from Indian population by Dave et al., [25]. They noted higher levels of total, direct and indirect bilirubin in patients without DR as compared to patients with retinopathy. However, in our study only total and direct bilirubin concentrations were found to be higher in patients without DR. Serum indirect bilirubin concentration was similar in both groups. Most studies on serum bilirubin and DR have focused on only total bilirubin without separating bilirubin types. Limited studies have shown a differentially protective effect of direct bilirubin on metabolic syndrome [26] and chronic kidney disease [27]. Further studies on the relation between bilirubin subtypes and DR are clearly needed.

In this study, we divided bilirubin levels into quartiles (<0.40, 0.41-0.50, 0.51-0.60 and >0.61 mg/dl and considered the lowest quartile as reference. This approach was to maintain adequate numbers within each quartile. The absolute values of serum bilirubin were low in our study compared to studies by Yasuda et al., and Najam et al., where the value of serum bilirubin in the lowest and highest quartile observed were<0.60 and >0.90 mg/dl respectively [17,18]. There are several potential reasons for the observed findings. Apart from differences in ethnicity, our hospital based study population was very much different from the above said epidemiologic studies in age distribution, anthropometry, comorbidities such as hypertension, cardiovascular disease and smoking habits, all factors that may affect the bilirubin levels and potentially the association between bilirubin and DR. Our study participants were non smokers and had no history of major systemic diseases.

Several potential mechanisms have been proposed for the observed relationship between serum bilirubin concentration and DR. Excessive production of free radicals and resultant oxidative stress has been said to contribute significantly to worsening of DR [28,29]. Bilirubin has been postulated as a potent antioxidant and cytoprotective agent that can protect cells from a 10,000 fold excess of hydrogen peroxide [30]. Therefore, lower serum bilirubin concentration would be expected to be associated with increased oxidative stress and thereby, accelerated progression of DR. Additionally clinical studies have demonstrated elevated levels of inflammatory markers like C-reactive protein and vascular cell adhesion molecules in patients with DR suggesting that inflammation is a critical factor leading to endothelial dysfunction in diabetic retinopathy [31,32]. Bilirubin has been proven to have anti-inflammatory properties and in-vitro studies have shown that bilirubin inhibited tumour necrosis factor α –induced upregulation of vascular cell adhesion molecules [33]. Hence, it could be hypothesized that higher serum bilirubin concentration is associated with a lower risk of development and progression of DR through its anti-inflammatory effects. Further, recent animal studies have shown that, increasing serum bilirubin levels either through endogenous synthesis or exogenous administration improves endothelial dysfunction in diabetes by activation of protein kinase B [34].

Considering these physiologic effects of bilirubin it can be postulated that bilirubin can effectively retard or interrupt the pathways to development of DR and therefore serve as a potential biomarker for risk of diabetic retinopathy.

We observed an inverse and graded association between serum total bilirubin and severity of DR in this study and the strength of serum total bilirubin concentration as an independent determinant of DR was similar to those of conventional risk factors such as HbA1c and duration of diabetes in multiple regression analysis. Serum total bilirubin concentration was an independent determinant of DR even after adjustment for other risk factors (p=0.001).

We also observed a negative association between serum total bilirubin and HbA1c among diabetic subjects. Our data are consistent with observations of Choi et al., who have also noted a significant inverse association between serum total bilirubin and HbA1c in their study on 690 Korean patients with Type 2 DM [35].

This can be partly explained by the fact that, increased serum bilirubin reduces the oxidative stress and thereby, inhibits the glycosylation of haemoglobin. Also, upregulation of the heme oxygenase system and increased generation of bilirubin/biliverdin have been proven to enhance insulin production and sensitivity in diabetic rats [36]. Therefore, it can be suggested that bilirubin improves glycaemic control through its effects on insulin. Further studies are needed to precisely elucidate the mechanism behind this association.

The strength of our study is based on the fact that our study participants were non-smokers and did not have other systemic diseases. We excluded these patients to focus on the association between serum bilirubin and retinopathy in patients with Type 2 diabetes.

LIMITATION

Our study has some limitations. First, our sample size was limited and the cross-sectional design of our study prevents determination of a temporal association or the cause-effect relationship between serum total bilirubin and the development of retinopathy. Only prospective studies can reveal whether serum bilirubin predicts the development of DR. Second, we performed only a single measurement of serum bilirubin which might have within subject variation. However, all subjects including controls were examined after overnight fast.

CONCLUSION

In conclusion, our cross-sectional study suggested that low total serum bilirubin level was independently associated with higher risk of DR in patients with type 2 diabetes, regardless of other conventional risk factors. Further, prospective studies on large samples are required to better assess the effects of bilirubin on diabetic retinopathy.

Brief Communication

Needs Assessment of Ophthalmology Education for Undergraduate Medical Students – A Study from a Medical College in South India

Karuppannasamy Divya[1], Kannappan Suvetha[2], Alo Sen[1], Devisundaram Sundar[1]

Departments of [1]Ophthalmology and [2]Community Medicine, PSG Institute of Medical Sciences and Research, Coimbatore, Tamil Nadu, India

ABSTRACT

Background: Adequate ophthalmic diagnostic and clinical skills are essential for practitioners in primary care settings as well as specialty care physicians. The objectives of this study were to assess the adequacy of ophthalmology teaching in undergraduate medical education and to evaluate the comfort of medical students in diagnosing common eye problems and performing ophthalmic skills. **Methods:** A questionnaire based, cross-sectional survey was conducted among third-year undergraduate students from a medical college in South India at the end of ophthalmology training from February 2014 to December 2014. The main outcome measures were hours of classroom-based instruction and clinical exposure to ophthalmology received by the students and their comfort level in diagnosing common eye problems and performing ophthalmic skills. **Results:** 134 students participated in the study. They had received an average of 96.2 ± 5.9 and 112.5 ± 11.3 hours of classroom and clinic-based instruction, respectively. The participants' comfort in diagnosing eye problems was satisfactory for cataract and eyelid disorders but not for ophthalmic emergencies. Only 45.5% had satisfactory knowledge in community ophthalmology. Respondents were more proficient in visual acuity testing (93.3%) and assessment of pupillary reaction (80.6%) than direct ophthalmoscopy (41%). **Discussion:** Undergraduate medical students from India received a greater amount of ophthalmology instruction compared to the International Council of Ophthalmology task force recommendations. Gaps in community ophthalmology and knowledge-skills discrepancies were noted. Review of curriculum, appropriate training resources, and effective teaching methods tailored towards primary care may be useful to improve the training.

Keywords: Comfort, knowledge, ophthalmology, undergraduate medical education

Background

Ophthalmology makes up a significant proportion of primary care consultations.[1] A basic knowledge of ophthalmology is essential in the management of several neurologic, endocrine, rheumatic, and infectious conditions. Despite the relevance of ophthalmology to medical practice, little time is allocated to teaching of ophthalmology in undergraduate medical education and the majority of primary care physicians do not feel that they have received adequate undergraduate ophthalmic education.[2] Also several studies have noted that medical students receive too little ophthalmic training.[3-5]

In India, the five and one-half year undergraduate medical training consists of four and one-half years of teaching of subjects comprising the medical curriculum and one year of internship. Ophthalmology is being taught in the third year after preclinical and paraclinical subjects.

The state of undergraduate ophthalmology training from medical colleges in India has not been studied so far. Evaluation

of ophthalmic knowledge and skills of undergraduates at the end of ophthalmology training would help in generating critical feedback on undergraduate ophthalmic curriculum planning. The objectives of this study were:

1. To assess the adequacy of ophthalmology teaching in undergraduate medical education
2. To assess the comfort level of medical students in diagnosing and treating common eye problems and performing ophthalmic skills.

Methods

After approval from the institutional review board, undergraduate medical students from a medical college in South India were included in the study at the end of their ophthalmology training (February 2014 to December 2014). The adequacy of ophthalmology education was quantified by determining the hours of classroom-based instruction and clinical exposure to ophthalmology received by the students and comparing these with the recommendations of the Medical Council of India (MCI) as well as the International Council of Ophthalmology (ICO).

A validated questionnaire [Appendix 1] was given to the students and their responses collected anonymously. The questionnaire consisted of three parts. Parts 1 and 3 assessed the students' comfort with respect to diagnosing specific ophthalmology conditions and performing ophthalmology-related skills on a Likert scale from 1 to 5 (1 = not at all comfortable, 2 = somewhat comfortable, 3 = moderately comfortable, 4 = comfortable, and 5 = very comfortable). In terms of comfort level, we examined the ease with which study participants reported they were able to diagnose common eye problems and perform ophthalmic skills.

The second part assessed knowledge on certain topics on a Likert scale, also from 1 to 5 (1 = very poor, 2 = poor, 3 = average, 4 = good, and 5 = very good). The conditions and skills covered in the questionnaire were based on the topics covered in the undergraduate ophthalmology curriculum recommended by the MCI.[6]

Participants were also asked about the number of hours spent in self-directed learning and how comfortable they felt in managing ophthalmology-associated issues overall.

Likert scale-based responses were subsequently dichotomized and reduced to proportions by categorizing scores 1–2 as unsatisfactory or inadequate and 3–5 as satisfactory or adequate. Data were entered using the Statistical Package for the Social Sciences (version 19 (SPSS, Inc., Chicago, IL, USA) and examined using descriptive and analytical statistics to yield frequencies, percentages, and proportions.

Results

Of the 150 undergraduate medical students, 134 responded to the questionnaire (response rate = 89.6%).

The main modes of ophthalmology exposure were didactic lectures (35 hours), tutorials (37.5 ± 3.8 hours), seminars (23.7 ± 2.2 hours), and clinic-based learning. Our study participants had received an average of 96.2 ± 5.9 hours of classroom-based instruction. They also had received 112.5 ± 11.3 hours of clinic-based instruction in the eight weeks of clinical posting. 121 participants (90.3%) had spent up to 10 hours in self-directed learning while 13 participants (9.7%) had spent more than 10 hours in self-directed learning.

The results of the participants' comfort in diagnosing ophthalmic conditions are presented in Figure 1. Figure 2 shows the students' adequacy of knowledge in community and systemic ophthalmology as well as indications for ophthalmic referral. Figure 3 shows the study participants' comfort in performing MCI recommended clinical skills. Tables 1-3 show the numerical data for the corresponding figures. Finally, 101 participants (75.4%) felt comfortable in managing ophthalmology associated issues overall.

Discussion

This cross-sectional observational study attempted to quantify the adequacy of undergraduate ophthalmic education and students' comfort with regard to the management of ocular conditions.

In comparison with MCI recommendations, our study participants received a satisfactory number of hours of both classroom and clinic-based instruction. The MCI recommends clinical training of 8 weeks and a total of 100 teaching hours in ophthalmology, which includes 30 h of didactic lectures,

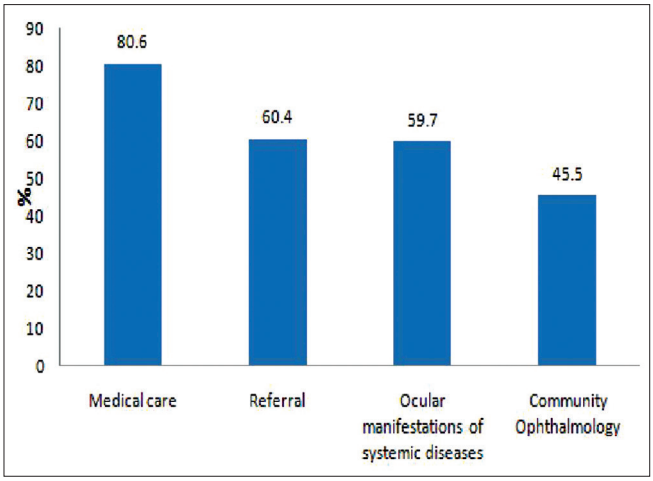

Figure 2: Students' adequacy of ophthalmic knowledge

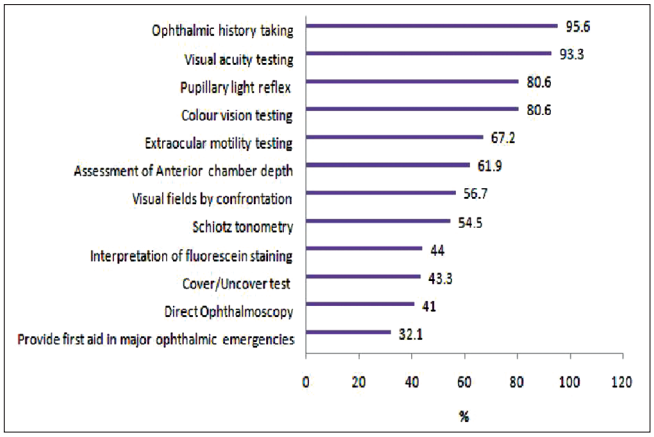

Figure 3: Students' self-reported proficiency in performance of ophthalmic skills

Table 1: Students' comfort in diagnosing common ophthalmic conditions

Ophthalmic conditions	Participants with adequate comfort in diagnosing common ophthalmic conditions (n=134), n (%)
Cataract	131 (97.8)
Eyelids and lacrimal pathology	114 (85.1)
Acute iridocyclitis	98 (73.1)
Cornea and external eye disease	91 (67.9)
Glaucoma	85 (63.4)
Squint	84 (62.6)
Leukocoria	80 (59.7)
Ophthalmic emergencies	54 (40.3)

60 h of tutorials and seminars (including integrated learning), and 10 h of self-directed learning.[7] These guidelines suggest a greater amount of ophthalmology exposure in undergraduate medical education in India when compared with ICO guidelines. The ICO recommends 40–60 h of ophthalmology exposure during undergraduate training.[8]

According to the curriculum recommended by the MCI, the goal of teaching ophthalmology to undergraduate medical students is to provide such knowledge and skills to the students that shall enable them to practice as a clinical and primary eye care physician.[6] The curriculum provides a list of competencies which need to be demonstrated by the student at the end of ophthalmology training. These include knowledge of common eye problems in the community; ability to manage common eye problems and identify indications for referral; recognize visual impairment and blindness in the community; and implement the National programme as applicable in the primary care setting.[7]

Most of the participants in the study reported a satisfactory level of comfort in diagnosing common ophthalmic problems. The fact that 97.8% reported a satisfactory level of comfort in diagnosing cataract is encouraging since cataract is the leading cause of preventable blindness in the developing world. Yet, despite this satisfactory level of comfort in managing common eye problems, most study participants' comfort in diagnosing ophthalmic emergencies such as endophthalmitis, rupture globe, and chemical injuries was found to be inadequate.

Nearly 60% reported to have adequate knowledge in ocular manifestations of systemic diseases. This could be because of better teaching resources as well as integration of ophthalmology topics into other subjects of the medical curriculum horizontally and longitudinally. The self-rated knowledge of more than one-half of the study participants was found to be unsatisfactory in community ophthalmology. With greater emphasis placed on teaching disorders of the eye, in theory lectures as well as in hospital settings, community ophthalmology is often neglected. A study on the status of ophthalmic medical education in the South-East Asia Region of World Health Organization has also highlighted this concern, where students have little exposure to community ophthalmology.[9]

The knowledge of most study participants on the indications of medical treatment and referral to eye clinics was adequate. With a significant shortage of ophthalmologists in developing countries, an adequate level of comfort of primary care physicians in providing medical care and accuracy in referral is essential. A high rate of referral places pressure on the limited resources of ophthalmic casualty departments and outpatient clinics.

More than 80% reported competency in ophthalmic history taking, visual acuity and color vision testing, and pupil examination. These are relevant not only in ophthalmology but also in general medicine, neurology, and trauma care. However, only 44% reported an adequate level of comfort in interpretation of fluorescein staining and 54.5% in Schiotz tonometry. This is an area of concern because corneal blindness

Table 2: Students' adequacy of knowledge

Ophthalmic knowledge	Participants with adequate knowledge (*n*=134), *n* (%)
Medical care	108 (80.6)
Referral	81 (60.4)
Ocular manifestations of systemic diseases	80 (59.7)
Community ophthalmology	61 (45.5)

Table 3: Students' proficiency in performance of ophthalmic skills

Ophthalmic skills	Participants with adequate comfort in performing ophthalmic skills (*n*=134), *n* (%)
Ophthalmic history taking	128 (95.6)
Visual acuity testing	125 (93.3)
Pupillary light reflex	108 (80.6)
Color vision testing	108 (80.6)
Extraocular motility testing	90 (67.2)
Assessment of anterior chamber depth	83 (61.9)
Visual fields by confrontation	76 (56.7)
Schiotz tonometry	73 (54.5)
Interpretation of fluorescein staining	59 (44)
Cover/uncover test	58 (43.3)
Direct ophthalmoscopy	55 (41)
First aid in major ophthalmic emergencies	43 (32.1)

and glaucoma contribute to a major extent to the burden of blindness in India; adequate proficiency of the primary care physician in these skills will help in early diagnosis and treatment or referral, thereby reducing the risk of visual loss.

Only 41% of respondents indicated that they had adequate proficiency in performing direct ophthalmoscopy which is consistent with studies elsewhere.[2,10] This could be because of the limited time devoted to teaching ophthalmoscopy in the medical school curriculum as well as the technical challenges involved.

Although most students were comfortable in managing ophthalmology associated issues overall, gaps were noted in certain key areas. Review of the curriculum with greater emphasis on community eye care and blindness control strategies, adequate training resources, and effective teaching methods tailored toward primary care would help to increase the medical students' comfort in managing common eye problems.

Since our observations are from a single center, generalization of results is limited. Subjective bias due to the candidates varying ability to accurately self-evaluate is also a limitation. The choice of the study population was medical students at the end of ophthalmology training rather than interns because of the possibility of recollection bias. A similar study on interns or junior medical officers would provide more insight into the knowledge and gaps in training.

In spite of these limitations, this needs assessment study is the first of its kind in India to assess the adequacy of ophthalmic teaching and the knowledge and clinical skills of undergraduate medical students. Ophthalmology in India is being taught as part of the essential undergraduate medical curriculum and not exclusively as an elective. Students receive adequate exposure to ophthalmology, and the undergraduate curricular hours are greater than the guidelines published by the ICO. Since ophthalmology related topics and examination skills are included in most of the standardized medical licensing examinations and internal medicine boards, medical graduates from India are at a distinct advantage.

Appendix

Appendix 1: Questionnaire

1. Using the table below, please indicate how comfortable You feel diagnosing the following issues based on your present knowledge:
   (1 = not at all comfortable, 2 = somewhat comfortable, 3 = moderately comfortable, 4 = comfortable, 5 = very comfortable)
   Conjunctiva/cornea 1 2 3 4 5
   Viral conjunctivitis
   Allergic conjunctivitis
   Subconjunctival hemorrhage
   Pterygium
   Corneal abrasion/ulcer
   Keratomalacia
   Corneal blindness
   Eyelid/lacrimal sac 1 2 3 4 5
   Blepharitis
   Chalazion
   Stye
   Dacryocystitis
   Lens/Uvea 1 2 3 4 5
   Cataract
   Acute iridocyclitis
   Glaucoma 1 2 3 4 5
   Primary open-angle glaucoma
   Acute angle-closure glaucoma
   Ophthalmic emergencies 1 2 3 4 5
   Globe rupture
   Chemical injuries
   Endophthalmitis
   Pediatric ophthalmology 1 2 3 4 5
   Strabismus
   Leukocoria

2. Using the table below, please indicate your knowledge on the following issues:
   (1 = very poor, 2 = poor, 3 = Average, 4 = good, 5 = Excellent)
   Ocular manifestations of systemic diseases 12345
   Diabetic retinopathy
   Hypertensive retinopathy
   Tuberculosis
   Toxemia of pregnancy
   HIV
   Community ophthalmology 1 2 3 4 5
   Magnitude of blindness in India
   NPCB and implementation at various levels
   Functions of ophthalmic assistant
   Organization of eye camp
   Medical care/referral 1 2 3 4 5
   Indications of topical antibiotics
   Indications of topical steroids
   Indications of antiglaucoma drugs
   Indications of ophthalmology referral

3. Using the table below, please indicate how comfortable You feel performing the following ophthalmology-related skills:
   (1 = not at all comfortable, 2 = somewhat comfortable, 3 = moderately comfortable, 4 = comfortable, 5 = very comfortable)
   Clinical assessment 1 2 3 4 5
   Ophthalmic history taking
   Visual acuity testing
   Test color vision
   Cover/uncover test
   Assessment of anterior chamber depth
   Pupil examination/swinging flashlight test
   Visual field testing by confrontation
   Extraocular movements
   Interpretation of fluorescein staining
   Schiotz tonometry
   Direct ophthalmoscopy
   Provide first aid in major ophthalmic emergencies

4. How many hours would you have spent in self-directed learning in ophthalmology?
   ("self-directed learning" describes a process by which individuals take the initiative, with our without the assistance of others, in diagnosing their learning needs, formulating learning goals, identify human and material resources for learning, choosing and implement appropriate learning strategies, and evaluating learning outcomes)
   1. 0–2 h 2. 2–5 h 3. 5–7 h
   4. 7–9 h 5. 0 > 10 h
5. How comfortable do you feel managing ophthalmology associated issues overall?
   1. Not comfortable at all 2. Somewhat comfortable
   3. Moderately comfortable 4. Comfortable 5. Very comfortable

THE END

Thank you for taking time for our survey.

Dry Eye Disease and Tear Dysfunction in Patients with Type 2 Diabetes: A Hospital-Based Study from South India

K Divya, N Dhivya, M Raaja Ganesh, D Sundar

Department of Ophthalmology, PSG Institute of Medical Sciences and Research, Coimbatore, Tamil Nadu, India

Abstract

Purpose: Diabetics are more prone to dry eye disease (DED) and tear film dysfunction. The aim of this study was to assess the frequency of DED and tear film abnormalities in patients with type 2 diabetes compared to healthy controls. **Materials and Methods:** This was a hospital-based prospective case-control study. One hundred patients with type 2 diabetes and 100 healthy controls were enrolled by consecutive sampling. All study participants completed the Ocular Surface Disease Index (OSDI) questionnaire to score dry eye symptoms. Tear film breakup time (TFBUT), ocular surface staining with fluorescein and Schirmer's test were performed, and results were analyzed. Student's *t*-test was applied for comparisons between groups. Correlation between variables was detected using Pearson's correlation coefficient. Statistical significance was set at $P < 0.05$. **Results:** Dry eye was encountered in 54 among the 100 diabetic patients studied. Age and sex of diabetic patients were not found to affect the dry eye status. Longer duration of diabetes was significantly associated with DED ($P = 0.03$). Significant differences in OSDI scores, TFBUT, fluorescein staining, and Schirmer's test values were observed between the study groups ($P < 0.001$). An increased level of glycosylated hemoglobin was significantly associated with abnormal tear function tests. **Conclusion:** Patients with longer duration of diabetes and poor glycemic control are more predisposed to have abnormalities of the tear film and DED. Apart from conventional therapies, optimal glycemic control should be an important consideration in the management of tear dysfunction in diabetic patients.

Keywords: *Diabetes, dry eye, tear film*

Introduction

The prevalence of diabetes mellitus (DM) has increased significantly in the past several decades and the disease continues to remain a global epidemic. Estimates suggest that 439 million people in the world are likely to have DM by 2030 and this increase in number of diabetics is predicted to be disproportionately more in developing countries.[1] The two major potentially blinding complications of diabetes, namely cataract and retinopathy, have been extensively researched in literature. Apart from these, people with diabetes are also prone for ocular surface disease that includes dry eye, persistent epithelial defects, decreased corneal sensation, and tear film dysfunction. Studies have shown an intimate, complex relationship between diabetes, dry eye, and ocular surface abnormalities.[2,3]

The reported prevalence rates of dry eye in diabetics have been found to vary widely between 27% and 54%.[4,5] A recent study from a cornea specialty clinic found the overall presence and the severity of dry eye to be similar in the diabetic and nondiabetic groups. However, significant differences were observed between groups with regard to individual diagnostic assessments.[6] Studies on changes in tear function parameters in diabetes have also shown conflicting results.[7,8] These can be attributed to major differences in the study characteristics of the population, methodologies, and wide array of diagnostic methods used for assessment. Limited data exist on the occurrence of dry eye and ocular surface disease among diabetics in the Indian population.[9]

This prospective study from India sought to study the frequency of dry eye disease (DED) and tear film changes in patients with type 2 diabetes compared to healthy controls.

Materials and Methods

This was a hospital-based cross-sectional study which included 100 patients

with type 2 DM. Consecutive patients attending the Ophthalmology Department of a tertiary care center in South India between June 2016 and 2017 were invited to participate. Exclusion criteria included the history of smoking, contact lens wear, past ocular surgery, intake of systemic medications such as antihistamines, tricyclic antidepressants, and other drugs known to cause dry eye. Patients with known ocular or systemic disease that might affect the ocular surface were also excluded from the study. One hundred individuals matched by age were enrolled as a control group. The controls were recruited from individuals attending the department of ophthalmology for routine eye examination and did not have any ocular or systemic disease other than refractive errors. The study protocol was approved by the Institutional Ethics Committee, and the study was conducted according to the principles of the Declaration of Helsinki. Informed consent was obtained from all participants.

For each participant, a detailed ocular and general medical history, including duration of diabetes, medications, and glycosylated hemoglobin (HbA1c) value within the past 3 months was obtained. All study participants completed the Ocular Surface Disease Index (OSDI; Allergan, Inc., Irvine, CA, USA) questionnaire to score dry eye symptoms. The OSDI consists of 12 questions based on symptoms within the past 1 week. The frequency of ocular subjective symptoms (soreness, blurred vision), difficulty with vision-related function (television, visual display unit, driving, and reading) and discomfort due to environmental triggers (low humidity, high wind) are assessed on a Likert scale. The scores range from 0 (least severe) to 100 (most severe).[10]

All participants underwent a general physical and comprehensive ophthalmic examination with slit lamp, including best-corrected visual acuity. Evaluation of the ocular surface and tear film was done by performing the following tests described below in a sequential manner.[11]

Tear film breakup time (TFBUT) was performed by applying a fluorescein strip (Fluostrip/India/Contacareophthalmics and diagnostics) moistening it with a drop of sterile saline, to the lower tarsal conjunctiva without the use of topical anesthesia. The participants were asked to blink several times and then cease blinking until instructed. The tear film was observed under slit lamp with cobalt blue filter. The time interval between the last blink to the appearance of the first random dry spot in the cornea was taken as the TFBUT. The average of three consecutive breakup times was calculated and recorded.

The ocular surface was evaluated by staining the cornea with fluorescein and Oxford grading scheme was used for the recording of staining severity. This scheme has five panels, labeled A to E, with staining represented by punctate dots that increase logarithmically between panels.[12] The appearance of staining on the exposed interpalpebral conjunctiva and cornea is compared with each panel, and the closest match gives the grade. Based on the number of dots seen a grade between 0 and 3 was given for staining on the cornea, nasal, and temporal conjunctiva. The individual scores were added giving a maximum possible total of 9 points. A score of 3 and above was considered to be abnormal.[13]

Schirmer's test was performed without topical anesthesia using standardized Whatman filter paper 41(Tearstrip/India/Contacareophthalmics and diagnostics). The strip was folded at the notch and placed at the junction of the middle and lateral thirds of the lower eyelids and left in place for 5 min. A value of <10 mm wetting in 5 min was considered abnormal.

Due to lack of consensus among the diagnostic criteria for dry eye described in different clinical studies we adopted the following criteria used by Alves *et al.*: OSDI score >20 and/or Schirmer test <10 mm or TFBUT <6 s and/or ocular surface staining score >3.[14] A diagnosis of DED was made if the participant had at least one positive test according to these criteria. In various clinical studies, authors have adopted different approaches for the diagnosis of dry eye on an *ad hoc* basis. Several studies have used the positivity of one or more of the tests (tear breakup time [TBUT] or Schirmer or OSDI) for the diagnosis of dry eye.[5,15,16] Since there is no uniform set of diagnostic criteria for DED, we considered a diagnosis of dry eye if the patient presented at least one positive test according to these preestablished criteria.

All measurements were performed by the same investigators on the same day under similar testing conditions. Clinical evaluations were done on both eyes, and the mean of the two eyes was used for analysis. To eliminate diurnal variation and possible diagnostic error, all tests were performed in the morning.

Statistical analysis

Statistical analysis was performed using the Statistical Package for the Social Sciences (SPSS Inc., Chicago, IL, USA) version 24. Descriptive statistics was presented as a mean ± standard deviation. The Shapiro–Wilk test was used to test the normality of data distribution. Student's *t*-test was applied for comparisons between two groups. Correlation between variables was detected using Pearson's correlation coefficient. Statistical significance was set at $P < 0.05$.

Results

The mean age of controls and diabetic patients was 54.7 ± 10.2 and 55.7 ± 9.5 years, respectively. There were 53 females among 100 controls and 45 females among 100 diabetics ($P = 0.25$). The baseline characteristics of the study participants are shown in Table 1. The mean duration of diabetes among diabetics with the dry

[Downloaded free from http://www.sjopthal.net on Monday, October 14, 2019, IP: 192.168.10.239]

eye was significantly higher compared to those without dry eye (P = 0.03).

Table 2 shows the comparison of OSDI, Schirmer test, fluorescein staining, and TFBUT between groups using the Student's *t*-test. Significant differences in OSDI scores, Schirmer test values, fluorescein staining, and TFBUT were observed between the study groups. OSDI Score was >20 in 32 participants (32%) in the diabetic group. Nineteen percent had OSDI scores between 12 and 20. In the diabetic group, 7 participants (7%) had Schirmer scores <10 mm and 30 (30%) had TBUT <10 s. Ocular surface staining score of >3 was encountered in 51% of the diabetic participants. None of the participants in the control group had abnormal OSDI, Schirmer test, fluorescein staining, or TFBUT.

We evaluated the relationship between HbA1c, duration of diabetes, and ocular surface parameters [Table 3]. The analysis showed significant positive correlation between the duration of diabetes and OSDI scores as well as fluorescein staining of the ocular surface. Although negative, the correlation between duration of diabetes and Schirmer/TFBUT was not statistically significant.

Table 1: Baseline characteristics of study participants

Characteristic	Controls	Diabetics without dry eye	Diabetics with dry eye
Number (%)	100	46	54
Age (years)	54.7±10.2	54.6±9.5	56.7±9.6
Females (%)	53 (53)	22 (47.8)	23 (42.6)
Duration of diabetes (years)	-	5.6±6.1	8.05±5.1*
HbA1c	5.3±0.3	8.5±2.2	9.4±2.3

*P=0.03. HbA1c: Glycosylated haemoglobin

Table 2: Comparison of ocular surface disease index scores, Schirmer test, fluorescein staining and tear film breakup time between groups

	Controls	Diabetics	*P*
OSDI	6.9±6.5	15.1±12.4	<0.001
Schirmer test	24.1±5.1	20.8±7.3	<0.001
Fluorescein staining	1.85±0.24	3.8±2.1	<0.001
TFBUT	16.7±3.6	12.6±4.5	<0.001

OSDI: Ocular surface disease index, TFBUT: Tear film breakup time

Table 3: Correlation coefficients between duration of diabetes, glycosylated haemoglobin and ocular surface parameters

Variable	Duration of diabetes (*P*)	HbA1c (*P*)
OSDI	0.342 (<0.001)	0.340 (<0.001)
Schirmer test	−0.07 (0.47)	−0.23 (0.01)
Fluorescein staining	0.3 (0.003)	0.3 (0.001)
TFBUT	−0.1 (0.27)	−0.21 (0.03)

HbA1c: Glycosylated haemoglobin, OSDI: Ocular surface disease index, TFBUT: Tear film breakup time

The HbA1c level was found to correlate positively with OSDI scores and ocular surface staining. HbA1c levels correlated negatively with Schirmer values and TFBUT.

Discussion

The purpose of this clinical study was to assess the frequency of DED and tear film abnormalities in people with diabetes and compare with that of healthy controls. The OSDI scores were higher, and tear film parameters were significantly altered in diabetic patients.

Out of the 100 diabetics studied, 54 were found to have dry eye. Mean age of diabetic individuals with and without dry eye were found to be similar (P = 0.262). Among the 100 patients with diabetes 45 (45%) were females, of which 23 (42.6%) had dry eye and 22 (47.8%) did not have evidence of dry eye (P = 0.600). Hence, there was no statistically significant association between dry eye and age or gender of the diabetic patients. The frequency of dry eye was significantly higher in patients with longer duration of diabetes.

Studies on dry eye in diabetics have revealed wide variation in the prevalence rates due to different diagnostic criteria as well as patient characteristics. Our observations are similar to that of Fuerst *et al*. who have noted a dry eye prevalence of 54% based on tear osmolarity.[16] Manaviat *et al*. performed Schirmer and TBUT tests and utilized the criterion of one positive test to diagnose dry eye. Out of the 199 participants studied, 108 (54.3%) were found to have dry eye.[5]

In contrast to these hospital-based studies, a community-based study from Shanghai has reported 17.5% prevalence of definitive DED.[17] Apart from methods used for diagnosis, several other factors such as age, gender, duration of diabetes, and metabolic control have also been reported to affect the prevalence of DED.[18,19]

Duration of diabetes was found to be significantly associated with dry eye in our study similar to observations of Manaviat *et al*.[5] Chronic hyperglycemia, diabetic neuropathy, decreased insulin levels, microvasculopathy, and systemic hyperosmotic disturbances in long-standing diabetes lead to dysfunction of the lacrimal functional unit as well as abnormal tear dynamics and DED.[20] However, some studies have found no correlation between DED and duration of diabetes.[4]

Diabetics in this study had significantly higher OSDI scores as compared to the control group. In contrast to our observations, Beckman found the mean OSDI scores to be higher in nondiabetic patients as compared to diabetic patients.[6] This could be attributed to the fact that the mean duration of diabetes in this study was much less (6.9 ± 5.7 years) compared to their study where the mean diabetic duration was 11.1 ± 9 years (range 1–41 years). Long-standing diabetes has been reported to

[Downloaded free from http://www.sjopthal.net on Monday, October 14, 2019, IP: 192.168.10.239]

be associated with reduced perception of dry eye symptoms due to impaired corneal sensation and therefore decreased OSDI scores.[16]

We found a significant positive correlation between OSDI scores and duration of diabetes in our study. One possibility for the observed positive correlation is that, as mentioned previously participants with shorter duration of diabetes have normal corneal sensation and therefore, will be aware of dry eye symptoms. Our findings are in agreement with the natural history of DED proposed by Bron *et al.* This model comprises three stages, namely initiation of DED, reflex compensation, and loss of compensatory response due to sensory nerve impairment.[21]

OSDI scores were found to correlate positively with HbA1c levels in our study. Our observations are in line with previous studies elsewhere, which have shown a positive correlation between OSDI scores and glycemic control.[22,23]

Although mean Schirmer test scores were in the normal range for both study groups, statistically significant differences were found between the Schirmer values in control and diabetic groups. Our observations are similar to that of Beckman and Yoon *et al*. who found the values of the Schirmer's test to be >10 mm in both diabetic and nondiabetic patients.[6,24] In contrast to these findings, the Schirmer values averaged 7.4 ± 0.38 mm in patients with diabetes versus 13.53 ± 0.50 mm in the controls in a series by Dogru *et al*.[7] Twenty eyes (22.7%) of the diabetic patients in their series had Schirmer test values <5 mm. In our study, only 3% had Schirmer scores <5 mm. Reduced Schirmer scores in people with diabetes compared with nondiabetic participants have been documented in several studies. Some studies have noted a reduction in basal tear secretion, whereas some authors have reported only the reflex tear secretion to be significantly reduced in diabetics.[8,19,25]

We found a significant negative correlation between Schirmer test scores and HbA1c levels. Our observations are in line with that of Ozdemir *et al*. who also found the Schirmer test and TBUT results to be worse in poorly controlled diabetics compared to those with good metabolic control. Kaiserman *et al*. have reported increasing consumption of ocular lubrication with increased mean annual levels of HbA1c.[18] Poor Schirmer test scores were not related to the duration of diabetes in our study which is in agreement with previous studies.[19]

Significant staining of the ocular surface with fluorescein was noted in diabetic patients in our study. Impaired corneal epithelial barrier function in diabetic patients has been reported by several studies and poor metabolic control, diabetic neuropathy, and advanced retinopathy have been found to correlate with epitheliopathy.[3,24] Ocular surface staining scores were found to correlate positively with duration of diabetes as well as HbA1c levels in this study. Accumulation of advanced glycation end products (AGE) on the basement membrane of the corneal epithelium has been shown to play a causative role in corneal epithelial disorders of diabetic patients.[26] Since HbA1c is a product of early stage glycation, it correlates well with AGE formation and hence impaired barrier function resulting in staining of the ocular surface.

Significant differences in TFBUT values were noted between diabetic and nondiabetic participants, and lower TFBUT scores were noted in patients with poor glycemic control. These results are comparable to that of Yoon *et al*. who had evaluated the tear film and ocular surface changes among diabetics from Korea.[24] Ma *et al*. have reported a significant inverse correlation between serum HbA1c levels and noninvasive TBUT in their study on 80 Chinese participants with type 2 diabetes.[23] These results suggest that poor glycemic control is associated with an unstable tearfilm and ocular surface disease in diabetic patients.

The study has few limitations. We had not performed tear film osmolarity assessment which is an objective test for the diagnosis and follow-up of DED. However, test combination of OSDI/Schirmer test/TFBUT has been shown to have an accuracy of 99.3% for the diagnosis of DED.[14] Sample size and conduct of the study at a single site are other potential limitations of the study. Further studies on large samples with the inclusion of tests such as corneal esthesiometry, tear osmolarity, and other markers of DED will provide valuable insight into the potential mechanisms and treatment options for diabetic DED.

Conclusion

There are limited data available in the literature about the frequency of dry eye and tear film dysfunction in diabetics from India. With the increasing prevalence of diabetes and its associated complications in India, there is need for more studies from this part of the world. Nearly half of the people with diabetes in this study had features consistent with DED. Patients with longer duration of diabetes and higher HbA1c levels are more predisposed to have abnormalities of tear film and DED. Examination of the ocular surface and testing for DED should be added to the routine screening of diabetes. Apart from conventional therapies such as lubricants, anti-inflammatory agents, and antioxidants optimal glycemic control should be an important consideration in the management of tear dysfunction in diabetic patients.

Acknowledgment

The authors are grateful and would like to acknowledge Dr.Suvetha.K, FAIMER fellow and Associate professor in community medicine, PSG Institute of Medical Sciences and Research, for statistical analysis and guidance in interpretation of results.

Evaluation of retrobulbar circulation in type 2 diabetic patients using color Doppler imaging

K Divya, Vikrant Kanagaraju[1], B Devanand[1], C Jeevamala, A Raghuram, D Sundar

Purpose: To investigate the retrobulbar circulatory parameters in type 2 diabetes mellitus patients with color Doppler imaging (CDI) and compare the results with nondiabetic controls. **Methods:** This prospective study included 50 type 2 diabetic patients and 50 age-matched controls. Seven field stereo fundus photography was used to diagnose and classify diabetic retinopathy (DR). Diabetic patients were further divided into two: Group 1, consisted of patients with no DR, mild and moderate non-proliferative DR (n = 36); Group 2, severe nonproliferative and proliferative DR (n = 14). CDI was performed using Philips iU22 xMATRIX ultrasound. The peak systolic velocity (PSV), end-diastolic velocity (EDV), resistivity index (RI) and pulsatile index (PI) of ophthalmic (OA), posterior ciliary artery (PCA), and central retinal artery (CRA) along with central retinal vein (CRV) were recorded. **Results:** RI in the ophthalmic artery was significantly higher in both DR groups than the control group (P = 0.000). Diabetic Group 1 had decreased blood flow velocity (PSV and EDV) in PCA compared to controls (P = 0.046 and P = 0.010, respectively). Group 2 DR had significantly reduced EDV and increased RI in CRA compared to Group 1 (P = 0.015). Binary logistic regression analysis revealed glycosylated hemoglobin and RI of OA to be independent risk factors of DR. **Conclusion:** Significant changes in resistivity index and flow velocities were observed in the retrobulbar vessels, especially in ophthalmic artery in diabetics compared to controls. CDI with results of increased resistance or decreased flow could be useful to predict individuals at higher risk for developing severe DR.

Key words: Blood flow velocities, color Doppler ultrasonography, diabetes mellitus, retrobulbar

Ocular manifestations of diabetes are numerous and among them, diabetic retinopathy (DR) is a major clinical issue for ophthalmologists. DR is the most frequent cause of preventable blindness in working-age adults (20–74 years) and is therefore considered as a major public health issue.[1] Though treatable in appropriate stages, the prevention of retinal complications of diabetes and consequent visual impairment is vital to reduce the burden of DR. There is a felt need for better diagnostic modalities and surrogate markers in the evaluation and management of DR.

In spite of decades of research, the mechanisms behind the onset and progression of DR still remain unclear. From a hemodynamic point of view, evidence has shown that there is an early reduction in blood flow to retina before the onset of DR followed by a gradual increase as the retinopathy progresses.[2] Color Doppler imaging (CDI) is an established, safe, and noninvasive ultrasonic method useful for qualitatively and quantitatively assessing the blood flow velocities and indirect blood flow.[3] CDI has been suggested to be valuable in the diagnosis and management of several ocular diseases with altered hemodynamics such as glaucoma, retinal vascular diseases, ischemic optic neuropathy, and ocular ischemic syndrome.[4] An analysis of retrobulbar hemodynamics in diabetes using CDI can provide insight into the pathogenesis and prospective treatment for DR as well as predict those at higher risk of developing vision threatening DR. Several authors have evaluated the circulatory changes in diabetics using CDI and reported conflicting results. While few studies have reported a reduction in the retrobulbar blood flow velocities,[5-7] others have noted an increase[8] or no change.[9] Studies on the resistive index (RI) of orbital vessels which is a measure of peripheral vascular resistance have also shown significant discrepancies.[10,11] Factors such as demographic variables, duration of diabetes, methods of DR assessment, positions of CDI, and sample sizes account for the observed discrepancies. Moreover, most studies have not excluded patients with hypertension and those on medications affecting systemic blood flow which can influence the results. Studies on orbital hemodynamic alterations among type 2 diabetics from India are relatively few. The diabetic population in India is close to hitting the alarming mark of 69.9 million by 2025 and 80 million by 2030, denoting an expected increase of 266%. Hence, India is deemed as the world's capital of diabetes.[12] With increasing prevalence of diabetes and DR, it is important to know the hemodynamic alterations among diabetics from the Indian population.

The objective of this study was to evaluate the flow velocities and vascular resistance of orbital blood vessels using CDI in a pure cohort of type 2 diabetic patients from India and compare the results with healthy controls.

Methods

This prospective hospital-based study was carried out at a tertiary care institution from south India between March 2017 and April 2019. The study included consecutive patients of type 2 DM (as per definition of the American Diabetes Association) attending the ophthalmology outpatient clinic for the screening of retinopathy. Exclusion criteria were history of any ocular disease that might affect ocular blood flow such as glaucoma, nondiabetic retinal vascular occlusion, ocular inflammation, high myopia, previous ocular surgery, or panretinal photocoagulation. Patients with systemic hypertension, dyslipidemia, nephropathy, and cardiovascular diseases were excluded from the study. Pregnant and breastfeeding women were not included. Patients taking medications known to affect systemic hemodynamics such as Angiotensin-converting enzyme inhibitors, calcium channel blockers, and anti-migraine drugs were also excluded.

50 age-matched healthy subjects were enrolled as a control group. The control subjects were recruited from individuals attending the department of ophthalmology for a routine eye examination. They were not on any medication and did not have ocular or systemic disease. The study was conducted according to the principles of the Declaration of Helsinki and the study protocol was approved by the institutional ethics committee. Informed consent was obtained from all participants.

Information regarding age, gender, body mass index, duration of diabetes, antidiabetic medications, and blood pressure were obtained from all participants. Serum glycosylated hemoglobin (HbA1c) was determined from fasting venous blood sample.

All study participants underwent a comprehensive ophthalmic examination including dilated fundus with slit-lamp biomicroscope using a 90 diopter lens and indirect ophthalmoscopy. A 30° stereoscopic fundus photograph of 7 standard early treatment diabetic retinopathy study (ETDRS) fields was taken from both eyes of diabetic patients using a digital fundus camera (TRC-50 DX Mydriatic retinal camera; Topcon Medical Systems, Oakland, NJ).

The presence, as well as the severity of diabetic retinopathy, was determined by grading of color fundus photographs following the international clinical disease severity scale for diabetic retinopathy which is based on the findings of WESDR (Wisconsin Epidemiological Study of Diabetic Retinopathy) and ETDRS.[13] The diabetic patients were assigned to one of the following groups namely no retinopathy, mild nonproliferative diabetic retinopathy (NPDR), moderate NPDR, severe NPDR, and proliferative diabetic retinopathy (PDR). The

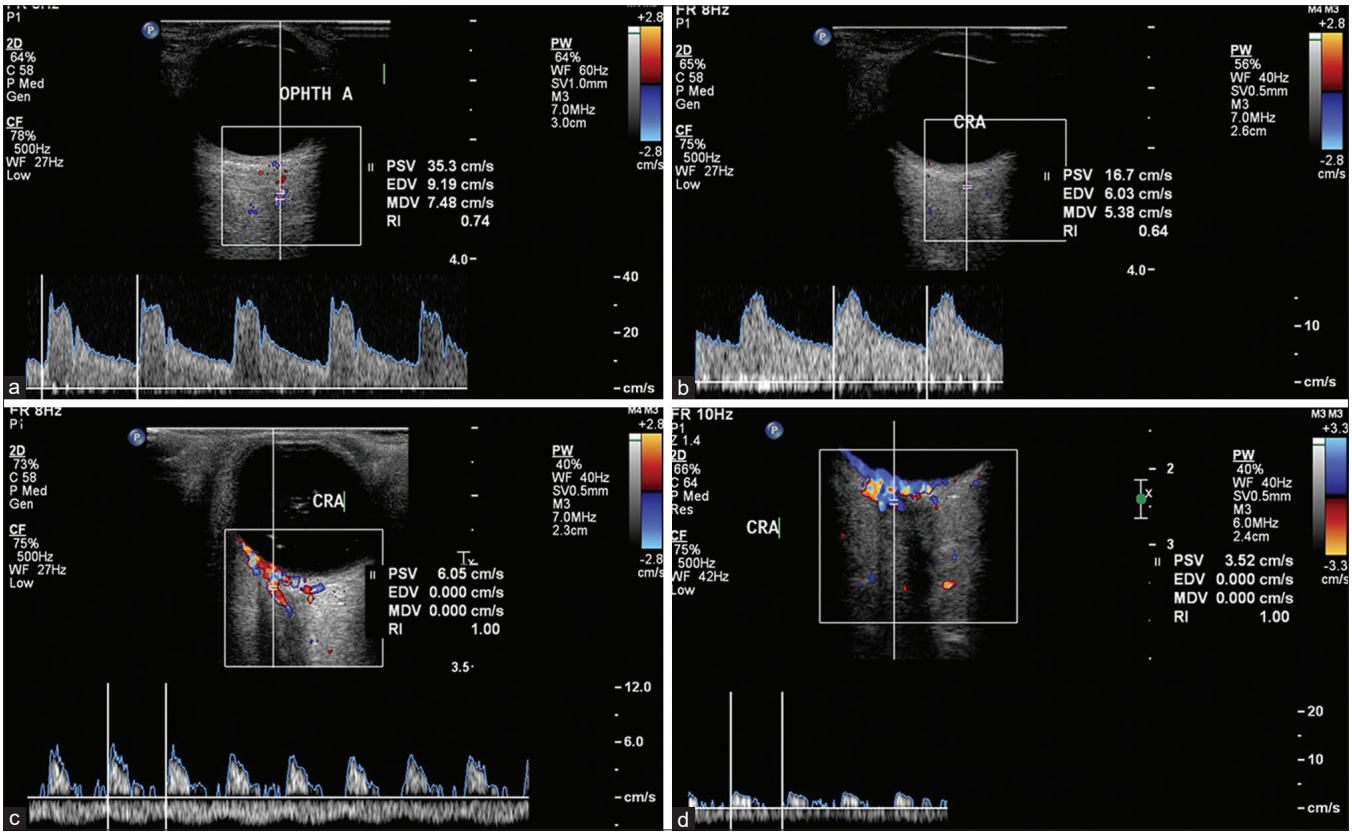

Figure 1: (a) Color Doppler image (CDI) showing normal color flow and spectral waveform in ophthalmic artery with preserved M wave pattern; (b) CDI showing normal color flow and spectral waveform in central retinal artery; (c) CDI showing low-velocity monophasic flow in central retinal artery in a patient with moderate NPDR; (d) CDI showing monophasic spectral waveform with absent diastolic flow in central retinal artery in a patient with severe NPDR

[Downloaded free from http://www.ijo.in on Thursday, June 4, 2020, IP: 192.168.10.239]

eye with worse retinopathy was included in the study. If both eyes had equal retinopathy, the right eye was assigned to the study.

Color Doppler sonography of the eye was performed for cases and controls by a masked expert Radiologist using a color Doppler unit and a 12 to 5 MHZ linear-array transducer (Philips iU22 xMATRIX ultrasound system). The patients were examined in the supine position and care was taken to avoid any undue pressure on the eye. Examiner's hand was rested on the orbital margin and sterile coupling gel was applied over closed eyelids. The Doppler signal was registered online after the cursor was positioned on the region of interest. To reduce errors in measurement of velocities, angle correction was applied to the pulsed Doppler recordings.

The peak systolic velocity (PSV) and end-diastolic velocity (EDV) readings were obtained from the ophthalmic artery (OA), central retinal artery (CRA), and the posterior ciliary artery (PCA). Since the velocity wave in a central retinal vein (CRV) is not in direct relation to the cardiac cycle its hemodynamic parameters were expressed as maximum (V max) and minimum (V min) blood velocity. Signals from the ophthalmic artery were obtained from the medial aspect of the eyeball, superior to the optic nerve. The central retinal artery and vein were located within the optic nerve, around 10 mm behind the eyeball. [Fig. 1] Signals from the temporal branch of the short posterior ciliary artery were located lateral to the optic nerve.

With the help of PSV and EDV, we calculated the vascular resistance expressed by the resistivity index and pulsatile index using Pourcelot's formula.

Resistive index (RI) = (PSV-EDV)/PSV; Pulsatile index (PI) = (PSV-EDV)/Vmean

Statistical analysis

For statistical analysis diabetic patients were further divided into two groups; Group 1 included patients with no retinopathy, mild NPDR, and moderate NPDR while Group 2 consisted of patients with severe NPDR and PDR.

Statistical analysis was performed using statistical package for social sciences (SPSS, SPSS Inc, Chicago, IL, USA) version 24. Data were expressed as mean ± standard deviation. The normality of data distribution was tested by the Kolmogorov-Smirnov test. One-way analysis of variance (ANOVA) with a *post hoc* Bonferroni was used for the analysis of normally distributed continuous data. Kruskal-Wallis analysis was used for analyzing non-normally distributed data. A comparison between hemodynamic parameters was calculated by ANOVA followed by Tukey-Kramer *post hoc* comparison. Pearson's coefficient was used to study the correlation between variables.

Table 1: Demographic and clinical characteristics of controls and diabetic subjects

Characteristic	Controls (*n*=50)	Group 1 (*n*=36)	Group 2 (*n*=14)	*P*

Binary logistic regression analysis was performed to determine independent risk factors for retinopathy. All tests for statistical significance were two-tailed and performed assuming a type I error probability of <0.05.

Results

Demographic and clinical parameters

The study included 52 males and 48 females. The age of patients ranged from 41 to 76 years. The duration of diabetes ranged from 6 months to 20 years. Among the diabetic patients, 29 were on oral hypoglycemic agents, 9 were on insulin, and 12 were on combination therapy. Group 1 (n = 36) consisted of 16 patients with no DR, 13 with mild NPDR, and 7 with moderate NPDR. Group 2 (n = 14) consisted of 6 patients with severe NPDR and 8 with PDR. There were no statistically significant differences in the age, body mass index and blood pressure between controls and diabetic groups. Glycosylated hemoglobin (HbA1c) levels were found to be significantly higher in Group 2 diabetic patients (P = 0.014). No significant difference was noted in the duration of diabetes among diabetic groups. The demographic and clinical characteristics of controls and diabetic subjects are presented in Table 1.

Hemodynamic parameters

Table 2 shows the hemodynamic parameters of retrobulbar blood vessels among controls and patient groups.

Ophthalmic artery

Significant differences were noted in the RI and PI values of the ophthalmic artery between controls and diabetic patients with various DR grades. OA flow velocities did not vary between groups.

Table 3: Pearson correlation coefficients between the duration of diabetes, HbA1c, and hemodynamic parameters

Variable	Duration of diabetes	HbA1c
OA PSV	0.021 (0.885)	-0.120 (0.407)
OA EDV	-0.141 (0.328)	-0.055 (0.706)
OA RI	0.314* (0.026)	0.097 (0.504)
OA PI	0.299* (0.035)	0.078 (0.588)
CRA PSV	-0.135 (0.349)	-0.269 (0.059)
CRA EDV	-0.464* (0.001)	-0.299*(0.035)
CRA RI	0.375* (0.007)	-0.046 (0.753)
CRA PI	0.487* (0.000)	0.131 (0.370)
PCA PSV	-0.052 (0.722)	0.170 (0.239)
PCA EDV	-0.234 (0.102)	0.196 (0.172)
PCA RI	0.332* (0.019)	-0.075 (0.606)
PCA PI	0.321*(0.023)	-0.085 (0.556)
CRV V max	0.134 (0.354)	0.128 (0.375)
CRV V min	-0.143 (0.322)	-0.058 (0.687)
CRV RI	0.390* (0.005)	0.172 (0.233)
CRV PI	0.415*(0.003)	0.210 (0.144)

Corresponding P values are shown in brackets. HbA1c=Glycosylated hemoglobin; OA=Ophthalmic artery; CRA=Central retinal artery; PCA=Posterior ciliary artery; CRV=Central retinal vein; PSV=Peak systolic velocity; EDV=End diastolic velocity; V max=maximum blood velocity; V min=minimum blood velocity; RI=Resistivity index; PI=Pulsatility index; *P<0.05

Central retinal artery and vein

The hemodynamic parameters of CRA were significantly different between controls, DR Group 1, and Group 2 whereas no such difference was seen in the CRV. *Post hoc* comparison revealed a significantly reduced PSV and EDV of CRA (P = 0.005 and 0.000, respectively) along with increased PI (P = 0.003) in DR group 2 compared to controls. Patients with group 2 DR also demonstrated a significant decrease of EDV and increased RI of CRA compared to group 1 (P = 0.015). PSV, EDV, and RI of CRA did not differ significantly between controls and DR group 1.

Posterior ciliary artery

The EDV and PI of PCA were found to vary significantly between controls and diabetic groups. Significant reduction in PSV and EDV of PCA was noted in DR group 1 compared to controls (P = 0.046 and P = 0.010, respectively after *post hoc* comparison).

Relation between duration of diabetes, HbA1c, and hemodynamic parameters

Duration of diabetes correlated positively with the resistive and pulsatile indices of all retrobulbar vessels studied namely ophthalmic artery, CRA, PCA, and CRV. HbA1c levels, as well as the duration of diabetes, were found to correlate negatively with EDV of CRA. No correlation was found between duration of diabetes and HbA1c levels (R = 0.183, P = 0.203). Table 3 shows the relationship between duration of diabetes, HbA1c levels, and hemodynamic parameters.

Binary logistic regression analysis revealed that HbA1c levels and RI of OA were independent risk factors of retinopathy.

Discussion

The main observations of our study are as follows: (1) RI in the ophthalmic artery was significantly higher in both DR groups than the control group and was an independent risk factor of retinopathy, (2) Patients with Group 1 DR had decreased blood flow velocity (PSV and EDV) in the posterior ciliary artery compared to control group, (3) Patients with Group 2 DR had significantly reduced EDV and increased RI in the CRA compared to Group 1, (4) Compared to the control group, patients with Group 2 DR had slower flow velocities and increased PI in CRA but RI values did not vary significantly.

Our finding of decreased EDV in the posterior ciliary artery in patients with Group 1 DR supports the hypothesis that choroidal blood flow is affected in the early stages of DR. Laser Doppler flowmetry has shown decreased choroidal blood flow in the foveal region in early DR.[14] Choroidal vascularity index (CVI) analysis by swept-source optical coherence tomography (OCT) has also shown reduced CVI in patients with mild/moderate NPDR.[15] Cao *et al.* have reported a 4 times more choriocapillary loss in diabetic eyes compared to non-diabetic eyes in histopathologic studies.[16] Ferrara *et al.* have demonstrated the loss of intermediate and large blood vessels in the Sattler's layer and Haller's layers in diabetic eyes in choroidal OCT.[17] Our observation of decreased EDV in the PCA suggests increased peripheral vascular resistance of the choroidal circulation in early DR and is in concordance with these studies. Dimitrova *et al.* reported decreased EDV and increased RI in PCA in patients

[Downloaded free from http://www.ijo.in on Thursday, June 4, 2020, IP: 192.168.10.239]

with background DR compared to controls in CDI of diabetic patients performed in sitting posture.[6] The authors have suggested that erect posture during CDI measurement is essential to appreciate significant alterations in posterior ciliary circulation. Supine posture has been suggested to increase EDV and decrease the RI.[18] As autoregulation and autonomic nervous responses are altered in diabetics, the correlation of change in circulatory parameters between normal individuals and diabetics associated with postural variation may not be expected to be equal. However, CDI was performed in supine posture in our patients. Our observations could be attributed to the shorter duration of diabetes in our patients than theirs.

RI in OA was higher in both DR groups compared with controls in our study. These findings are similar to those of previous studies.[5,19] Basturk *et al.* evaluated the association between the resistivity index of orbital arteries and DR in 91 types 2 diabetics with microalbuminuria using CDI. The authors have demonstrated increased RI values of all orbital arteries in patients with DR compared to those without DR and controls. RI value of ≥ 0.72 in OA indicated the presence of DR with 78.4% sensitivity and 70% specificity.[10] Our finding of increased RI in the OA in both DR groups can be attributed to the statistically nonsignificant reduction in EDV observed in diabetic subjects because of downstream vascular changes in the retina and choroid. We did not observe significant differences in CRA parameters between controls and DR Group 1. Hence, we believe that the OA hemodynamic parameters in our study probably represent alterations in choroidal blood flow. It has been suggested that of the total ocular blood supply from OA, less than 10% flows to the retina while the remainder is directed to choroid via the ciliary circulation due to the high metabolic demand of photoreceptors.[20] Moreover, the diastolic blood flow of PCA is higher than CRA since these vascular channels of choroid have low resistance.[21]

Table 4: Various published studies on ocular circulation in diabetic patients using color Doppler imaging

Study	Country	Sample size	Duration of diabetes (years)	Findings
Arai *et al.*, 1998[9]	Japan	74 Controls: 22 NDR: 27 DR: 25	NA	Significant increase in RI of CRA in patients with DR compared to those without DR and controls (P<0.01)
MacKinnon *et al.*, 2000[5]	Scotland	62 Controls: 17 NDR/BDR: 24 PPDR/PDR: 21	NDR/BDR: 10 PPDR/PDR: 12	Significant decrease in both PSV and EDV of CRA in the PPDR/PDR group compared to NDR/BDR and control group (P<0.05) while RI showed no significant change. RI of OA was increased in diabetics compared to controls.
Dimitrova *et al.* , 2001[6]	Japan	95 Controls: 22 NDR: 38 BDR: 35	NDR: 9.0±7.2 BDR: 18. 9±11.2	Significant decrease in EDV and increase in RI of PCA in BDR group compared to controls (P=0.01 and 0.0003, respectively)
Gracner *et al.*, 2004[8]	Slovenia	66 Controls: 22 NPDR: 22 SNPDR/PDR: 22	13.5±9.31	Significant increase in PSV of OA in the SNPDR/PDR group compared to controls. Significant increase in RI of PCA in SNPDR/PDR group compared to NPDR and controls
Sullu *et al.*, 2005[7]	Turkey	34 Controls: 20 PDR: 14	13.5±6.1	Decrease in mean EDV and increase in RI of both OA and CRA in PDR compared to controls (P<0.05)
Baydar *et al.*, 2007[11]	Australia	44 (65 eyes) Controls: 11 Diabetics: 33	4.94±3.90	The RI of CRA was significantly higher in the control group than in the NDR group. RI of OA was significantly higher in NDR than in the moderate NPDR group.
Basturk *et al.*, 2012[10]	Turkey	118 Controls: 27 NDR: 40 DR: 51	NDR: 6.87±4.37 DR: 8.23±2.55	Patients with DR had significantly higher mean RIs of OA, CRA and PCA compared to those without DR and controls (P<0.001)
Karami *et al.*, 2012[30]	Iran	123 Controls: 25 BDR: 74 PPDR: 24	BDR: 5.6±0.7 PPDR: 12.6±1.1	RI of OA and CRV were significantly higher in patients with DR compared to controls (P<0.005)
Our study	India	100 Controls: 50 NDR/mild/ moderate NPDR: 36 SNPDR/PDR: 14	NDR/mild/moderate NPDR: 8 SNPDR/PDR: 11	RI of OA was significantly increased in diabetics compared to controls. Significant decrease in both PSV and EDV of PCA in mild/ moderate NPDR compared to controls (P<0.05) Significantly reduced EDV and increased RI of CRA in SNPDR/PDR compared to mild/moderate NPDR group (P=0.015)

NDR=No diabetic retinopathy; BDR=Background diabetic retinopathy; PPDR=Preproliferative diabetic retinopathy; NPDR=Nonproliferative diabetic retinopathy; SNPDR=Severe nonproliferative diabetic retinopathy; PDR=Proliferative diabetic retinopathy; OA=Ophthalmic artery; CRA=Central retinal artery; PCA=Posterior ciliary artery; CRV=Central retinal vein; PSV=Peak systolic velocity; EDV=End diastolic velocity; RI=Resistivity index; NA=Not available

Khatri *et al.* assessed the correlation between RI of OA and topographic alterations of retinal pigment epithelium (RPE) on spectral-domain optical coherence tomography (SD-OCT).[22] In their study involving 75 patients with type 2 diabetes and 24 controls, a significant increase in OA RI was noted with the severity of DR ($F = 14.23$, $P < 0.001$). A positive correlation was noted between RI of OA and grades of RPE alterations on SD-OCT suggesting that decreased blood flow contributes to RPE dysfunction. Studies demonstrating early retinal damage in experimental diabetes have reported morphological changes in RPE and animal studies have also shown reduced choroidal blood flow in young diabetic animals suggesting that blood flow deficit could be an early pathological change in DR.[23,24] Although it is difficult to propose a causal association it can be postulated that changes in choroidal circulation (as reflected by increased RI of OA) lead to downregulation of antiangiogenic PEDF (pigment epithelial-derived factor) and upregulation of VEGF (vascular endothelial growth factor) thereby contributing to progression of DR. Differential expression and secretion of these growth factors derived from the retinal pigment epithelium have been suggested to lead to nonproliferative and proliferative DR.[25]

Patients with Group 2 DR had significantly reduced EDV in the CRA compared to Group 1 DR as well as healthy controls. Our observations are in line with previous studies.[5,6,8] These can be attributed to the increased peripheral vascular resistivity with the progression of DR. Pathological findings in DR such as capillary basement membrane thickening, retinal capillary leukostasis, loss of retinal capillaries, and altered blood rheology support this circulatory feature.[2,26,27]

Another observation of our study was that DR Group 2 had significantly reduced flow velocity in the CRA but an increase in RI was not statistically significant compared to the control group. This can be due to the concomitant decrease of both PSV and EDV in patients with Group 2 DR. Neudorfer *et al.* evaluated the long-term changes in the retrobulbar circulation of 138 eyes of diabetic subjects at a 10-year follow-up.[28] Patients were divided into four groups, namely, nondiabetic controls, diabetics without DR, nonproliferative DR, and proliferative DR. RI values of CRA and PCA had increased in the two no retinopathy groups and in the nonproliferative DR group, with a surprising nonsignificant decrease in the proliferative DR group. The authors have concluded that an increase of resistance in the retrobulbar blood vessels due to DR can decrease over time and may even be reversed. It has been suggested that the decrease in resistance reflects the beginning of an increase in retinal blood flow with the progression of DR due to the short-circuiting of the obstructed retinal capillary network.[28] This is supported by histopathologic studies, which have shown areas of capillary closure being traversed by preferential dilated anastomotic channels.[29]

Our finding of a positive correlation between duration of diabetes and RI of all retrobulbar vessels was similar to the observations of Karami *et al.*[30] We found negative correlation between EDV of CRA and duration of diabetes as well as HbA1c levels ($R = -0.464$, $P = 0.001$; $R = -0.299$, $P = 0.035$, respectively). Poor glycemic control (as reflected by increased HbA1c) and longer duration of diabetes can be associated with increased peripheral vascular resistance and thus reduced EDV in CRA. Our findings of HbA1c and RI of OA as independent risk factors of DR are similar to that of Basturk *et al.*[10]

Table 4 shows the various published studies on ocular circulation in diabetic patients using CDI.

Our study has several strengths. None of the diabetic patients had associated vascular diseases. Hypertension as well as antihypertensive medications significantly alter the resistive indices of blood vessels and therefore confound the results. We intentionally excluded these patients to study the influence of diabetes alone on ocular hemodynamics. A single masked, experienced radiologist performed all the Doppler examinations gently with the least pressure on the globe thus eliminating interobserver variability. The presence and severity of DR were graded based on seven field stereo fundus photography for accuracy.

To our knowledge, this study is the first of its kind in a pure cohort of diabetics from India.

There are a few limitations to our study. The sample size was small which accounts for the limited subgroup analysis. CDI provides information on blood flow velocity only and absolute volumetric blood flow cannot be quantified since it is not possible to study the diameter of retrobulbar vessels with CDI accurately. In spite of this limitation, blood velocity is probably a good indicator of blood flow within a given vessel.[31,32] Moreover, measurement of retinal blood flow is difficult and no accurate method to quantitatively assess perfusion is currently used clinically.

Conclusion

In conclusion, significant changes in the blood flow velocities and RI were observed in the retrobulbar vessels, especially in an ophthalmic artery in diabetics compared to controls. RI could be potentially useful for early diagnosis and follow-up of DR. CDI with results of increased resistance or decreased flow can be of help to identify diabetic individuals at higher risk for developing severe DR. This is especially useful in patients with opaque media where conventional methods are of little use.

Relationship between myopia and central corneal thickness – A hospital based study from South India

ABSTRACT

Background and Purpose: The prevalence of myopia has been increasing steadily, and studies on the relationship between myopia and central corneal thickness (CCT) have shown conflicting results. The purpose of this study was to investigate the relationship between myopia and CCT in a hospital based population from South India. **Materials and Methods:** This prospective, cross-sectional study was carried out from a tertiary care institution in South India between January 2017 and June 2018. One hundred and ninety-four myopic individuals between 11 and 40 years of age with spherical equivalent (SE) ranging from -0.5 to -6 Diopters after cycloplegic refraction were enrolled in the study. CCT was measured in both eyes of each patient using Tomey EM-3000 noncontact specular microscope (Tomey Corporation, Nagoya, Japan). The relation between CCT and myopia was analyzed using Pearson's correlation coefficient. Statistical significance was set at $P < 0.05$. **Results:** A total of 388 eyes were analyzed. 50% (n=97) of study participants were females. The mean age of the study participants was 25.47 ± 7.25 years (range: 12–40 years). The mean SE was -2.79±1.34 D (range: -0.5 to -6.0 D). The mean CCT was 540.53 ± 56.16 μm (range: 441–664 μm). No significant association was observed between CCT and age or gender of the study participants ($P = 0.706$ and 0.550, respectively). No correlation was observed between mean CCT and SE (Pearson, $r = 0.095$, $P = 0.062$). **Conclusion:** There was no correlation between CCT and degree of myopia. These data contribute to the ongoing discussion on the structural alterations in ocular coats and susceptibility to glaucoma in myopia.

Keywords: Central corneal thickness measurement, myopia, noncontact specular microscope, spherical equivalent

INTRODUCTION

Myopia, referred to as "short sight," is increasing in prevalence at an alarming rate and has emerged as a major cause for visual impairment globally. Estimates suggest that around 1.5 billion people or 22% of the present world population is myopic.[1] Apart from the ethnic and genetic factors, environmental and lifestyle changes have contributed significantly to the increasing prevalence of myopia. A recent meta-analysis on the prevalence of myopia in South-east Asia has shown an estimated pool prevalence of 4.9% (95% confidence interval [CI]: 1.6–8.1) in children and 32.9% (95% CI: 25.1–40.7) in adults.[2] The recent shift to younger age at the onset of myopia is even more worrisome considering its impact on the economic burden and quality of life.

With an increasing prevalence of myopia, there has also been a tremendous rise in the number of laser refractive procedures for the correction of myopia. Central corneal thickness (CCT) is a major factor determining the choice of refractive surgery for myopia, and a thin cornea is a recognized risk factor for corneal ectasia postrefractive surgery.[3] Corneal refractive surgery for myopia results in reduced corneal thickness and thereby leads to the underestimation of intraocular pressure.[4,5] This is relevant in the diagnosis and treatment of any glaucoma later in life,

since both myopia and reduced CCT are well-known risk factors for glaucoma.[6-8]

Studies evaluating the relationship between myopia and CCT have revealed conflicting results. While few studies have found a correlation between CCT and myopia,[9-11] some have reported no significant correlation.[12-15] This can be attributed to the differences in ethnicity, characteristics of the population studied as well as varied methods of the measurement of corneal thickness. Two population-based studies using ultrasonic pachymetry (UP) from India have reported thinner corneas in Indians than that of other populations.[12,16] Relatively fewer studies have evaluated CCT using noncontact specular microscopy, which is a noninvasive and accurate method with good reproducibility of CCT measurements.[17-19]

Given the increasing prevalence of myopia from India and conflicting evidence on the association between CCT and myopia, we attempted to study the relationship between myopia and CCT among patients attending the refraction clinic of a tertiary care institute using a noncontact specular microscope (NCSM).

MATERIALS AND METHODS

This prospective, hospital-based, cross-sectional study was carried out from a tertiary care institution in South India between January 2017 and June 2018. Individuals between 11 and 40 years of age who presented with visual impairment and found to have myopic refractive error (spherical equivalent [SE] more than −0.5 D) on cycloplegic refraction were included in the study. The exclusion criteria were myopia >−6 D, prior refractive or other ocular surgery, contact lens wear, trauma, corneal diseases, cataract, glaucoma, and ocular hypertension. Pregnant and lactating females and individuals with systemic diseases such as diabetes mellitus and collagen vascular disease were also excluded from the study. The study was performed according to the principles of the Declaration of Helsinki after prior approval from the Institutional Human Ethics Committee. Informed consent was obtained from all the participants.

All the study participants underwent a comprehensive ophthalmic examination, including slit-lamp biomicroscopy and fundus evaluation using +90 D lens and indirect ophthalmoscopy. Cycloplegia was achieved with three topical applications of 1% cyclopentolate at 15-min intervals. Cycloplegic refraction was performed 30–60 min after the first instillation of drug and spherical equivalent (SE, sphere + half-cylindrical component) was calculated.

CCT was measured by a single experienced ophthalmologist using Tomey EM-3000 NCSM (Tomey Corporation, Nagoya, Japan). The participants were instructed to fixate on the central target with chin and forehead positioned appropriately. Then, the participants were asked to blink completely once before measurements to spread an optically smooth tear film over the corneal surface. The measurements were taken using the auto-alignment and capture mode, thereby eliminating observer bias. Three consecutive valid measurements were taken, and the average of the three readings was used for the analysis. The CCT values were considered valid when the endothelial cells were focused clearly and bright corneal reflections were centered on the monitor. All measurements were performed in midday (between 12 and 4 PM) to eliminate diurnal variation.[20]

Statistical analysis

Statistical analysis was performed using the Statistical Package for the Social Sciences (SPSS, SPSS Inc., Chicago, LA, USA) software version 24. Descriptive statistics were presented as mean ± standard deviation. Discrete variables were presented as numbers (n) and percentages (%). Patients were classified into the following three groups according to SE: Group 1 included patients with SE -0.5 to <-2 D; Group 2 consisted of patients with SE -2 to < -4 D; and Group 3 individuals with SE -4 to < -6 D. The normality of CCT distribution was determined by the Shapiro–Wilk test. One-way analysis of variance followed by *post-hoc* Bonferroni was used for the analysis between the groups. The student's t-test was used to analyze the mean difference between two independent samples. Pearson's coefficient was used to study the correlation between variables. $P < 0.05$ was considered to be statistically significant.

RESULTS

This study included 388 eyes of 194 individuals with varying grades of myopia. 50% ($n = 97$) of the study participants were females. The mean age of the study participants was 25.47 ± 7.25 years (range: 12–40 years). The mean SE was − 2.79 ± 1.34 D (range: -0.5 to -6.0 D). The mean CCT was 540.53 ± 56.16 µm (range: 441–664 µm).

The CCT measurements were found to be nonnormally distributed. Figure 1 shows the distribution of CCT readings among the study participants. Figure 2 shows the distribution of SE among study participants.

Table 1 shows the association of gender of study participants with CCT. No significant differences were noted in the mean CCT between males and females ($P = 0.550$, Student's t-test).

[Downloaded free from http://www.kjophthal.com on Thursday, June 4, 2020, IP: 192.168.10.239]

Table 2 shows the association between mean CCT and age of study participants. No significant differences were noted in mean CCT values between various age groups ($P = 0.706$).

Table 3 shows the mean CCT values among the SE groups. Figure 3 shows the correlation between mean CCT and SE. No correlation was observed between mean CCT and SE (Pearson, $r = 0.095$, $P = 0.062$).

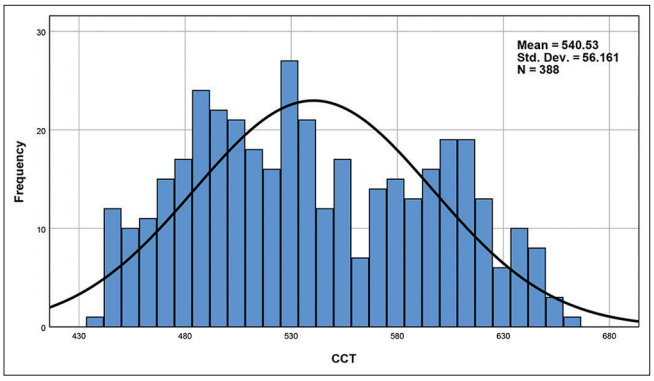

Figure 1: Distribution of central corneal thickness readings among the study participants

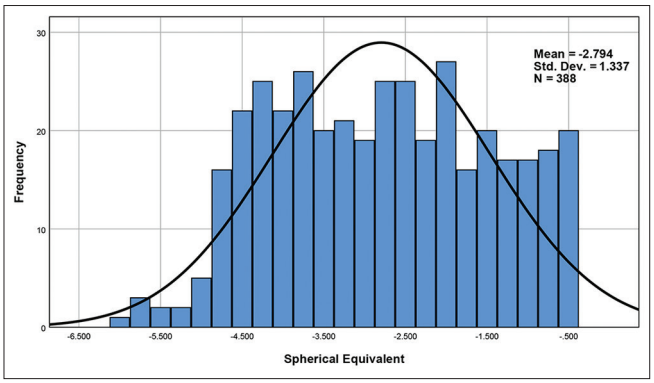

Figure 2: Distribution of spherical equivalent among the study participants

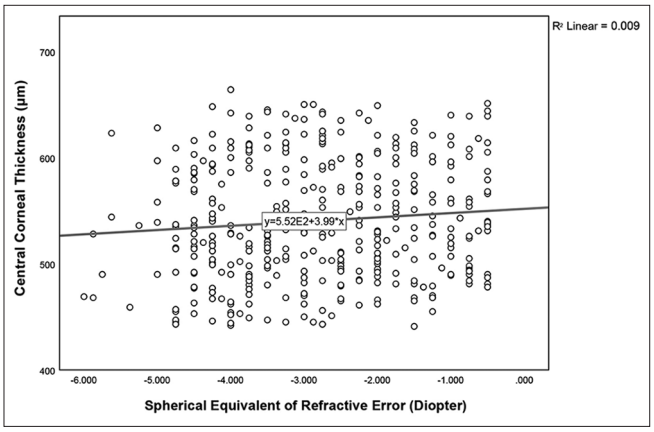

Figure 3: Scatter plot showing the correlation between mean central corneal thickness and spherical equivalent; no correlation was observed between mean central corneal thickness and spherical equivalent (Pearson, $r = 0.095$, $P = 0.062$)

DISCUSSION

In this hospital-based study from South India, we evaluated the CCT measurements of young myopic individuals with mild-to-moderate myopia using NCSM and found no correlation between mean CCT and degree of myopia.

Population-based studies from India using UP for CCT measurements have reported significantly thinner corneas among Indians compared to Africans (530 µm),[21] Nepalese (539 µm),[22] Caucasians (540 µm),[23] and Chinese (542 µm).[24] Nangia *et al*. evaluated the distribution of CCT among adults aged 30+ from rural Central India using UP. Mean CCT among 9370 eyes studied was 514 ± 33 µm (range: 290–696 µm). CCT was associated significantly with younger age, male gender, and lower corneal refractive power ($P < 0.001$). However, no statistically significant association was found between CCT and refractive error ($P = 0.54$).[12] Vijaya *et al*. evaluated 6754 adults aged 40+ from South India using UP and found the mean CCT to be 511.4 ± 33.5 µm.[16]

A hospital-based, prospective study involving 156 participants from South India, with a mean age of 29.27 years and mean refractive error of −3.10 D revealed a mean CCT value of 533.87 µm using UP. CCT had a positive correlation with axial length and negative correlation with SE, suggesting that axial

myopes tend to have thicker corneas.[10] Kunert *et al*. measured the CCT of 615 myopic patients of Indian origin (aged 18+) before laser *in situ* keratomileusis with UP as well as Orbscan scanning-slit topography/pachymetry.[25] Mean CCT reported was 519.92 ± 33.36 µm (range: 420–640 µm) using ultrasound method and 518.23 ± 31.03 µm (range: 428–607 µm) using Orbscan. No significant differences were noted in the CCT values measured using these two methods. Lower CCT readings were observed in individuals with myopia −0.5 to −4.9 D compared to those with myopia ranging from −5 to −9.9 D.

Mean CCT measurements obtained with EM-3000 (NCSM) in our study were 540.53 ± 56.16 µm (range: 441–664 µm). Módis *et al*. reported that the CCT values obtained using EM-3000 NCSM were higher than that found using ultrasound pachymetry ($P < 0.0001$).[26]

It would not be appropriate to compare our CCT measurements with other studies from India because we measured CCT using noncontact specular microscopy EM-3000 while others have utilized ultrasound pachymetry. The operating principles behind these two instruments are entirely different which explains the variation in measured values. While UP measurements depend on the reflection of ultrasonic sound waves from the anterior and posterior corneal surfaces, NCSM measurements rely on the reflection of light. CCT may be under or overestimated due to high inter-device variations, and studies have shown poor inter-device agreement among CCT measurements taken with different instruments.[27,28]

Although ultrasound pachymetry is the gold standard for CCT measurements, it is a contact method that needs topical anesthesia and user skill with regard to the placement of the probe. Furthermore, studies have reported alteration in corneal thickness values after the application of local anesthetic eye drops.[29,30] Unlike ultrasound pachymetry, NCSM is noninvasive and provides reproducible measurements of CCT.

There was no significant association between CCT and gender or age in our study. The role of gender on CCT has been reported to be variable, with few studies showing thicker CCT in males,[18,31] while others have reported no significant differences between males and females.[32] Few studies in patients older than 40 years of age have reported a negative association between CCT and age.[16,21,33]

The effect of refractive error on CCT has been analyzed by several investigators with contrasting results. Our study results demonstrate that CCT does not correlate with the myopia of different grades. Our observations are in agreement with the majority of studies elsewhere.[12-15] Chen *et al*. correlated the CCT measurements and degree of myopia among 528 Taiwanese adults enrolled for myopic laser refractive surgery.[13] No statistically significant association was found between CCT and refractive error ($P = 0.49$). The authors also studied the relation between CCT and myopia by intraindividual comparison in myopic anisometropia. The mean myopic anisometropia was 3.09 ± 1.06 D in their series, and the CCT in more myopic eye was not significantly different from the other less myopic eye. The authors have concluded that the cornea does not thin in the same way as the sclera in myopic eyes. Similarly, Fam *et al*. evaluated 714 consecutive Chinese patients with mean SE of − 5.3 D (range: −17.5 to −0.625).[15] No correlation was found between CCT and the degree of myopia ($r = -0.13$, $P = 0.719$). Ortiz *et al*. studied the relationship between CCT as well as mid-peripheral corneal thickness (PCT) in 175 myopic participants using Orbscan II.[34] Participants were divided into three groups, namely myopia <−6 D ($n = 76$), -6 to -12 D ($n = 72$), and more than −12 D ($n = 27$). No statistically significant differences were found in both CCT and PCT between the groups ($P > 0.05$).

A recent study comparing the thickness of preocular tear film, corneal layers (epithelium, Bowman layer, stroma and Descemet's membrane-endothelium complex in the central cornea), and anterior sclera using anterior segment spectral-domain optical coherence tomography found no statistically significant differences between emmetropia and those with moderate-to-high myopia ($P > 0.05$).[35]

However, few authors have found a significant correlation between CCT and myopic refractive error. Kadhim and Farhood evaluated CCT measurements of 418 eyes of 209 healthy individuals using UP.[9] The mean CCT was 543.95 ± 32.58 µm. CCT measurements significantly negatively correlated with age and myopes were noted to have significantly thinner corneas than emmetropic individuals ($P = 0.019$). Chang *et al*. evaluated a total of 216 participants, with a mean age of 22.2 years and mean refractive error of −4.17 D using UP.[36] A significant correlation was observed between CCT and SE ($r = 0.16$, $P = 0.021$). Corneas tended to be thinner in more myopic eyes. The authors have concluded that a decrease in corneal thickness is one among the changes in the anterior segment of the eye as myopia progresses. In contrast, Pedersen *et al*. measured CCT in 57 emmetropes and 48 high myopes using a high-precision Haag-Streit optical low coherence reflectometry pachymeter.[37] No statistically significant differences were noted between myopic participants and emmetropes (527.7 ± 35 µm versus

[Downloaded free from http://www.kjophthal.com on Thursday, June 4, 2020, IP: 192.168.10.239]

538.6 ± 32.1 μm), suggesting that the process by which myopia progresses does not influence the central cornea to a measurable degree.

The wide discrepancy in the observed results can be attributed to the varied age groups of patients, smaller sample sizes, nonelimination of contact lens wearers as well as the influence of diurnal variation, and use of pachymeters with variable reproducibility. The relatively new NCSM EM-3000 (Tomey, Japan) used in this study has been suggested to have high intraoperator repeatability in normal corneas.[27]

Our study has a few limitations. Observations are from a single-center, and axial length was not measured to differentiate axial myopia from other causes for myopia. However, we intentionally excluded patients older than 40 years to eliminate index myopia. To the best of our knowledge, this is the first study from India using NCSM to evaluate CCT measurements among myopic individuals.

CONCLUSION

In summary, we evaluated CCT measurements using noncontact specular microscopy in a cohort of young individuals with mild-to-moderate myopia. The mean CCT values did not correlate with myopic SE. Further studies with a larger sample size and different grades of myopia are needed to better understand the relation between myopia and CCT.

Relationship between Levels of Vascular Endothelial Growth Factor in Blood and Severity of Diabetic Retinopathy

Jebinth Brayan, D. Sundar[1], Sanjana B. Singh[2], Niranjana B. Singh[2], Manu Thomas, Prithvi Chandrakanth[3]

Department of Ophthalmology, Aravind Eye Hospital, Udumalaipettai, [1]Department of Ophthalmology, PSG Institute of Medical Sciences and Research, [3]Department of Vitreo Retinal Services, Aravind Eye Hospital, Coimbatore, [2]Department of Cornea and VItreoretinal Services, Bejan Singh Eye Hospital, Nagercoil, Tamil Nadu, India

Abstract

Aim: The aim of the study was to establish the relationship between levels of vascular endothelial growth factor (VEGF) in blood and severity of diabetic retinopathy (DR). **Background:** The importance of VEGF in the pathogenesis of DR is evident from numerous studies demonstrating a significant increase in VEGF levels in samples obtained from the eye. However, a correlation between blood levels of VEGF and DR has not been conclusively proven or disproven. In this article, we demonstrate the relationship between blood levels of VEGF and the severity of DR. **Materials and Methods:** This is a hospital-based descriptive analytic study. The study population consisted of 75 Type 2 diabetic patients attending outpatient department for routine DR screening. After obtaining informed consent, 5 ml of blood was drawn from each patient and estimated for the levels of serum VEGF. The data thus obtained were correlated with the grade of DR. Additional parameters studied were duration of diabetes mellitus (DM), hemoglobin levels, blood urea, serum creatinine, fasting blood sugar (FBS) and random blood sugar (RBS), and hemoglobin A1c (HBA1c) levels. Statistical analysis used in this study was Chi-square test, Student's *t*-test, independent one sample *t*-test, and analysis of variance using SPSS software version. 19. **Results:** Overall mean VEGF levels for the study population of 75 diabetic patients were 577.01 ± 291.13 pg/ml. The average duration of DM in the study population was 7.2 years. The average hemoglobin level in the study population was 11.53 ± 2.00 g/dl. The mean urea levels in mg/dl of the whole population were 35.47 ± 25.80 mg/dl. The mean creatinine levels for the population were 1.42 ± 1.55 mg/dL. The mean RBS levels for the whole population were 228.95 ± 74.499 mg/dL. The mean FBS levels for the 75 patients were 165.87 ± 59.04 mg/dl. The mean HBA1c levels were 9.49 ± 2.37%. **Conclusion:** Levels of blood VEGF are elevated in diabetic patients regardless of whether they have DR or not. There is no statistically significant relationship between blood levels of VEGF and the severity of DR. Even though severe grades of DR showed more anemia, there is no statistically significant relationship between anemia and DR. The levels of urea and creatinine were elevated in the more severe grade of DR. VEGF, therefore, could present a potential treatment and preventive strategy for not only DR but also DM and its complications in general.

Keywords: Diabetes mellitus, diabetic retinopathy, ELISA, ETDRS, vascular endothelial growth factor

Introduction

Diabetic retinopathy (DR) is one of the most debilitating complications of diabetes mellitus (DM). It can either be a nonproliferative or proliferative pathology of the retina. It is probably the most significant complication of a systemic disease in the eye. Over a period of half a century, the world has witnessed remarkable progress in the field of DR and its management. From the early days of the Arlie house classification for staging of DR, we have now entered firmly into the realm of antivascular endothelial growth factor (anti-VEGF) therapy. Literature review shows five major points of change in the field of DR. First, diabetes and its complications have become a global problem; to the extent that DR has assumed the status of a global epidemic. DR has thus become the leading cause of blindness in the middle-aged population.[1] Second, a number of randomized control trials, strict control of blood sugars, and additional systemic comorbidities play a major role in the disease progression.[2,3] Third, optical coherence

tomography has become a major component in DR staging and management. With the improved resolution of images, ophthalmologists can cut down on the use of fundus fluorescein angiography. Fourth, timely retinal photocoagulation can protect the retina from developing end-stage disease. And Finally, the role of VEGF appears to be central to the pathogenesis of DR. Thus, anti-VEGF therapy has become one of the first lines of treatment, especially of diabetic macular edema.

The importance of VEGF in the disease pathogenesis was realized when the vitreous cavity of patients with DR had higher levels of VEGF than those of controls. To the best of our knowledge, previous studies were mainly based on measurements of VEGF in the vitreous cavity.[4-8] We aim to study the serum levels of VEGF in diabetic patients with DR and also the correlation, if any, between serum VEGF and the grading of DR.

Materials and Methods

This was a hospital-based descriptive analytic study performed at a tertiary health-care institution and hospital in the department of ophthalmology over a period of 12 months after obtaining institutional ethical committee approval. A total of 75 Type 2 DM patients with or without DR were included in the study. Patients with Type 1 DM, with other retinal pathologies, terminally ill and those who have previously received anti-VEGF therapy were excluded from the study.

A written informed consent in patient's own language was obtained. A detailed history and a thorough ocular examination were performed. The 75 patients were divided into five groups consisting of 15 patients each according to the ETDR classification of DR – no DR, mild nonproliferative DR (mild NPDR), moderate nonproliferative DR (moderate NPDR), severe nonproliferative DR (severe NPDR), and proliferative DR (PDR). Fundus examination through 90D slit-lamp biomicroscopy and 20D indirect ophthalmoscopy was done followed by fundus photographs with a field of 50°. 5 ml blood samples were then withdrawn to measure the concentration of serum VEGF levels quantitatively using ELISA kit for human VEGF (Neogen USA Human VEGF Product #452610).

Statistical analysis of data was done using SPSS (IBM SPSS Statistics for Windows, Version 23.0. Armonk, NY: IBM Corp.). Correlation of data between the study variables were done by Chi-square test, Student's *t*-test, independent one sample *t*-test, and analysis of variance.

Results

In this study, of 75 patients, 15 patients were grouped each on the basic of the ETDRS classification of DR into no DR, mild NPDR, moderate NPDR, severe NPDR, and PDR. The age of the patients ranged from 41 to 82 years, and the mean age of the patients was 58.16 ± 8.6 years and the mean age in each group is as listed in Table 1. The gender distribution of population was 56 males and 19 females. The average male-to-female ratio was 2.75:1 and for each group is listed in Table 1.

Primary outcome measures

Vascular endothelial growth factor levels

Overall mean VEGF levels for the study population of 75 diabetic patients were 577.01 ± 291.13 pg/ml. The lowest value of VEGF was seen in the no DR group (34 pg/ml). The highest value was seen in the mild DR group (1296 pg/ml). Overall, there was no statistical significance in the variation of VEGF and the grade of DR ($P = 0.544$) [Table 2].

Secondary outcome measures

Duration of diabetes mellitus

The average duration of DM in the study population was 7.2 years. The subpopulation without any DR had the minimum duration of 6.53 years. The population with mild NPDR had the maximum duration of 12.80 years. There was no statistically significant difference in the duration of DM and the grade of DR ($P = 0.137$) [Table 2].

Hemoglobin levels

The average hemoglobin level in the study population was 11.53 ± 2.00 g/dl. There was no significant difference in the hemoglobin levels and the severity of DR ($P = 0.791$) [Table 2].

Urea levels

The mean urea levels in mg/dl of the whole population were 35.47 ± 25.80 mg/dl. There was no significant difference in the levels of urea and the severity of DR ($P = 0.138$) [Table 2].

Serum creatinine levels

The mean creatinine levels for the population were 1.42 mg/dL ± 1.55. The minimum value was seen in the patients with no DR (0.91 mg/dL). The highest values were seen in the group with PDR (2.26 mg/dL). However, any intergroup variation of creatinine was not statistically significant ($P = 0.11$) [Table 2].

Random blood sugar levels

The mean random blood sugar (RBS) levels for the whole population were 228.95 ± 74.499 mg/dL. The normal RBS was taken to be 70–140 mg/dL. After statistical analysis, the rise in the mean RBS was found to be significant. However, there was no statistically significant change in the RBS levels and the severity of DR ($P = 0.430$) [Table 2].

Table 1: Demographic characteristics of the population under study

	Average in study population	No DR	Mild NPDR	Moderate NPDR	Severe NPDR	PDR	*P*
Age (years)	58.16±8.6	58.67±10.4	58.53±8.4	59.07±7.3	56.00±7.8	58.53±9.1	0.880

VEGF: Vascular endothelial growth factor, HBA1c: Haemoglobin A1c, DR: Diabetic retinopathy, NPDR: Nonproliferative diabetic retinopathy, PDR: Proliferative diabetic retinopathy, RBS: Random blood sugar

Fasting blood sugar levels

The mean fasting blood sugar (FBS) levels for the 75 patients were 165.87 ± 59.04 mg/dl. However, there was no significant difference in the FBS levels and the severity of DR ($P = 0.408$) [Table 2].

Haemoglobin A1c levels

The mean hemoglobin A1c (HBA1c) levels were 9.49% ± 2.37%. The lowest HBA1c levels were seen in the group with no DR (8.45%) and the highest was seen with the group with severe NPDR (10.46%). However, the difference was not statistically different ($P = -0.230$) [Table 2].

Discussion

DR is without doubt one of the most significant ocular complications of a systemic disease. Several studies have showed that the VEGF plays a prime role in the pathogenesis of DR. The vitreous levels of VEGF are elevated in patients with DR in particular active, advanced stages of DR is an undisputable fact. However, previous studies show conflicting data with the association of blood VEGF and DR.

The aim was to study the comparison between the serum VEGF levels of DM patients with and without DR, and if there was any association between serum VEGF levels with the severity of DR.

Demography

The average age of the patients in the study population was 58.16 years, of which only Type 2 diabetics was included in the study. Any patient with Type 1 diabetes was excluded from the study.

Earlier studies done in similar populations from South India report age and longer duration of DM as risk factors for DR.[9-11] However, in our study, further analysis of the age and the severity of diabetes showed no statistical significance. Regarding the association with gender, majority of the patients were male, with an overall male-to-female ratio of 2.75:1. A similar result was reported by Raman *et al*., where they report an increased risk of DR among male patients (odds ratio = 1.41).[11]

Primary outcome measures

The serum VEGF level in the 75 patients was taken as our primary outcome. The average serum VEGF levels were 577.01 g/ml. On comparing this value with the known normal serum VEGF levels, our result was proven to be very significant. This result has been reported in a number of other studies as well.[12,13]

We then analyzed the elevation between the group with no DR and the normal population values. This too was significantly elevated ($P = 0.0076$). Therefore, it appears that VEGF is elevated in diabetics *per se* and not specifically in patients with DR. This can be explained by the fact that VEGF is a systemic factor and not confined to the eye. VEGF has been implicated in the pathogenesis of not only DR but also in diabetic

[Downloaded free from http://www.tnoajosr.com on Sunday, March 28, 2021, IP: 10.232.74.22]

nephropathy, neuropathy, and even diabetic macrovascular disease.[14-16]

Paradoxically, the group with PDR had the minimum mean value of VEGF. The group with mild NPDR had the maximum mean VEGF value. On testing the relation between VEGF and the severity of DR, there was no statistical significance detected. Similar results have been obtained in other studies.[17] Hence, serum VEGF levels are elevated in diabetics when compared with the normal population. However, there is no relationship with the severity of DR.

Secondary outcome measures

Duration of diabetes mellitus

In our study, the average duration of DM was 7.2 years. There was no statistically significant relationship between the duration of DM and severity of DR. However, the group with the minimum duration of DM was the group with no DR. This is in keeping with the established fact that the duration of DM is an important risk factor for the development of DR.

Hemoglobin level

The mean hemoglobin level was 11.53 g/dL. Taking the normal range of hemoglobin to be 12–15 g/dL, our population appears to be on the anemic side. In addition, the group with PDR had the lowest mean hemoglobin of 11.29; the group with the highest hemoglobin was the group with no DR. Although this is not statistically significant, this trend is in keeping with the fact that anemia worsens the retinopathy status. In addition, treating anemia has been proven to improve retinopathy and delay its progression.[18]

Urea and creatinine levels

The average urea level for our population was 35.47 mg/dL. Taking the normal range of serum urea to be from 14 to 40 mg/dL, this value falls into the high normal range. The mean creatinine levels were 1.42 mg/dL. As the normal range of creatinine is 0.66–1.09 mg/dL, this definitely falls into the high range. There was no statistically significant relationship between the creatinine levels or urea levels and the severity of diabetes. Even though the group with PDR had the highest urea levels and creatinine levels, this is very much in keeping with the fact that both nephropathy and retinopathy are microvascular disease and often the presence of one indicates the presence of the other. However, there is also a good chance of this renal disease being nondiabetic in origin. As highlighted in an earlier study by Prakash *et al*., nondiabetic renal disease versus diabetic disease was 22.6% versus 3.2% when the duration of DM was between 5 and 10 years. It is only after 10 years of DM that diabetic renal disease jumped ahead to 32.2% versus 6.5% for nondiabetic renal disease.[19] As our population, mean duration of diabetes was 7.2 years, it is likely that any renal impairment is more of a nondiabetic origin.

Random blood sugar and fasting blood sugar levels

The average RBS levels for the whole population were 228.95 mg/dL and the mean FBS was 165.87 mg/dL. Both these values are elevated when compared with normal values. This fact has important long-term prognostic value as it has been proved in numerous studies that control of blood sugar and other comorbidities play a major role in the control of diabetic complications. There was no statistically significant association between the levels of RBS and FBS and the severity of diabetes.

Hemoglobin A1c levels

The mean HBA1c level for our study population was 9.49%. The normal upper limit is taken to be 6.3%. As the HBA1c level indicates the state of blood sugar control for a prior 3 months, this indicates a very poor control. However, there was no significant relationship between HBA1c levels and the severity of DR. Moreover, no general trends were observed.

Limitation of this study

Many of the parameters studied showed wide standard deviations. This could be because of a small sample size. Possibly due to this same reason, many of the outcome measures did not show a statistically significant relationship with the severity of DR. Therefore, by increasing the sample size, it is possible that we could have obtained more significant results.

We did not have a population of healthy controls. Hence, we could only compare our study population with known normal ranges. Having a group of age- and sex-matched healthy control could have eliminated any confounders which might have arisen.

We did not study other comorbid conditions such as blood pressure, obesity, and hypercholesterolemia. All these factors have been proven to affect the complications of diabetes and they would have been useful in this study.

Conclusion

Serum VEGF levels were found to be significantly elevated in our study population when compared with the normal VEGF levels. This elevation of VEGF was observed in the entire diabetic population irrespective of whether they had retinopathy or not. There was no significant relationship between the serum VEGF levels and the severity of DR. Anemia was associated with severe grades of retinopathy. There was an elevation of urea and creatinine levels in the study population; this elevation was higher in the more severe grades of DR. RBS and FBS levels were high in the study population indicating a state of chronic hyperglycemia and also suboptimal control of blood sugars. The trend in HbA1c levels mirrored that of RBS and FBS again highlighting a poor control of sugars. In conclusion, an elevated serum VEGF level is significantly associated with DM and is linked to many of its complications. Although we are yet to discover about VEGF and its exact role in the pathogenesis of DR, one thing is certain, levels of VEGF lie a potential treatment and preventive strategy of not only DR but also of many of the complications of DM.

Effect of Antenatal Yoga on Labour Outcome- A Non-Randomized Control Study from a Tertiary Hospital in South India

[1]Dr. Saira Rajan, [2]Dr. Reena Abraham, *[3]Dr. Chippy Tess Mathew
[1]Senior Resident, Department of Obg, Kmch Institute of Health Sciences and Research, Coimbatore, Tamil Nadu, India
[2]Professor, [3]Associate Professor, Department of OBG, PSG Institute of Medical Sciences and Research Coimbatore (Affiliated to the Tamil Nadu Dr. MGR Medical University), Tamil Nadu, India

INTRODUCTION: Giving birth to a healthy baby is one of the happiest moments in a woman's life. Yoga is a 'body-mind' practice. The prospective of yoga to create balance along emotional, mental, physical, and spiritual dimensions is immense. It uses physical positions (asana), meditation (dharana and dhyana), concentration, breathing exercises (pranayama) and contemplative practice. OBJECTIVE: To study the effect of yoga on antenatal outcome. MATERIALS AND METHODS: It is a Prospective study done during the time period July 2013 to July 2014.In a series of 50 women who fit in the inclusion criteria, attending the antenatal clinic of a private medical college in Tamilnadu, training to practice yoga as relaxation therapy during pregnancy and labour was given and it was compared with 50 antenatal women who obtained regular care. The various outcomes like Mode of delivery, Bishop's score, Duration of active labour; Administration of analgesics and Weight of infant were studied. RESULTS: The major advantage noted in this study was reduced duration of active phase of labour. 70% of the antenatal women doing yoga went into spontaneous labour. 34% of induced labour in the control group were noted. All the patients in the yoga arm delivered at term. Whereas 4% of the patients in control arm had preterm delivery. CONCLUSION: Practicing yoga in the antenatal period decreases induced labour and shortens the duration of active phase of labour. The mode of delivery has a multifactorial contribution and cannot be compared in this study.

Keywords: Yoga, Pregnancy, Labour, Active Phase

INTRODUCTION

Motherhood transforms a woman forever. It extracts out a life lying dormant for months deep within her. Remaining physically active during pregnancy is the best a woman can do. At least thirty minutes of moderate exercise each day is recommended for improving the health and wellbeing of non pregnant women according to Len Kravitz (1998). In accordance with the American College Of Obstetrics and Gynaecology (2002), exercise during the period of pregnancy is very good and appropriate in pregnant women without any obstetric and medical complications. Yoga may be able to provide a gentle alternative to physical activity.Yoga is a 'body - mind' practice .It is a combination of various physical positions, breathing and relaxation exercises according to Smith C.A (2011). The word 'Yoga' comes from the Sanskrit word which means "to join" and can be understood as unity or oneness It uses physical positions (asana), meditation (dharanaanddhyana), concentration, breathing exercises (pranayama) and contemplative practice. Yoga mends psychological wellbeing. Labour is the active process of delivering a foetus and is characterised by regular, painful uterine contractions which increase in frequency and intensity. It is difficult to predict the length of labour. Duration of labour was positively corelated with the weight of the infant, duration of pregnancy, weight gain and prepregnant weight. It was negatively corelated with mother's height. Mother's age did not influence duration of labor according to Britt-Ingjerd Nesheim (1988). According to Kelly Riley (2017) Malpositions of the head prolonged labor in nulliparas, but not in multiparas, while breech presentation had no influence. 35 trials lecturing the outcomes of yoga on anxiety and stress were reviewed by LiAW et al in (2012) and the results were indicative of the role of yoga in alleviating stress and concern· Randomized controlled study on 74 women by Pamela Jones (2008) who

reported that in yoga group there was improved comfort during labour and after labour. The interval of first stage of labour was also shorter as well as the total labour duration according to a study done in Prince of Songkla university in Thailand by Chuntharapat S(2008) .So ours is an attempt to evaluate the effect of yoga on antenatal outcome in our study population.

METHODOLOGY

Study Design: Prospective non randomized control study
Time period: July 2013 to July 2014
Ethical approval: OBTAINED FROM ETHICS COMMITTEE OF PSGIMSR AND INFORMED CONSENT TAKEN.

A series of 50 women attending the antenatal clinic of a private medical college in Tamilnadu were given training to practice yoga as relaxation therapy during pregnancy and the labour outcome was compared with 50 antenatal women who obtained regular care.

Pregnant women of gestational age> 12 weeks are given training in 6 separate sessions by specially trained people in yoga through training sessions. They are encouraged to practice this on a regular basis. The regularity is assessed through personal interview. They are advised to do yoga minimum of 5 times a week.

Inclusion criteria
- Singleton pregnancy
- Primi less than 35 years
- Spontaneous conception
- No antenatal complications
- Co-operative and compliant patients

Exclusion criteria
- Multiple pregnancy
- Threatened abortion or previous preterm delivery
- Elderly Primi
- Multigravida
- Patients not willing to participate in the study

Types of outcome measured
- Mode of delivery
- Bishop's score
- Duration of active labour
- Administration of analgesics
- Weight of infant
- Type of delivery was assessed as normal vaginal delivery, assisted vaginal delivery (instrumental) or caesarean section.

➢ BISHOP'S SCORE (TABLE-1)

Table 1: BISHOP'S SCORE

Sign	Points				Score
	0	1	2	3	
Position	Posterior	Intermed.	Anterior		
Consistency	Firm	Intermed.	Soft		
Effacement	0-30%	31-50%	51-80%	>80%	
Dilation	0 cm	1-2 cm	3-4 cm	>5 cm	
Fetal station	-3	-2	-1, 0	+1, +2	
Results	The Bishop Score is: Calculate Bishop Score Reset				

The Bishop Score scores patients who would be most likely to accomplish a successful induction. It is a pre induction record. A score that go beyond 8 defines the patient most likely to accomplish a fruitful vaginal birth. A low Bishop's score frequently designates that induction is unlikely to be fruitful. Kelly C (2019) specify that only a score of 8 or more is reliably prognostic of a positive induction

➢ Active phase duration

Cervical dilatation of 4cm or more with uterine contractions can be taken to dependably signify the onset of active labour .According to Friedman the mean duration of active phase of labour in nullipara was 4 .9 hours .As the standard deviation of 3 .4 hours is large ,the active phase was testified to have a numerical maximum of 11 .7 hours .In all patients in labour we plot a partogram and the active phase duration was calculated.

➢ Analgesia

The various analgesia options in labour are epidural, sedation and inhalational analgesia with entonox. The use of epidural analgesia was examined in our study.

THE VARIOUS POSTURES OF YOGA PRACTICED IN PREGNANCY ARE AS FOLLOWS: TABLE 2

Table 2: THE VARIOUS POSTURES OF YOGA PRACTICED IN PREGNANCY ARE AS FOLLOWS

Figure 12: MukhaDhauti

Inhale. exhale and press the thighs and knees downward towards the floor. Make a gentle effort to keep pressing them forward. Start flapping both the legs up and down.

SURYA NADI PRANAYAMA - FIGURE 4

This refers to the Breathing Exercise. Inhale through the right nostril, Exhale through the left, press the index and middle finger of the right hand against the palm of that hand. Use thumb to occlude the right nostril. Ring and little fingers to occlude the left nostril.

KADICHAKRASANA - FIGURE 5:

Exhale and twist from the waist to the right and look back over the right shoulder. Keep the distance between your palms constant. Inhale comeback to the center, Exhale and turn to left and repeat the yoga posture on your left side.

CHOPPING WOOD POSE – FIGURE 6

Sit in a squatting position with your back straight .Clasp the hands in front and with inhalation raise the hands gently up in the air and come down with an exhale .

PAWANAMUKTHASANA PART 1

Sit outstretched, keep both the knees together and the heel on floor spine and the neck in the same level. put the palms of the hands on the floor. Keep the fingers outstretched. Apply pressure on the palm. Close eyes and breath. Begin the exercise with open eyes

VAJRASANA - FIGURE 7

The name comes from the Sanskrit words *vajra* - "thunderbolt". Sit on heels with the calves beneath thighs. There should be four finger gap between the knee-caps., sit straight.

WARRIOR POSE - FIGURE 8

VEERABHADRASANA – FIGURE 9

Breathe in as you come up and exhale as you go down with your hands from side. Redo the same from left side

CAT STRETCH FIGURE:10

STEP 1: Position your palm directly below your shoulders. Place knees directly below your hips . Spread your fingers with the middle fingers pointed straight.

STEP 2: Press towards the floor using your hands and then lift yourself up out of your shoulders. Go back and forth several times. Exhale and sag shoulders.

SEATED SIDE STRETCH - FIGURE 11

Rotate your head to look beyond your left elbow. Retain this position for 5 seconds. Now inhale and lift trunk and move left upper limb upward. Breathe out by bringing down left upper limb.

MUKHA DHAUTI- FIGURE 12

Lean forward and rest the arms on the respective thighs keeping the arms straight. Inhale through the nose and exhale forcefully through the mouth. Stand in Tadasana and relax.

Ethical approval: OBTAINED FROM ETHICS COMMITTEE OF PSGIMSR WITH IHEC APPROVAL NUMBER-13/121
SPSS SOFTWARE USED FOR DATE MANAGEMENT AND CALCULATION

RESULTS

In the study of antenatal yoga on labour outcome 100 antenatal women who were not age matched were included. 50 women were doing yoga and 50 received regular antenatal care.

TABLE 3: The age distribution is as follows

Age Distribution			
Age	Group		Total
	Yoga	Control	
<20	0	4	4
21-25	25	24	49
26-30	21	20	41
31-35	4	2	6
Total	50	50	100

The result shows that there is no significant age difference among the antenatal in group who were doing yoga and in routine care category

NO OF YOGA CLASSES ATTENDED BY THE ANTENATAL WOMEN IN YOGA GROUP.

46% of the antenatal women in yoga group had attended 4 classes. Only 10% of the women attended 5 yoga classes. 44% of the antenatal women who were practicing yoga attended only 3 yoga classes.

Table 4: Distribution of preterm or term deliveries

Term/ Preterm			
Out come	Group		Total
	Yoga	Control	
Term	50	48	98
Pre Term	0	2	2
Total	50	50	100

All the patients in the yoga arm delivered at term. Whereas 96% in the control arm delivered at term and 4% of the patients had preterm delivery, but this was not statistically significant as the p value was >0.5.

Table 5: The bishop's score among the antenatal women in yoga group and control group

Bishop Score	Group		Total
	Yoga	Control	
< 5	28	28	56
> 5	19	20	39
Total	47	48	95

As per the result there is no significant difference in Bishop's scoring among the two groups.

Table 6: The onset of labour among the yoga group and the control

Labour	Group		Total
	Yoga	Control	
Spontaneous	33	33	66
Induced	14	17	31
Total	47	50	97

The onset of labour is comparable in both the groups. 70% of the antenatal women doing yoga went into spontaneous labour. 34% of induced labour in the control group were noted. In the yoga group only 30% were induced labour.

Table 7: Distribution of mode of delivery

Mode of Delivery			
Delivery	Group		Total
	Yoga	Control	
NVD	20	36	56
LSCS	17	10	27
Instrumental	13	4	17
Total	50	50	100

The percentage of patients went in for lscs was 34 % in the yoga group where as it was 20% in the control group. Only 66% of women doing yoga had a vaginal delivery out of them 26% was instrumental delivery. Whereas in the control group 80% had a vaginal delivery. This finding was also not statistically significant,

Table 8: Distribution of Instrumental Delivery

Delivery Instrumental			
	Group	Total	
Instrumental	Yoga	Control	
VACUUM	12	3	15
FORCEPS	1	1	2
Total	13	4	17

Vacuum assisted delivery was significantly high among the yoga patients.

Table 9: Indications for lscs

LSCS	Group		Total
	Yoga	Control	
CPD	1	2	3
NPL	1	1	2
ARREST	2	2	4
FETAL DISTRESS	3	5	8
MSL	4	0	4
CONDYLOMA	1	0	1
DTA	1	0	1
FAILED	1	0	1
MATERNAL WISH	1	0	1
TRANSVERSE LIE	1	0	1
MOBILE HEAD	1	0	1
Total	17	10	27

The common Indication for LSCS in yoga patients were meconium stained liquor in early labour and fetal distress.

Table 10: Duration of active phase of labour

Duration	Group		Total
	Yoga	Control	
<= 2 HRS	3	0	3
2 - 3 HRS	16	7	23
3 - 4 HRS	10	16	26
> 4 HRS	4	17	21
Total	33	40	73

There is significant difference in the duration of active phase among the women practicing yoga and the control group. Majority had an active phase duration of< 2-3 hours in the yoga group when compared to the controls who had an average duration more than 4 hours which was statistically significant.

THE USE OF ANALGESICS

There is no significant difference among both the groups in usage of analgesics .

Table 11: Effect on birthweight

Birth Weight [kgs]	Group		Total
	Yoga	Control	
< 2 .5	2	5	7
2 .5 - 3 .5	43	42	85
> 3 .5	5	3	8
Total	50	50	100

The mean birth weight of the babies born to women practicing yoga was 3.10kg .

MEAN OF CLINICAL PARAMETERS – TABLE 12

Mean duration of active labour , in the yoga group came about 190 minutes ,whereas the mean duration of active phase of labour for the control group was 244 minutes which was statistically significant.

Table 12: Mean of clinical parameters								
		Mean	SD	95% CI for Mean		Minimum	Maximum	p value

DISCUSSION

This study which was conducted in a Tertiary hospital in Tamilnadu was done with the objective to analyse the effect of yoga on antenatal outcome. We enrolled 100 antenatal patients-of which fifty underwent yoga classes and fifty had routine antenatal care and the outcomes were analysed and the results were given above.

The age group of the antenatal patients who did yoga and the control group was similar in our study. All the patients practicing yoga had a term delivery which is similar to the study by Narendran et al (2005) where preterm deliveries were significantly low. In our study there was no significant difference in the Bishop's score at admission in the yoga and control group. There was no data to compare this.

There was also no difference in the onset of labour for both the groups.28% had induced labour in the yoga group and 34% in the control group in our study. This is similar to the study by Jahdi et al (2017) where there was a decreased percentage of labour induction in the yoga group.

In our study 34% of the yoga group patients had caesarean delivery while only 20% of the control group had caesarean delivery. This is in contrast to the study by Jahdi et al (2017) and Satyapriya Maharana et al in 2013 who showed reduced incidence of caesarean delivery after yoga therapy i.e.15% versus 40% in the control group.Since the mode of delivery has got multifactorial contribution ,it is difficult to compare it in these two groups. Even though the mode of delivery is not significantly altered, larger sample size is required to conclude this fact.

The major advantage noted in our study was the reduced duration of active phase of labour.This is very much significant as the duration of labour is an important factor in patient comfort,experience with childbirth and satisfaction.The reduction in active phase duration is consistent with the studies conducted by Songporn chuntharapat (2008), Sathyapriya M et al (2013) where there was significant reduction in labour duration.

The mean birth weight of the babies born to women practicing yoga was 3.10kg and 2.99kg in the control group which was not statistically significant. This is similar to the study by Maria Pais in 2016 where the mean weight of the yoga group was 3kg and the control group was 2. 7kg.This may be due to the increase gestational age of delivery in the yoga group. This was also consistent with the study by Shamanthakamani Narendran et al. in (2005) where there was significant higher babies with birth weight more than 2.5kg in the yoga group.

CONCLUSION

As per my study antenatal women doing yoga had significant reduction in the duration of active phase of labour than who receive regular care. Although not statistically significant, all of the patients in yoga group had term deliveries and good mean weight of babies. May be a larger study group in the future can give more definitive results.

One year retrospective analysis of PAP smears-from a tertiary hospital in Tamil Nadu

Dr. Chippy Tess Mathew, Dr. Uma Maheswari and Dr. Arthi Ramu

DOI: https://doi.org/10.33545/gynae.2019.v3.i4d.320

Abstract
Introduction: Cervical cancer is one of the leading causes of maternal mortality in India and worldwide, it usually takes 3–7 years for high-grade changes in cervical cells to become cancer. There are many effective screening tests for cervical cancer. PAP smear is one such test
Aim: To analyse the pap smears done in our hospital for a period of one year
Objectives: 1). To determine the percentage of abnormal smears detected 2). To analyse the myriad of findings in a PAP smear.
Materials and methods: It is a Retrospective Observational study, Data was collected from the PAP smears taken in the Gynaecology department outpatients and master health check-up of our hospital. Data was collected for a period of one year from January 2017 to December 2017.
Results: Around 2333 PAP smears were analyzed over a period of one year, of it 885 was from our OPD and 1448 was from the master health check-up, the detection of precancerous lesion was 1.2%, in addition to detecting pre-cancerous lesions, additional information showed a variety of infections like a Candida, Trichomonas, Actinomyces, etc.
Conclusion: Cytology based screening is one of the most cost effective and easy method of cervical cancer screening.

Keywords: Ca cervix, Pap smear, screening, pre malignant lesions

Introduction
Cervical cancer is one of the leading causes of morbidity and mortality in women worldwide. Cervical cancer is the fourth most frequent cancer in women with an estimated 570,000 new cases in 2018 representing 6.6% of all female cancers. The high mortality rate from cervical cancer globally could be reduced through a comprehensive approach that includes prevention, early diagnosis, effective screening and treatment programmes [1]. The screening methods range from VIA (visual inspection with acetic acid) and VILI (visual inspection with Lugol's Iodine in low resource setup where pathologist is not available, to the PAP smear and liquid base cytology with or without HPV testing and sophisticated colposcopy in high resource centres.

Materials and Methods
This is a retrospective study conducted in PSGIMSR. Data was collected from the PAP smears taken in the Gynaecology department outpatients and master health check-up.
Of our hospital. Data was collected for a period of one year from January 2017 to December 2017

Inclusion criteria
1) All PAP smears taken in our OP
2) All PAP smears taken as a part of master health check-up in our hospital

Exclusion criteria
1) Women without sexual exposure

Procedure
Cells from ectocervix and endocervix are collected simultaneously with the broom like spatula. The central bristles of the broom are inserted into the endocervical canal until the lateral bristles bend fully against the ectocervix. The sampling device is rotated 360º in the same direction five

times while maintaining gentle pressure. The broom is removed and with a single paint stroke motion the cellular sample is transferred along the long axis of the labelled surface of the slide. Minimum of two slides are taken except for vault smears where a single slide is taken. The slide is rapidly fixed by immersion in 95%ethanol and ether mix in a Koplik's jar and transferred to the cytology lab [2].

Slides are analysed by the pathologists and reported based on Bethesda classification.

Bethesda classification (2014) [3].

Specimen Type
Indicate conventional Pap smear vs. liquidbasedpreparation vs. other

Specimen Adequacy
Satisfactory fore valuation /Unsatisfactory for evaluation

Interpretation/Result
Negative for intraepithelial lesion or malignancy Non-neoplastic findings (optional to report*)*

Organisms
Trichomonas vaginalis/ *Candida* spp/ Bacterial vaginosis/ *Actinomyces* spp. /Herpes simplex virus/Cytomegalovirus

Other Endometrial cells

Epithelial Cell Abnormalities
Squamous Cell
Atypical squamous cells of undetermined significance (ASC-US) cannot exclude HSIL (ASC-H) low grade squamous intraepithelial lesion (LSIL) High-grade squamous intraepithelial lesion (HSIL) Squamous cell carcinoma

Glandular Cell
Atypical
- Endocervical cells NOS /favour neoplastic
- Endometrial cells NOS *or specify in comments*
- Glandular cells (NOS /*favour neoplastic*)

Endocervical adenocarcinoma in situ
Adenocarcinoma
Endocervical/endometrial /extra uterine/not otherwise specified

Other Malignant Neoplasms: *(specify)*
Adjunctive Testing
Computer-Assisted Interpretation of Cervical Cytology

Results
Around 2333 PAP smears were analysed over a period of one year from Jan 2017 to Dec 2017, of it 885 was from our OPD and 1448 was from the master health check-up. The age distribution, the indications for taking a smear and the cytology report was analysed and is put up in the tabular column.

Table 1: Age distribution of Pap smear

Age of the patient in years	Number of patients in MHC	Number of patients in OPD	Total	Percentage
20-29	37	68	105	4.50
30-39	221	274	495	21.22

Discussion

PAP smears are analytical tools for screening of cervical cancer. It is a cost effective way for detecting the pre-invasive cervical lesions. In addition it also gives supplementary data on a variety of infections like Candidiasis, Bacterial vaginosis etc.

Of the 2333 pap smears taken over a period of one year, the maximum number of patients was of the age group 40-49 years accounting for 31.63%. The lowest age of the patient was 20 years –a married woman with severe itching and who's Pap smear showed inflammation. The oldest lady was 84 years old who came for a routine screening and the report was negative for IEL. According to a study by Kalyani *et al*. [4] the rate was 28.7%in the same age group and 32.5% in the 30-39year group which was maximum. According to Vijayalakshmi *et al.* [5], the maximum number of patients was in the age45-55 age group which was 34% The most common indication for Pap smear was for routine screening, accounting for 87.96% of the smears, Leucorrhea was the next common indication in those patients in the OPD- 4.59% with AUB being close behind - 4.37%. There were 0.4% of post Malignancy surgery follow up. Post ca endometrium being the commonest. The most common indication was leukorrhea accounting for 30% in a study by Vijayalakshmi *et al.* [5] while the routine screening was around 23%. The high rate of screening in our study might be due to increased awareness among the city population. Around 10.29% where vault smears.

Of the 2333 smears analyzed 2280 were negative for malignancy though they detected inflammation and infections. We had a detection rate of 1.03% (24 cases) of abnormal PAP smears. of the 24 cases there were 4 each of HSIL, LSIL, ASC-H AND AGUS and 8 of ASC-US, only 50% of these patients underwent colposcopy and directed biopsies and except two LSIL all the biopsy reports confirmed the lesions. This abnormal reports-1.03% in our study is close to the study conducted by Tamrakar *et al*. [6] which was 1.7%, but was less than the international and Indian studies done by Sherpa *et al.* [7]. (3.6%) and Sankaranarayanan *et al.* [8] (3.4%) respectively. There were around 1.24% of unsatisfactory smears were opinion was not possible which iscomparable to the study by Crasta *et al.* [5] which is 1.36%, The rate of unsatisfactory smear was high in the study by Kalyani *et al.*, [5] i.e., 17.8%.

Among the negative smears -Inflammmatory smears were found in 54.1% which was comparable to the study by Patel *et al.* [10] (51.5%).In our study, the various organisms detected where candida in 6.44% followed by bacterial vaginosis in 5.27%.in the study by Kalyani *et al.* [8] the inflammatory smears where 83.1%.. candida was found in 2.03% and bacterial vaginosis in 9.8%.while Candida was 3.71% in the study by Patel *et al.* [10]. In our analysis there were two cases of Actinomycosis also and 13cases of Trichomonas Vaginalis of which one patient had strawberry vagina. The comparison of the unsatisfactory and the pathological reports in the various studies are put in a tabular column below:

Table 6: The comparison of the unsatisfactory and the pathological reports in the various studies

Diagnosis	Kalyani *et al.* [5]	Crasta *et al.* [9]	Narasimha *et al.* [3]	Sankaranarayanan *et al.* [8]	Our study
Unsatisfactory	17.80%	1.36%	24.42%	4.10%	1.24%
ASCUS	1.46%	0.37%	4.14%	8.80%	0.34%
LSIL	0.24%	0.19%	2.70%	6.20%	0.17%
HSIL	0.41%	0.61%	2.50%	1.60%	0.17%

Conclusion

PAP smear examination is an economic method for screening forcervical pre-malignant lesions and help us to deal with the global scare of cervical cancer. Mass educational and awareness programs should be conducted to increase the detection rate and

r d Preeclampsia is a systemic disorder that affects multiple organs and is characterized by the new onset of hypertension and proteinuria or end-organ dysfunction or both in the second half of pregnancy. NGAL is a 25-KDa protein of the lipocalin family and is considered to be a novel biomarker for ischemic injury. The objective of this study is to compare the levels of serum NGAL in preeclamptic patients and gestational age matched normotensive controls.

M d The study design is case control study in which pregnant women with preeclampsia (n=40) are selected as cases. Cases were selected from pregnant women attending OG-OPD and IP satisfying the inclusion criteria and not coming under exclusion criteria. 0.5ml of blood was collected in vacutainers and was centrifuged at 3500rpm for 10 minutes. The serum thus separated was aliquoted into smaller plain containers and stored at -20 degree Celsius for analysis. The urine sample was also collected. Controls were also selected from the OP patients.

In present study, the serum NGAL ranged from 40-900ng/ml in cases and from 110-795ng/ml in controls. There is no difference in NGAL between cases and control. The correlation coefficients between the NGAL levels and other parameters like maternal age, gestational age, systolic Blood pressure, diastolic Blood pressure, uric acid levels, urine PCR are also not statistically significant.

Serum NGAL levels are not significantly elevated in patients with preeclampsia when compared with the normotensive controls and also there is no significant correlation between serum NGAL levels and other assessed parameters.

rd Neutrophil gelatinase associated lipocalin (NGAL), Preeclampsia, Urine PCR

Introduction

Hypertensive disorders of pregnancy are a group of complications encountered in up to 10% of all the pregnancies worldwide. This is one of the leading causes of maternal and perinatal morbidity and mortality. Hypertensive disorders during pregnancy are of four categories: Gestational hypertension, preeclampsia-eclampsia, chronic hypertension (of any cause), chronic hypertension with superimposed preeclampsia. Of this preeclampsia is the most prevalent and most serious form of hypertensive disorder that complicates pregnancy.[1,2] With mortality due to preeclampsia and its complications estimated to be 50,000-60,000, it is one of the leading causes of maternal morbidity and mortality.[3,4] The pathogenesis of preeclampsia is due to an imbalance between the angiogenic and anti-angiogenic factors that leads to the release of inflammatory cytokines. As kidney

is a highly vascular organ, this endothelial dysfunction results in kidney injury. The development of AKI in pregnancy is termed as pregnancy-related AKI (PRAKI). Studies revealed that preeclampsia and eclampsia accounted for most of PRAKI cases.[5] There are many biomarker studies for AKI prediction. One of them is serum neutrophil gelatinase-associated lipocalin (NGAL). NGAL is a 25-KDa protein of the lipocalin family. NGAL reduces renal damage by inhibiting cell death and escalating the usual proliferation of kidney tubule cells. So, this protein is up regulated in conditions of kidney injury. Rise of NGAL levels has been recognized in the plasma and urine of animal models of ischemic and nephrotoxic acute kidney injury. Hence, NGAL is considered to be a novel biomarker for ischemic injury. In the study by Patel et al, the study population included the entire spectrum of hypertensive disorders of pregnancy and it was done in North Indian population.[6] In present study authors have measured the serum NGAL levels in preeclamptic patients in south Indian population and have compared them with control population. If the association between preeclampsia and NGAL levels could be proved in south Indian population also, further studies could be done to use it as a biomarker for preeclampsia thus reducing the morbidity and mortality associated with it.

M□□□□□□

The study was conducted at PSG Institute of Medical Sciences and Research, Coimbatore. Ethical clearance was obtained from the Institutional Human Ethics Committee.

An informed consent was taken from the patients before sample collection. The study design is case control study in which pregnant women with preeclampsia (n=40) are selected as cases.

The diagnosis of preeclampsia is based on case record description which is based on blood pressure measurements and urine protein creatinine ratio at the time of diagnosis. Cases were selected from pregnant women attending OG-OPD and IP.

Patients satisfying the diagnosis, inclusion criteria and not coming under exclusion criteria were given explanation about this study. If they were willing to participate, the consent forms were filled, and the samples were collected. 5ml of blood was collected in red topped vacutainers and was centrifuged at 3500rpm for 10 minutes. The serum thus separated was aliquoted into smaller plain containers and stored at-20degree Celsius for analysis. The urine sample was also collected.

Control individuals were also selected from the OG-OPD. Pregnant women fulfilling the control group criteria were requested to participate in the study. If they were willing, the consent forms were filled, and samples were collected from them. Their samples were also processed and stored for analysis.

Inclusion criteria

Cases

- All pregnant women more than 20 weeks of gestation diagnosed with pre-eclampsia with blood pressure ≥140/90mm of Hg or urine PCR ≥0.3.

Controls

- Normal pregnant women more than 20 weeks of gestation without preeclampsia matched for gestational age.

Exclusion criteria

Subjects with:

- Known chronic hypertension
- Known diabetes mellitus
- Multiple pregnancy
- Any other known medical disorder.

Collection of blood samples: for both cases and controls, blood was collected in red topped serum tube for the estimation of uric acid and urine was also collected for estimation of spot urine protein creatinine ratio. The left-over serum after the estimation of uric acid was transferred to secondary labelled plain tube. This sample was stored at-20-degree Celsius for NGAL assay.

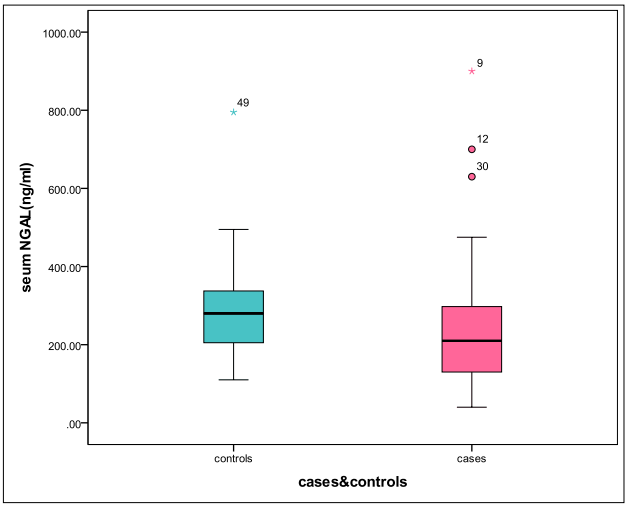
Serum NGAL	ELISA
Serum uric acid	Enzymatic colorimetric test
Urine protein creatinine ratio	Turbidimetric method
Urine protein: urine creatinine	Enzymatic colorimetric method
The ratio of urine protein to urine creatinine is calculated.	

Statistical analysis

The data obtained were statistically analyzed using IBM SPSS software version19. The data distribution was displayed by box and whisker plot and bar diagram. To find any statistically significant difference in the distribution of the demographic characteristics and measured parameters independent t-test was used. The dependence of categorical variable was tested with Chi Square test.

The correlation between quantitative parameters was done using Pearson correlation coefficient and the parameters with statistically significant correlations were further checked by scatter plot analysis. The correlation between quantitative parameters was done using Pearson correlation coefficient and the parameters with statistically significant correlations were further checked by scatter plot analysis.



□□□□□□□

The characteristics like maternal age and gestational age are equally distributed in both the cases and controls showing that the two study groups are well matched for these parameters. The socioeconomic status of the two groups is also similar as shown by their distribution.

The distribution of various other parameters including systolic blood pressure, diastolic blood pressure, serum uric acid, urine protein creatinine ratio is also studied. As expected, systolic Blood pressure, diastolic blood pressure, serum uric acid level, urine protein creatinine ratios are higher in cases when compared with the control population.

The values of the t-test done to compare the means of these two groups' maternal age, gestational age, body mass index, socioeconomic status, serum uric acid, urine-PCR is shown in Table 3.

This also shows that there is a significant difference between the two groups with respect to parameters like systolic and diastolic blood pressure, body mass index, serum uric acid, urine PCR. It also shows that there is no significant difference between the two groups with regard to maternal age, gestational age of the mother at the time of sampling and socioeconomic status. This implies that the two groups are well matched in these parameters. The serum NGAL level appears to be equally distributed in both the cases and controls as shown in Figure 1.

□□□r□1 □□□r□□ □□ □ □ □ □□□□□□□□□□□□□□□□d □□r□□□□□□

The t-test also does not show any significant difference in NGAL levels in these two groups as shown in Table 2.

There is no significant difference in NGAL level between the two groups. The correlation coefficients between various parameters are shown in Table 3.

The r values are significant for gestational age and urine PCR, BMI and urine PCR, Uric acid and urine PCR, diastolic Blood pressure and urine PCR, BMI and systolic Blood pressure, BMI and diastolic Blood pressure, diastolic blood pressure and uric acid, systolic Blood pressure and uric acid, but only diastolic Blood pressure and uric acid, systolic Blood pressure and uric acid, uric acid and urine PCR showed positive linear relation.

[illegible]

Preeclampsia is a systemic disorder that affects multiple organs and is characterized by the new onset of hypertension and proteinuria or end-organ dysfunction or both in the second half of pregnancy. The acute complications associated with preeclampsia include eclampsia, renal failure, stroke, permanent neurologic impairment, cardiac dysfunction or arrest, respiratory compromise, coagulopathy and liver failure.[7] The diagnosis of preeclampsia is based on the increase in blood pressure in a previously normal patient on two occasions 4hours apart after 20 weeks of gestation or the presence of proteinuria (>300mg/day). Preeclampsia can be mild/severe. Severe preeclampsia is characterized by more substantial blood pressure elevations (systolic ≥160mm Hg, diastolic ≥110mm Hg), a greater degree of proteinuria (>5g/24 hours) and the presence of symptoms associated with target organ involvement.[8] Xiao et al, evaluated a combination of biomarkers for diagnosing AKI with considerable accuracy in preeclampsia.[9] Serum cystatin C, urine retinol-binding protein, urine NGAL and urine kidney injury molecule-1 levels in the preeclampsia group were higher than the normal pregnancy group. When these markers were combined, the sensitivity and specificity for diagnosing AKI were almost 100%. Patel et al, reported that NGAL level was significantly associated with serum creatinine in the Indian pregnant population with hypertension.[6] Serum NGAL level in oliguric patients was significantly higher compared with non-oliguric patients. Serum NGAL level also had a positive correlation with disease severity including blood pressure level, blood urea nitrogen (Bun), serum creatinine, and serum uric acid in hypertensive pregnant patients. The distribution of the maternal age and gestational age are similar in the cases and the control population and their t-values are also not significant. This shows that the two groups are well matched in these characteristics. The two groups showed different distributions in case of parameters like systolic Blood pressure, diastolic Blood pressure, serum uric acid levels, urine protein creatinine ratio. The t-values are also

significant in these parameters among the two groups. This is expected because the diagnosis of preeclampsia is based on the systolic Blood pressure, diastolic Blood pressure, serum uric acid levels, urine protein creatinine ratio and the division of the study population into two groups is based on these parameters.

When the correlation between various parameters are studied using Pearson correlation coefficient, the resulting R-values are significant for gestational age and urine PCR, BMI and urine PCR, uric acid and urine PCR, diastolic Blood pressure and urine PCR, BMI and systolic Blood pressure, BMI and diastolic blood pressure, diastolic Blood pressure and uric acid, systolic blood pressure and uric acid. In consistent with the studies done by Aliyu et al, Bodnar et al, in this study, the distribution of body mass index is in the higher range in women with preeclampsia when compared with the normotensive controls. The t-test value (p=0.001) obtained by comparing the means of the two groups is also significant. This finding suggests that increased body mass index poses a threat for developing preeclampsia. Pandinis D et al, and Lou et al, have shown in their study that there is a significant correlation between serum NGAL levels and body mass index.[10,11] But, in present study no significant correlation is found between serum NGAL levels and body mass index

In the studies done by Anna et al, Simonazzi et al, Patel et al, to find out the correlation between serum NGAL levels and preeclampsia, the two study groups, cases and controls were matched for body mass index as elevated BMI was considered as a confounding factor.[6,12,13] But in present study, the cases and controls are not matched for BMI. Since NGAL is also produced by adipocytes, a positive correlation was expected between serum NGAL levels and the body mass index. But the Pearson correlation coefficient between NGAL and BMI is not significant to prove any correlation (r=0.076, p=0.502). This suggests that obesity and preeclampsia are correlated but not obesity and NGAL. So, it can be said that obesity may not be a confounding factor in estimation of serum NGAL levels and the pre-pregnancy BMI rather than the BMI at the time of sampling could be considered. In present study, serum uric acid level was also significantly higher in the preeclamptic women than in the normotensive controls as indicated by t-test value (p=0.00).Since estrogen is a uricosuric agent serum uric acid levels fall by 25-35% in pregnant women.[14] Apart from estrogen, expanded plasma volume, elevated GFR also leads to decrease in uric acid levels in pregnancy.[14] In women with preeclampsia, hyperuricemia is a regular finding. Impaired renal function has been considered the causative factor for hyperuricemia in preeclampsia.

In the study done by Pereira et al, to evaluate the use of uric acid as a marker of severity of pre-eclampsia, they were able to find significant correlations between uric acid and systolic blood pressure.[15] In a similar study done by Pramanik et al, to assess whether serum uric acid can be used as a biochemical indicator or not in preeclamptic patients, they were able to demonstrate a positive correlation between serum uric acid levels and elevated systolic pressure and diastolic blood pressure.[16] Consistent with these findings, in this study, a significant positive correlation is found between serum uric acid levels and systolic BP (r=0.549,p=0.00). A linear relation is found between these two parameters by scatter plot analysis.

Nischinta et al, have done a study to find out the correlation between 24-hour urine protein, spot urine protein creatinine ratio and uric acid.[17] They were able to demonstrate a positive and statistically significant correlation between serum uric acid level and urine protein creatinine ratio. Similarly, in this study, a statistically significant positive correlation is found between serum uric acid level and spot urine protein creatinine ratio (r=0.626, p=0.00).

In the study done by Anna et al, they have concluded that serum NGAL levels were higher in the preeclamptic women in all three trimesters when compared with the control population.[12] Although Kim et al, have also demonstrated a statistically significant difference in NGAL level between the two groups, the range of NGAL levels in the two groups were similar (66.1-575.4 ng/ml in cases and 7.0-669.7 ng/ml in controls).[18]

Simonazzi et al, have done a cross sectional case control study to compare the serum and urinary NGAL levels in preeclampsia and in normal pregnancies and also to find out the correlation between NGAL and blood pressure, creatinine, uric acid,24-hour proteinuria.[13] They could not demonstrate a statistically significant difference in the NGAL levels between the two populations. They were not able to demonstrate a positive correlation between NGAL and uric acid, creatinine, blood pressure. In a study done by Dogan et al, to evaluate the serum NGAL levels and plasma Nitric oxide in preeclamptic women and normal controls, the investigators were not able to find a statistically significant difference in the NGAL levels between the two groups.[19] But they were able to find a statistically significant correlation between NGAL levels and BMI.

In present study, the serum NGAL ranged from 40-900ng/ml in cases and from 110-795ng/ml in controls. The distribution range of NGAL in cases covers the distribution range of controls. This shows that there is no difference in NGAL between cases and control. The correlation coefficients between the NGAL levels and other parameters like maternal age, gestational age, systolic Blood pressure, diastolic Blood pressure, uric acid levels, urine PCR are also not statistically significant.

These findings of this study are consistent with those of Simonazi et al, and Dogen et al, and contrast from the findings of Anna et al, Kim et al.[12,13,17,19]

□□□□□□□□□□

Serum NGAL levels are not significantly elevated in patients with preeclampsia when compared with the normotensive controls. There is no significant correlation between serum NGAL levels and systolic Blood pressure, diastolic Blood pressure, serum uric acid, urine PCR, maternal age and gestational age.

ABSTRACT

Background: Under normal circumstances, a woman's uterus sheds a limited amount of blood during each menstrual period (around 80 ml). Bleeding that occurs erratically or excessive menstrual bleeding is called abnormal uterine bleeding (AUB). The causes of AUB are many and varied. Initial investigations include transvaginal ultrasound and histopathologic assessment of the endometrium. Objective of this study was to evaluation of endometrial thickness with trans-vaginal ultrasound and its correlation with histopathology by dilatation and curettage in abnormal uterine bleeding. To determine the efficacy of transvaginal ultrasound in evaluating the endometrial thickness. To correlate the endometrial thickness by transvaginal ultrasound with endometrial histopathology in women with AUB.
Methods: It is a retrospective observational study. All reproductive and perimenopausal age group women who underwent dilatation and curettage for abnormal uterine bleeding during the period June 2014-June 2016 was taken and analyzed and correlated with their endometrial thickness measured with Transvaginal ultrasound.
Results: Around 478 patients who underwent endometrial sampling over a period of two years were analyzed. Maximum number of patients were in the fourth decade and the overweight category 36.6%. Proliferative endometrium was the most common histopathologic picture (44.76%). Detection of precancerous lesions were-5.87% and endometrial cancer was 1.05%.
Conclusions: An ET of 8 mm and above gave 100% sensitivity and negative predictive value for precancerous and cancerous lesions.

Keywords: Abnormal uterine bleeding, Dilatation and curettage, Endometrial hyperplasia and cancer, Endometrial thickness, Transvaginal ultrasound

NTRODUCTION

Abnormal uterine bleeding is one of the most common gynecological problems in patients approaching the outpatient clinics in the country. These complaints definitely affect the quality of life of the patient. The etiology of AUB varies with the age group of the patient. There is the PALM COEIN classification for AUB by FIGO.[1] There are many diagnostic modalities for evaluating endometrial pathologies in women who have AUB. Transvaginal sonogram (TVS) has permitted the use of higher frequency ultrasound waves at greater proximity of the uterus. It is a relatively cheap and non-invasive diagnostic modality for studying the endometrial pattern and its thickness and at the same time to exclude organic pathology in case of AUB while dilatation and curettage gives us a definitive histopathologic picture. This study attempts to correlate the USG findings and histopathology in patients with AUB. The gold standard

for diagnosing AUB is hysteroscopy and directed biopsy but it is expensive when compared to the simple endometrial sampling. According to the PALM COIEN classification the causes of AUB can be divided into structural and non-structural cause which is given in detail in Table 1.

Table 1: PALM COEIN classification for AUB.[1]

Structural	Non structural
Polyps	Coagulopathy
Adenomyosis	Ovulatory dysfunction
Leiomyomas	Endometrial hyperplasia
Malignancy	Iatrogenic
	Not yet specified

Aims and objectives of this study were

- Evaluation of endometrial thickness with trans-vaginal ultrasound and its correlation with histopathology by dilatation and curettage in abnormal uterine bleeding.
- To determine the efficacy of Transvaginal ultrasound in evaluating the endometrial thickness.
- To correlate the endometrial thickness by Transvaginal ultrasound with endometrial histopathology in women with AUB.

METHODS

Retrospective observational study included all reproductive and perimenopausal age group women who underwent dilatation and curettage for abnormal uterine bleeding during the period June 2014 to June 2016.

Inclusion criteria

- AUB in all reproductive and perimenopausal women
- Only gynecological indications for dilatation and curettage.

Exclusion criteria

- Unmarried women
- Pregnancy and related causes of bleeding
- Postmenopausal bleeding
- Puberty menorrhagia.

From minor and major OT registers, list of all D and Cs which were done during 2014 June to 2016 June was taken. Cases which satisfied the inclusion and exclusion criteria was taken and analyzed

Statistical analysis

Chi square test was used for the statistical analysis.

RESULTS

All the patients with abnormal uterine bleeding, fitting the inclusion criteria, who underwent endometrial sampling was taken for analysis. There were around 478 patients. All of them had a premenstrual ultrasound before the procedure. The age distribution, parity, BMI, presenting complaints, the histopathology and the endometrial thickness by TVS was evaluated. The results are given below:

Of the 478 patients, the youngest patient was 22 years old and the oldest was 55 years, the mean age was 38.5 years. Maximum number of patients were in the 41-50 years age group which was 60.25% and the least in the 20-30 years group and was 4.6% (Table 2).

Table 2: Age distribution of patients with AUB.

Age	No. of cases	%
20-30	22	4.60%
31-40	117	24.48%
41-50	288	60.25%
51-60	51	10.67%
Total	478	100%

Majority of the patients were multiparious i.e. 79.71% and 2.93% was nulliparous as seen in (Table 3).

Table 3: Parity of the patients with AUB.

Parity	No. of cases	%
Nullipara	14	2.93%
Primipara	83	17.36%
Multipara	381	79.71%
Total	478	100%

A total 35.8% of the patients under analysis were of the normal BMI and maximum numbers of patients were overweight-36.6% and the least number of patients were underweighted i.e. 3.3% as given in Table 4.

Table 4: BMI of patients with AUB.

BMI	No. of cases	%
Underweight	16	3.3%
Normal	171	35.8%
Overweight	175	36.6%
Obese	116	24.3%
Total	478	100%

A total 98.3% had heavy menstrual bleeding among the 478 patients and 72.4% had undergone tubal ligation. Among the other USG findings, adenomyotic changes were found in 11.1%, fibroids seen in 18.6%, while simple ovarian cysts were found in 11.7% and PCO in 4.2%.

There were 42 cases of hormone induced changes, 25 menstrul endometium, 17 were inadequate and 2 were TB endometritis which were all entered under others.44.7%

were having proliferative phases (Figure 1), of which 29.7% was disordered proliferative (Figure 2). 30.33% showed secretory changes (Figure 3) endometrial adenocarcinoma (Figure 4) was found in 1.05% of the cases and hyperplasia was seen in 5.86% (Table 5).

Table 5: Histopathology findings in study population.

HPR	No. of cases	Percentage	
Disordered proliferative	142	29.7%	44.76%
Proliferative	72	15.06%	
Secretory	145	30.33%	
Endometrial hyperplasia	28	5.86%	
Endometrial carcinoma	5	1.05%	
Others	86	17.99%	
Total	478	100%	

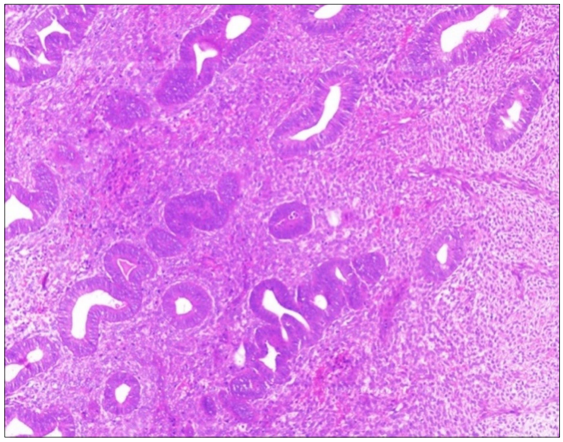

Figure 1: Proliferative endometrium.

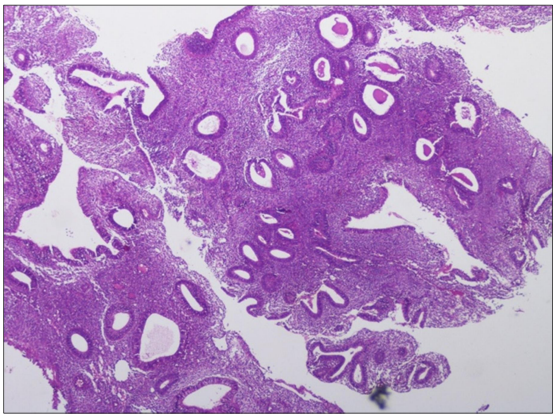

Figure 2: Disordered proliferative.

Among the hyperplasia, 50% was simple hyperplasia without atypia. Atypical hyperplasia (Figure 5) was found in 12 cases. Complex hyperplasia was found in 13 out of the 28 cases of hyperplasia of which complex atypical was 11 cases (Table 6).

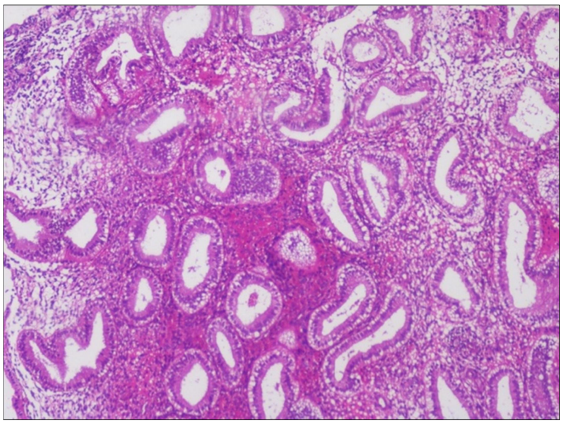

Figure 3: Secretory endometrium.

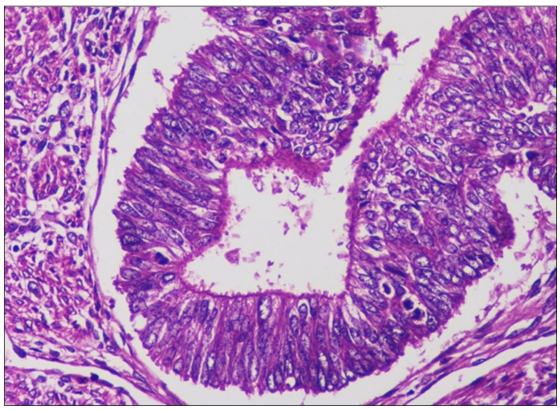

Figure 4: Adenocarcinoma.

Table 6: Cases of endometrial hyperplasia.

Type of hyperplasia	Number	%
Simple hyperplasia without atypia	14	50%
Simple hyperplasia with atypia	1	3.57%
Complex hyperplasia without atypia	2	7.14%
Complex hyperplasia with atypia	11	39.29%
Total	28	100%

Endometrial thickness was 8mm and above up to 15 mm in majority of cases of AUB-54.81%. ET less than 8mm was found only in 19.3% of the study population.ET 15 mm and above was also less which was 25.5% (Table 7). ET less than 4mm in AUB was very less-only 1.67%. One ET was not measured due to diffuse adenomyosis. Out of the 477 patients whose endometrial thickness were measured, all the five cases of endometrial carcinoma was found with an ET ≥15 mm among the 28 cases of endometrial hyperplasia 12 cases of hyperplasia were also found with ET ≥15 mm and the rest 16 cases had ET ≥8-15 (Table 8). Surprisingly all the five cases of carcinoma was endometrioid adenocarcinoma.

It was found in this study that proliferative and secretory endometrium was maximum when the endometrial

thickness was ≥8-15 mm and least with an ET less than 4 mm (Table 9).

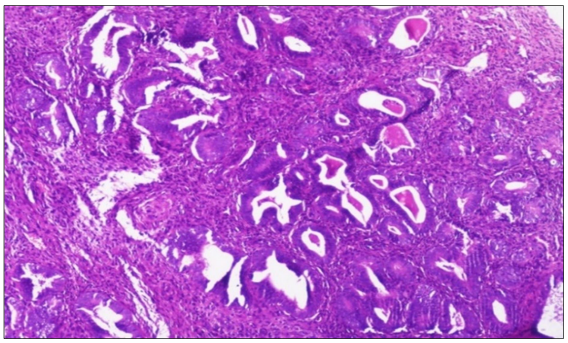

Figure 5: Atypical hyperplasia.

Table 7: Endometrial thicknesses by transvaginal ultrasound.

ET IN mm	Number	%
<4	8	1.67%
4-8	85	17.78%
≥8-15	262	54.81%
≥15	122	25.52%
Not measured	1	0.22%
Total	478	100%

If we take 8 mm as the cut off, we can see that in this study population all the cases of hyperplasia and malignancy had an ET ≥ 8 mm. Out of the 384 cases with ET ≥ 8 mm 28 cases had hyperplasia and five patients had endometrial carcinoma i.e. 8.59% (Table 10).

Table 8: Co-relation of et with endometrial hyperplasia and carcinoma.

ET in mm	Number	Endometrial hyperplasia	%	Endometrioid carcinoma	%
≥15	122	12	9.84%	5	4.46%
≥8-15	262	16	6.11%	0	0%
4-8	85	0	0%	0	0%
<4	8	0	0%	0	0%
Total	477	28	5.87%	5	4.46%

Table 9: Co-relation of et by TVS and histopathology.

ET in mm	Number	Hyperplasia and carcinoma	%
≥8	384	33	8.59%
<8	94	0	0%

Table 11: Co-relation of endometrial thickness with HPR.

ET in mm	Number	Hyperplasia and carcinoma	Not having carcinoma
≥8	384	33 (a)	351 (b)
<8	94	0 (c)	94 (d)

Sensitivity, specificity, the positive and negative predictive value for an ET of ≥8 mm was calculated. 94 patients with ET less than 8 and 351 patients with ET ≥8 mm did not have carcinoma (Table 11).

- Sensitivity = a/a + c =33/33 = 100%
- Specificity= d/b + d = 94/445 = 21.12%
- Positive predictive value = a/a + b = 33/384 = 8.59%
- Negative predictive value = d/c + d = 94/94 = 100%

DISCUSSION

Abnormal uterine bleeding is a very common diagnosis in the op population. According to this study the maximum age groups of the patients were in the perimenopausal age of 41-50 years-around 60.25%. This is similar to the study by Shobitha et al -68.1% in the same age group while it was 38% in a study by Mahapatra M et al where the study group was less.[2,3]

The youngest patient was a 22-year-old primary infertility patient with heavy menstrual bleeding for which diagnostic curettage was done and had an ET of 6 mm and secretory endometrium.

In this study, 79.7% were multiparious while 2.93% were nulli, in almost all the studies this is similar. This is in accordance to the study by Nidhi et al, where 88% were multipara and 1.2% were nulliparous.[4] In a study by Betha K et al 81% were multipara.[5]

BMI was in the overweight category in 36.6% and obese in 24.3% in this study which is similar to the study in Iran by Kazamijalezah et al, where it was 33% and also with the study by Sahai A et al, where 56.2% were in overweight category and obese was 25%.[6,7]

There was heavy menstrual bleeding in 98% of patients.

Of these 478 patients only 39 had diabetes as risk factor and out of 39 one had endometrial carcinoma.

When we analyze the histopathologic findings of the 478 cases 44.5% was proliferative endometrium, of this disordered proliferative endometrium seems to be the commonest, in a study by Elavarasan et al, where disordered proliferative endometrium seems to be the commonest pattern observed i.e. 31.1%.[8] The term disordered proliferative endometrium refers to proliferative phase that does not seems to be appropriate for any one time in the menstrual cycle and mimics simple hyperplasia, but the process is focal rather than diffuse. Histologically there shows mild disorganization of architecture, with focal dilated glands, with normal gland to stromal ratio. In this study 30% was secretory endometrium; endometrial hyperplasia was found in 5.8% and endometrial cancer in 1%.

Transvaginal ultrasound was done to assess the endometrial thickness and it was done in the premenstrual phase, of the 478 cases 54.8% had an ET of ≥8-15, 25.5% had ET more than 15 mm. In a study by Jikki et al, 57% had et ≥8 mm which is similar to this study of 54%.[9]

In the study by Jikki et al, the endometrial hyperplasia was seen in 96.4% cases when ET was more than 8 mm and in this study 100% of the patients with endometrial hyperplasia had ET ≥8 mm.[9] In this study 100% cases of endometrial carcinoma occurred with ET ≥15 and all cases of hyperplasia had ET ≥8 mm.

Simple hyperplasia without atypia was 50% in this study which was comparable to 62% in a study by Tabata et al.[10]

Complex endometrial hyperplasia was 14.8% in a study conducted by Idris et al, while their atypical hyperplasia was only 2% whereas atypical hyperplasia was 42.4% in this study.[11] This may be because of the fact that most of the patients in the study group were in the fourth decade (60%) and in their study was in the third decade (80%).

Of the 384 cases with ET ≥8 mm, 33 had endometrial hyperplasia and carcinoma, and 351 did not have e/o hyperplasia and carcinoma, none of the cases below 8mm had any e/o hyperplasia or carcinoma. Sensitivity and negative predictive value was 100% for an ET of ≥8 mm. This is similar to studies by Chatpavit Getpook an ET of 8 mm showed optimal sensitivity and specificity -83.9% and 58.8% respectively and 90.4% negative predictive value for an abnormal endometrium.[12] They concluded that an ET of 8mm or less is less likely to be associated with malignant pathologies. In this study the negative predictive value was 100% and sensitivity was 100% but the specificity was only 21.1%. According to a study by Ozdemir S et al, there was negative predictive value of 95.6%, sensitivity and specificity of 83.6 and 56.4% respectively for an ET of 8 mm.[13]

Kurman et al, classified hyperplasia in to simple and complex and subcategory as atypical.[14] The 2014 revised WHO classification simply separates endometrial hyperplasia into 2 groups-hyperplasia without atypia and atypical hyperplasia.[15] According to the EIN classification all atypical endometrial hyperplasia is classified as endometrial intraepithelial neoplasia.[15] Progesterone was found to cause regression in 90% cases with hyperplasia.

The RCOG cutoff of ET is less than 7 mm below which there is no endometrial hyperplasia in a prospective study of 56 women with pcos.[11,16] In studies by Gianella et al, 11 mm was taken as the cut off.

The most common presenting symptoms of endometrial hyperplasia is abnormal uterine bleeding. According to studies, the risk of progression of simple hyperplasia to carcinoma is 1% and complex hyperplasia with atypia is 29%.[18]

CONCLUSION

The clinical importance of endometrial hyperplasia is because of its progression to endometrial carcinoma. An ET of 8 mm in this study gives a 100% negative predictive value for hyperplasia and carcinoma and can be taken as a cut off for deciding the patients for dilatation and curettage especially in low risk patients.

Abstract

Background Recent literature supports the removal of myomas during cesarean section, which traditionally was considered a relative contraindication, given a higher complication rate. This study is to share our experience of cesarean myomectomy in the last decade.

Methods This study is a retrospective review of our prospectively maintained database, from January 2008 to December 2017, at a tertiary care level teaching institution. All patients who underwent myomectomy during cesarean section were included. There were no exclusions.

Results A total of twenty patients underwent myoma removal along with the cesarean operation during this period with a mean age of 30 years. Majority of patients were nulliparous (70%). Common comorbidities were diabetes mellitus (40%) and hypothyroidism (20%). Mean size of myomas were 5.33 cm (± 2.08), and the number varied from one to three. The most common location was the posterior surface of the uterus with the commonest variety being subserous. Most patients were discharged on the fifth postoperative day.

Conclusion This study demonstrates that cesarean myomectomy to be a safe and feasible procedure in experienced hands. It offers the advantage of avoiding a second surgery in selected patients.

Keywords Cesarean myomectomy · Myoma uterus · Cesarean delivery · Myomectomy

Introduction

The myomas are the most common benign tumors of the uterus. The highest reported incidence of myomas during pregnancy is 10.7% [1]. The myomas are common during the reproductive period due to an influence of higher estrogen levels. Their increased incidence during pregnancy can be partly explained by the late age of conception [2]. Myomas in pregnancy are associated with a significantly higher risk for cesarean section (CS).

Conventionally, concomitant myomectomy during CS was considered a relative contraindication, given perceived higher complication rate. Last decade has witnessed emerging literature evidence supporting myoma excision along with CS, with acceptable results [3]. This study aims to share our experience of cesarean myomectomy during the last decade.

Materials and Methods

This study is a retrospective review of our prospectively maintained database of the last decade, from January 2008 to December 2017, at a tertiary care teaching hospital. All consecutive patients who underwent myomectomy during cesarean section, in this mentioned duration, were included.

This formed a small subset, among the patients, having uterine myomas and pregnancy, a majority of those underwent vaginal delivery or had LSCS, without myomas removal. Those not matching the inclusion were not considered. There were no exclusions. The institutional ethical committee approved the study, and waiver of consent was obtained, in view of retrospective nature.

Data were collected from outpatient and inpatient records, operative and discharge notes. Data included maternal demographics such as age, parity, medical diseases, prior surgery, gestational age at the time of CS, type of anesthesia, indication for CS, elective/emergency and number of previous operations including CS. Myoma characteristics such as size, number, location and variety were noted. Other parameters like an indication for myomectomy, the number of incisions made and the presence of adhesions were observed. The total duration of surgery was taken as the time from the initial skin incision to skin closure. Approximate intraoperative blood loss was measured, and record of transfusion if any was noted. Postoperative drop in hemoglobin was checked at 48 h after surgery, and blood transfusion was given if the fall was more than 3 gm/dl. Postoperative complications like pyrexia (> 38-degree C) and wound infection were analyzed. Duration of hospital stay was noted, and patients were followed up after 2 weeks in the outpatient department.

Patients were counseled during the early third trimester regarding the need for myomectomy depending on the mode of delivery and consent obtained for the same.

Experienced gynecologists performed surgery with minimum of 10 years of experience. Preoperatively, half an hour before skin incision Inj. Tranexamic acid 1 gm in 100 ml isotonic saline was infused over 20 min. Except in four cases, myomas were situated at the incision site, and in other instances, CS preceded myomectomy. When myomas were located at the lower uterine segment, myomectomy was performed before delivery of the fetus. During CS, myomas were inspected for their size, number, type and location after the closure of the uterine incision (Fig. 1).

Though myomectomy was tried with a single incision, in few cases where multiple fibroids were present, more than one incision over uterus was needed. An incision was made over myoma by using monopolar cautery, and the tumor was enucleated. To achieve hemostasis, bipolar cautery was used. The defect in the myometrium was closed with 1-0 vicryl suture (Fig. 2). High-dose oxytocin infusion was continued postoperatively for 24 h to prevent bleeding.

Results

A total of twenty patients underwent myoma removal along with the cesarean operation during this period with a mean age of 30 years. Majority of patients were nulliparous (70%).

Fig. 1 Multiple fibroids over the anterior surface of uterus postdelivery of the baby

Fig. 2 Postmyomectomy, closure by baseball sutures

Common comorbidities were diabetes mellitus (40%) and hypothyroidism (20%). One except all patients received regional anesthesia (spinal/epidural); the only case needed general anesthesia due to the presence of idiopathic intracranial hypertension. Sixty-five percent of surgeries were elective operations. The details of various preoperative characteristics are shown in Table 1.

Intraoperatively, two patients had small bowel and omental adhesions at the operative site. Two patients (10%) received a blood transfusion during the procedure. The mean hemoglobin drop reported 24 h postoperative was 1.23 (± 1.16) grams. No patient warranted blood transfusion in the postoperative period (Table 2).

Majority of patients got the discharge on the fifth day of surgery. There were no incidences of postpartum pyrexia or

surgical site infections. The patients were regularly followed in the outpatient department.

Discussion

Fibroid excision along with caesarian section was considered difficult until recently. Fibroids with pregnancy might cause miscarriage, preterm delivery, premature rupture of membranes, early separation of the placenta, labor dystocia, postpartum hemorrhage and increased rate of operative deliveries. Fibroids might also undergo red degeneration and associated complications. Myomectomy during CS has not been done routinely due to the risk of uncontrolled bleeding and the possibility of hysterectomy [4]. If myomectomy is not performed along with CS patient might need another surgery to remove it, which amounts to two operations, two anesthetic exposures and increasing cost, and there is also an enhanced risk of complications caused by fibroids in a subsequent pregnancy.

The average age of mothers in our study was 30 years. Most studies have shown myomas to be more common in nulliparous women [5]. We too observed a higher incidence of myomas among nulliparous women (70%) [6]. This could be explained due to hormonal changes and reduced sensitivity of leiomyoma to estrogen receptor [7].

Similar to many other studies, the average gestational age at the time of CS was 37 to 38 weeks in our study [4, 6, 8]. We had four patients delivering at 35 to 36 weeks of gestation. Among these four patients who had delivered prematurely, three deliveries can be attributed to the presence of fibroids. Two out of these patients have already undergone fibroid removal before becoming pregnant. The possible explanation for preterm labor could be decreased distensibility of uterine myometrium due to the presence of fibroids as the pregnancy advances [9].

Though CM is to be avoided in cases of the previous myomectomy due to more chances of complications [10], we had the opportunity to do repeat CS for one of our patient who underwent CS myomectomy 3 years ago. The indication for primary CS was a transverse lie. The malpresentation was suspected to be due to a single large (8 cm), intramural fibroid located in the lower uterine segment. Incidentally, this was the largest myoma we had come across in our study. As the fibroid was situated in the incision site, myomectomy was followed by CS. During repeat CS, which was done 3 years later, there was no fibroid detected intraoperatively. There were three more cases of lower uterine segment (LUS) fibroids; if they were less than 5 cm, then myomectomy were done following the delivery of the baby. All fibroids present in the LUS were removed through the same CS incision, without any additional incision on the uterus. The same technique was suggested in several other studies [11, 12].

Three of our patients had undergone myomectomy previously in the non-pregnant state. One of the women had undergone myomectomy twice before becoming pregnant. This confirms the well-established fact that fibroids are recurrent [13]. Among the study group, the patients who had undergone previous myomectomies had a high incidence of intraoperative adhesions as expected. However, in all three patients, the surgery was uneventful with minimal blood loss and no added morbidity.

Eight of our study subjects had multiple fibroids. Six patients had fibroids of size 8 cm (largest dimension). 55% of the myomas had size > 5 cm. The smallest dimension encountered was 2.5 cm. We had more anterior wall fibroids than posterior [4]. Traditionally myomectomy is avoided in cases of fundal and cornual sites because of excessive

bleeding and possible obstruction of fallopian tubes [14, 15], but in our study, myomectomy was done regardless of the location of the myomas.

Except for a single instance of the submucosal fibroid, there was an even distribution of intramural and subserosal fibroids. Removal of submucosal fibroids during cesarean section is usually avoided as it involves resection of the full thickness of myometrium and reduced contractility might lead on to increased hemorrhage [16]. Secondary changes due to red degeneration were found in a case with single sizeable fundal fibroid. Histopathological reports of all myomectomy specimens were closely followed up, and none showed malignant change.

The same incision removed fibroids in the anterior wall and close to CS incision. Whenever possible, a minimal number of incisions were made, and adjacent ones removed through the same incision. This was done to reduce blood loss and future adhesions and improve reproductive outcome. While the operating time was more or less uniform in most of our cases, two of the cases exceeded the average operating time significantly. In these two instances, the increased operating time could be explained by multiple fibroids needing more than a single incision for removal. Other studies have also observed more than average operating time in cases of multiple fibroids [17].

Intraoperative blood transfusion was done in two cases only as they met the criteria for blood loss of more than one liter. One case had a fibroid at the incision site. The second patient who had a loss of more than two liters which was the largest in our series had three fibroids at different locations and they were removed by as many incisions. Despite intraoperative transfusion and other pharmacological measures to attain hemostasis, she had a significant drop in hemoglobin at 48 h postoperatively and needed another transfusion. She had no other postoperative morbidity like pyrexia or ileus and was discharged on the fourth day after surgery.

CM is not done routinely, because of the associated hemorrhage and the need for the hysterectomy [15]. Specific hemostatic techniques have been advocated by various authors [18, 19], but we have followed tranexamic acid infusion, vasopressin instillation, uterine artery ligation, electrocautery and high-dose oxytocin. There was not a single case which needed a hysterectomy in our study of twenty cases, though patients were counseled regarding the possibility in the prenatal period due to intractable hemorrhage. We also found no increased postoperative morbidity or expanded hospital stay in any of our patients who underwent CM as was observed by Dam Hye Kwon et al. [8].

There are a few limitations to our study. Its retrospective design coupled with proportionally small sample size limits generalization of results. This study also lacks long-term follow-up of these patients and thus to highlight effect on future pregnancies. Additionally, as this study was conducted in a tertiary level medical college setup with available expertise, the results cannot be generalized, especially in comparison with smaller installations or in the absence of an expert.

We author would like to stress this to the readers that routine use of myomectomy during CS is neither advisable nor been followed in the current study. The CM should be carefully planned for selected patients in an appropriate setup and expertise. A similar conclusion is drawn by a recent review on this topic [20], recommending standardization of best practices for CM, with the availability of more robust data and in the presence of necessary facilities.

Conclusion

Overall, our series has shown CM to be a safe and feasible procedure in well-selected patients in a tertiary care center with experienced hands. It can offer an advantage of avoiding a second intervention in selected patients. Appropriate hemostatic techniques can curtail hemorrhage which is the most severe complication. Long-term morbidity concerning future reproductive outcome should be addressed in a study with large participants and reliable design.

Authors' Contributions All authors have a significant contribution for preparation of this manuscript, following ICMJE Guidelines. First and second authors share the first position.

Compliance with Ethical Standards

Conflict of interest No author has any potential conflict of interest.

Ethical approval The current study is approved by the responsible institutional ethics committee for human research and fully comply with the declaration of Helsinki for guideline on human research.

Abstract

Background: Surgical site infections (SSI) are one of the major health problems throughout the world with an incidence of 3%-16%. Hospital acquired surgical site infection is further complicated by the emergence of multi drug resistant strains. SSI surveillance is an established monitoring tool and has been shown to reduce infection rates. The importance of preventing surgical site infections is well recognized since they lead to increased morbidity, prolonged hospital stay, need for readmission, high end antibiotic treatment and re-surgery. This study was undertaken to determine the incidence, risk factors, and microbiological spectrum of surgical site infections and to identify the multidrug resistant strains. Analysis of the effectiveness of the existing surveillance methods was also done.

Methods: This retrospective study was done for a period of 1-year form Jan 2016 to Dec 2016. All patients with infection following caesarean section and abdominal and vaginal hysterectomy were included. Laparoscopic surgery and patients with preexisting infection were excluded.

Results: Incidence of SSI in present study is 5.27%. The major risk factors identified were obesity, diabetes and prolonged operating time. The commonest infective organism was Klebsiella Pneumoniae in 37% of which 19% were ESBL producing and 3.8% were carbapenemase producing. E. coli was identified in 20% of isolates. The incidence of ESBL in both isolates was higher.

Conclusions: Regular audit of SSIs is a very effective tool to analyse risk factors, identify causes and plan strategies to prevent infection.

Keywords: Drug resistance, Hospital acquired, Surgical site infection, Surveillance

Introduction

Surgical site infections (SSI) are significant source of morbidity, prolonged hospital stay and recovery and rarely mortality. They complicate 3 to 16%.[1-4] of all surgeries but even these estimates are likely to be low as some infections occur after the patient's discharge from the hospital or they report to other hospitals with infection. Hospital acquired SSIs are further complicated by the emergence of multidrug resistance strains. The importance of preventing surgical site infections is well recognized since they lead to increased morbidity, prolonged hospital stay, need for readmission, high end antibiotic treatment and resurgery.[1,3]

The Center for Disease Control (CDC) defines SSI as an infection related to an operative procedure that occurs at or near the surgical incision within 30 days. This time frame is extended to 12 months if a surgical implant is used. Infections are further divided into:

- Superficial involving skin and subcutaneous tissue
- Deep involving deeper soft tissue of the incision like fascia or muscle
- Organ or space involving any part other than the incised body layers.

Surgical wounds are further classified as clean, clean contaminated, contaminated and dirty.

Most obstetric and gynaecological procedures are classified as clean contaminated as the genital tract is entered into controlled fashion and there is no unusual contamination. Some surgeries like pelvis abscess, perforated bowel or positive culture pre-op are classified as dirty. SSI surveillance is an established monitoring tool and has been shown to reduce infection rates.

M□□□□□□

This retrospective study was conducted in the department of Obstetrics and Gynaecology at a teaching hospital in South India from the period of January 2016 to December 2016.

Inclusion criteria

- All emergency and elective obstetric and gynaec procedures like caesarean section, abdominal and vaginal hysterectomies and laparotomies were included.

Exclusion criteria

- Laparoscopic surgeries and patients who had pre-op infection.

The departmental protocol includes two visits after surgery: the first visit a week after discharge and second visit a month later. The charts were analysed at the end of a month after surgery to identify patients with infection. Their case records were analyzed for pre-op risk factors, intra-operative factors like timing of prophylactic antibiotics and duration of surgery and post-operative course. All patients with wound infection had a culture and sensitivity done. The culture report was analysed for the infecting organism and sensitivity pattern. A monthly audit of all SSIs in the department was done to determine the incidence and microbiological spectrum of the infecting organisms. Infection control practices currently in place were also reviewed and analysed to determine if there was a scope for improvement.

□□□□□□□

The numbers of surgeries in present study period who fulfilled in present inclusion criteria were 982 caesarean sections and 497 gynaec surgeries. The results are shown in Table 1.

C section	982	55	5.6%
Gynaec surgeries	497	23	4.62%
Total	1479	78	5.27%

The patients who had wound infection were analysed for pre-operative risk factors like obesity, diabetes, other medical disorders and intra operative factors like prolonged operating time, previous surgeries and presence of malignancy.

As shown in Table 2, obesity was the major risk factor as 48.7% of patients had BMI of >25. Other risk factors included diabetes and prior surgery with adhesions in 19.2%, anemia and hypertension was seen in 12% of patients. 9% of patients had prolonged operating time of >3 hours.

Prophylactic antibiotics given	Given in all patients			

All patients who had discharge from the wound had a culture taken prior to starting antibiotics. The culture report was analysed for infecting organism and sensitivity pattern. The pathogens isolated is shown in Table 3.

Figure 1 shows the month wise analysis of the organisms which were MRSA (Methicillin Resistant Staph Aureus), ESBL (Extended Spectrum Beta Lactamase) and Carbapenemase producers.

□□□

giving an incidence of 5.6 %. 23 of patient who underwent gynaec surgeries had SSI giving an incidence of 4.62%. The total incidence was 5.27%.

This compares favorably with the reported rate of 11.8 % in the WHO review of SSIs in low and middle-income countries.[5] 93 % of these were superficial infections. Three patients had wound debridement and re-suturing under anaesthesia. One patient had a pelvic collection that got infected. However, it drained spontaneously through the vagina.

SSIs are hospital acquired infections and their occurrence is dependent on many factors. The profile of patients undergoing surgery is also changing. There is increase in the number of patients with multiple co-morbidities and in the older age group. Preoperative factors include patient characteristics like obesity, diabetes, other medical disorders, prior surgery and steroid use. Other pre-operative factors include skin cleaning and hair removal techniques.

Intra operative factors include timing and dose of prophylactic antibiotics, abdominal and vaginal preparation, duration of surgery and technique of wound closure. Post-operative factors include glycemic control in diabetic patients and presence of anemia and blood transfusion.

Table 2 shows the pre-op and intra-op risk factors identified in present study. A systematic review of 57 studies by the WHO from both high income and low and middle income countries identified high body mass index (BMI) , diabetes and prolongation of duration of surgery as risk factors associated with increased risk of SSIs .In patients with high BMI, various factors like increase in adipose tissue, need for larger incision, decreased circulation in fat tissue and increase in local tissue trauma related to retraction contribute to the increased SSIs in these patients. Obese patients also have an altered hemostatic balance and decreased immune function.

Hyperglycemia in patients with diabetes is a well-known risk factor for infections including SSIs. A study by Al-Niaimi et al compared 2 groups of post-operative patients after gynaecological oncology surgery. Patients whose blood sugar > 150mg/dl were managed either with intermittent subcutaneous insulin injection or insulin infusion. Patients who were on insulin infusion had significantly lower infection rates (19% versus 29% P=.001).[6] Hyperglycemia can have several deleterious effects on host immune functions, stimulation of inflammatory markers, increased thrombotic activity and endothelial cell dysfunction. This is of importance even in non-diabetics as stress hyperglycemia can have the same effects.

Prolonged duration of surgery was associated with increased incidence of SSIs in the majority of studies. There was also a linear correlation between operative time and the likelihood of SSIs. The reasons postulated for this are:

1. With increased operative time the patient's open incision is exposed to the environment for a longer time.
2. Tissue desiccation is more.
3. Tissue concentration of antibiotics will decrease as the procedure continues.

However, it is important to remember prolonged surgery may also mean more complex procedures and other intra operative factors like adhesions which by themselves can increase the likelihood of infection.

Other risk factors included anemia which diminishes the resistance to infection in 12.8% prolonged PROM >24 hours in 3.6% of caesarean sections and malignancy in 3.8%.

Other risk factors considered important in SSI in a study by Devjani et al included pre-operative hospital stay with exposure to procedures, therapies and hospital micro flora and administration of blood products. Allogenic blood products have immunomodulatory effects that may increase the risk of post-op infections.[7]

The prophylactic antibiotic policy at present in the hospital is administration of Injection Cephazolin 1 gm given within one hour of skin incision and the second dose 6 hours later. All the patients received the prophylaxis however the time was >1 hour in few patients. David Classen et al reported that administration of antibiotics within a 2-hour period before an operation was associated with the lowest infection rate.[8]

On analyzing the culture report, Table 3 shows the organisms isolated in present patients. *Klebsiella pneumonia* was seen in 29 patients (37.2%) of these 51% were ESBL producers and 10% were carbapenamase producers. The second commonest organism was E coli in 16 patients (20.5%) of these 43% were ESBL producing. Pseudomonas was isolated in 10%. Routine anaerobic cultures were not performed. More than one organism was isolated in 31 out of 78 patients (39.7%).

In a study conducted by Devjani De et al the most frequently isolated organism was Acinetobacter species in 32% followed by *Staphylococcus aureus* in 22.3%.[9] In mild infections, patients were started on Levofloxacin and Metrogyl pending the culture report. In more severe infections Cefotaxime and Metrogyl or Piperacillin/ Tazobactam was started.

The resistance pattern of the infecting organism was also analysed. Figure 1 and Table 4 shows the number and percentage of drug resistant organisms. MRSA infections are of concern and there is need to screen both the patients and the health care workers involved for asymptomatic nasal carriers. In 51 out of 78 patients

(65%) infection occurred after discharge from the hospital. This may be due to the policy of early discharge from the hospital. So, post discharge surveillance is important to arrive at a correct estimate of the magnitude of the problem. A WHO review on Global guidelines for SSI prevention reported that 13% to 71% of infections occurred after discharge from the hospital. Rosenthal et al determined that 63.8% of SSIs were detected in hospital and 36.2% after discharge.[10]

Surveillance of SSIs also includes a review and analysis of the preventive strategies in place in the hospital. Prevention of SSIs requires a multifaceted approach including proper air conditioning and ventilation engineering, appropriate cleaning and disinfection of the operating theatres and proper sterilization of instruments. Proper safeguards for checking sterilization of instruments, maintenance of OR discipline and sustained education of all OR personnel regarding safe practices are no less important.[11] Hence every hospital should have protocols for prevention of SSIs and follow continuous surveillance of infections.

As part of this, the hospital infection control committee met on monthly basis. The rates of various hospital acquired infections were discussed in the monthly hospital infection control committee meetings. SSI surveillance by surgical staff can also be cross checked by the infection control team.[10] In addition to the SSI rates in various surgical specialties, ventilator associated pneumonia and catheter associated urinary tract infection and blood stream infection rates were also discussed. Environmental surveillance included air sampling done by settle plate in all OTs and the results were analyzed. The incidence of multi drug resistant organisms in all areas in the hospital was analysed and compared to the previous months. To audit the usage of antibiotics, patients on high end antibiotics was analysed department wise and feedback was disseminated to the concerned department. Hand hygiene compliance by health care workers was also analysed in all acute care areas and feedback disseminated.

The information on Hospital Acquired Infection in developing countries is limited because of the lack of national surveillance systems.[12] Most of the reported studies are from single hospital and therefore are not representative of the entire country. Prevention of hospital acquired infection is one of the key agendas of various international bodies like the WHO, CDC and others.

Both the WHO and Center for Disease Control and Prevention guidelines for prevention of surgical site infection (2017) included the following strong recommendations[5,13]:

- Patients are advised to bathe with soap or antiseptic agents at least the night before surgery.
- Skin preparation: Hair removal if required is done only by clipping Shaving is strongly discouraged at all times Intra op skin preparation with alcohol-based chlorhexidine gluconate is recommended.
- Prophylactic antibiotics should be administered 1 hour before skin incision so that serum and tissue concentration are established before the incision is made. For clean and clean contaminated procedures additional prophylactic antimicrobial agents should not be administered after the surgical incision is closed in the operating room even in a presence of a drain. Topical antimicrobial agents should not be applied on the surgical incision.
- Protocols for perioperative glycemic control to be implemented using blood glucose target level of <200mg/dl in patients with or without diabetes.
- Perioperative normothermia should be maintained in all patients. Increased fraction of inspired oxygen should be administered during surgery and after extubation in the immediate postoperative period for patients with normal pulmonary function undergoing general anesthesia.

Transfusion of blood products should not be withheld from surgical patients as a means to prevent SSIs.

□□□□□□□□□□

Prevention of SSI is an important part of providing optimum care for patients. Throughout the world there is a growing concern about patient safety. This prompted the WHO to launch the World Alliance for patient safety. Prevention of health care acquired infection is the one of the first targets of the Alliance. “Clean care is safer care” was launched in October 2005. A key objective of the programme is to launch a feasible practical approach to improve hand hygiene in healthcare globally. Continuous audit and implementation of infection prevention strategies should part of the standard protocols of every hospital. It is challenging and requires dedication of both time and resources. This includes simple things like hand hygiene, pre-operative bathing and skin preparation that are no less important than tracking of multi drug resistant organisms and usage of high end antibiotics.

ABSTRACT

Objectives: To analyse patients with moderate to severe thrombocytopenia in labour, to identify the etiology, assess severity, correlate with the maternal disease and management.
Methods: A retrospective study of all pregnant women admitted in labour or in obstetric critical area and found to have a low platelet count were included in a study period of 18 months from July 2013 to Dec 2014.
Results: 25 women out of 2738 deliveries were identified and commonest cause was severe pre-eclampsia with or without HELLP. Coincidental dengue with super added pre-eclampsia was found in 3 women. Severe thrombocytopenia was found in haematological conditions like ITP and aplastic anemia.
Conclusion: Low platelets or fall in platelets showed a worsening of disease condition. Platelet transfusion needs to be done if the cut off is below the desired target level. Timely administration of platelets and discrete use of SDP especially when massive platelet transfusion is required required as mandatory. Delivery should be as atraumatic as possible, avoidance of episiotomy to be practiced. Sometimes treatment can be challenging and involve multi-disciplinary approach.

INTRODUCTION

Thrombocytopenia is the most common hemostatic abnormality in pregnancy occurring in approximately 10% of all pregnant women. Abnormalities of platelet count may either be mild when the platelet count is between 150,000 and 100,000/mm^3, moderate when the count is between 100,000 and 50,000/mm^{3}or severe when the count is < 50,000/mm^3 (1). Gestational thrombocytopenia is the commonest cause of low platelets in pregnancy, however the count rarely falls below 70,000/mm^3 and is not of much clinical significance. Moderate to severe thrombocytopenia may occur due to either pre-existing disease like immuno thrombocytopenia (ITP), Systemic lupus erythematosus (SLE), anti-phospholipid syndrome (APLA) or pregnancy related conditions like pregnancy induced hypertension (PIH), HELLP, acute fatty liver of pregnancy (AFLP), ect (Kam, 2004). In labour low platelet count is a risk not only to the mother but also to the fetus. Most patients with mild thrombocytopenia do not have any hemostatic risk and do not require treatment unless the degree of thrombocytopenia worsens.

However moderate to severe thrombocytopenia is associated with adverse effects. The threshold for significant spontaneous bleeding is a count of 10,000/mm^3 and in the case of surgical interventions or delivery the threshold is higher >50,000/mm^3. The underlying disorder may manifest as thrombocytopenia and warrant immediate termination. The obstetrician concern is how to obtain hemostasis in the event of delivery and may involve multidisciplinary approach. Many articles describe thrombocytopenia in pregnancy however in labour only few references could be found. The aim of this article is to analyse the etiology of thrombocytopenia in labour, clinical features, management, platelet transfusions and fetal outcome.

MATERIALS AND METHODS

A retrospective study of all pregnant women admitted in labour or in obstetric critical area and found to have a low platelet count were included in a study period of 18 months. Only women with counts less than 1,00,000/mm^3 were included. The cases were analysed for the following:

- Etiology
- Clinical features
- Platelet count on admission
- Correlation with platelet count and maternal disorder.
- Need for platelet transfusion
- Gestational age at presentation.
- Outcome of pregnancy.

The condition of the baby in terms of gestational age, live birth or stillbirth were also assessed. Problems during transfusion were also assessed. The criteria for severe pre-eclampsia were blood pressure > 160/110mmhg, proteinuria +++ or more, oliguria, visual disturbance, epigastric pain, thrombocytopenia or impaired liver function.

Criteria for HELLP were

- Hemolysis as shown by peripheral smear or elevated billirubin > 1.2mg/dl
- Elevated liver enzymes : AST > 72IU/L, LDH > 600 IU/L
- Low platelets : count < 100,000/mm^3.

Management of these women, when and how they were terminated, type of transfusions and problems encountered were also analysed.

RESULTS

Table 1. Analysis of etiology

Cause	Number of cases
Severe pre-eclampsia with and without HELLP	18
PIH with Dengue	3
Megaloblastic anemia	1
ITP	1
Aplastic anemia	1
DIC	1
Total cases	25

Table 2 : Clinical features – combination of clinical features were seen

Clinical feature	Number of cases
Elevated BP	21
HELLP	7
Severe anemia	2
Eclampsia	4
Abruption	2
Renal failure	4
Bleeding episodes	6
Fever	3
Abdominal distention	1

Table 3. Correlation between platelet count on admission and diagnosis

Platelet Count	PIH	PIH with Dengue	Megaloblastic anemia	ITP	Aplastic anemia	DIC
100,000-50,000	10		1			1
50,000-20,000	6					
20,000-10,000	2	1		1		
<10,000		2			1	

The total number of deliveries were 2738 in the study period. The number patients with severe to moderate thrombocytopenia were 25.

The etiology was predominantly PIH seen in 18 women. PIH with super added dengue was seen in 3 women. Hematological disorders like ITP, aplastic anemia and megaloblastic anemia were seen in one each. One patient was found to have hemoperitoneum after caesarean and was found to have DIC. The clinical features at presentation were predominantly those of severe pre-eclampsia as shown in table 2. Combination of features like elevated blood pressure, HELLP, eclampsia, abruption and renal failure were seen. Bleeding episodes like haematuria, malena, bleeding from IV sites, bleeding gum, purpuric spots were seen in 6 women. Fever with elevated BP, abdominal distention following caesarean were also seen.

Table 3 shows the correlation between the platelet count on admission and diagnosis. The platelet count was moderate thrombocytopenia in 12 women, severe thrombocytopenia in 13 women. In the severe thrombocytopenic group 3 women had counts <10,000 cells/mm^3 and 4 women had counts between 10,000 to 20,000 cells/mm^3. In the PIH group platelet count was moderate thrombocytopenia in 10 out of 18 women. 6 women had counts between 50,000 to 20,000 cells/mm^3 and only 2 women had counts between 20,000 to 10,000 cells/mm^3. In patients with dengue and superadded PIH (3 women) the platelet count was <20,000 cells/mm^3 in all. The woman with megaloblastic anemia and dilutional coagulopathy had counts of 60,000/mm^3. Woman with ITP and aplastic anemia had very low counts <20,000cells/mm^3 and <10,000cells/mm^3 respectively. On analysis of platelet transfused in PIH women only 8 received transfusion and 10 did not. All women with dengue received multiple transfusions of 20 to 24 units. The woman with ITP received 44 units of platelet transfusion and the women with aplastic anemia received 40 units of platelets and 10 units of single donor platelets (SDP) as shown in table 4. There was one spontaneous expulsion at 26 weeks of pregnancy, live births were seen in 19 women and 5 women had IUD or stillbirth. 8 women delivered before 34 weeks and 16 women delivered 34 to 38 weeks of pregnancy. Table 5 shows the gestational age at presentation and fetal outcome.

DISCUSSION

Pregnancy is a hypercoagulable state with increased level of clotting factors. However platelet count declines as pregnancy advances. A platelet count < 150,000/mm^3 occurs in 1% of population but occurs in 6 to 12% of pregnancy women at term (McCrae, 2003; Boehlen, 2000). Approximately 1% of all pregnancy women have a count <100,000/mm^3 and about 1 in 1000 to 2000 have a count <50,000/mm^3. In our series also the incidence was similar around 1% of all patients had counts <100,000/mm^3 and severe thrombocytopenia was seen in 4-5/1000 women. In general, patients with a platelet count < 20,000//mm^3 are at risk of spontaneous bleeding. Platelet counts between 20,000 to 50,000/mm^3 have a risk of bleeding during procedures or delivery (Andra, 2013). Patients with counts >50,000/mm^3 generally have minimal risk of bleeding. PPH is the leading cause of maternal mortality (Lale, 2014) and when a patient enters the labour room with a low platelet there is great fear as to whether she would bleed during delivery, how much and how to prevent PPH. Therefore there is great concern to ascertain the diagnosis and immediate treatment. In our study pre-eclampsia was the commonest cause of severe and moderate thrombocytopenia.

Table 4: Transfusion chart

Platelet Count	PIH		Dengue		Megaloblastic anemia		ITP		Aplastic anemia		DIC	
	R	NR	R	NR	R	NR	R	NR	R	NR	R	NR
100,000-50,000	2	8			1						1	
50,000-20,000	4	2										
20,000-10,000	2		1				1					
<10,000			2						1			

R – Received, NR – Not Received

Table 5. Gestational age at presentation & fetal outcome

Gestational age	PIH	Others	IUD/Still birth
< 28 weeks	1	0	1
28 to 34 weeks	7	1	3
34 to 38 weeks	13	3	2
>38 weeks	0	0	0

Pre-eclampsia is said to be present in 21% of maternal thrombocytopenia[6]. Thrombocytopenia occurs in 50% of pre-eclampsia and occasionally precedes other manifestation of the disease. A decrease in platelet count is considered as an early sign of worsening of pre-eclampsia and may occur even before other clinical manifestation of disease are apparent (McCrae, 2003). The severity of thrombocytopenia directly correlates with the severity of the lesion. HELLP syndrome is often considered to be a variant of pre-eclampsia and in 1982 Weinstein coined the term HELLP and also stated that its presence is an indication for delivery as there is increased risk of maternal and fetal mortality (Weinstein, 1982). The hallmark of HELLP is microangiopathic hemolytic anemia, elevated liver enzymes and low platelet count. The reported cutoff value have ranged from 75,000/mm^3 to 229,000/mm^3 with a level of <100,000/mm^3 most often cited. HELLP may be complete with all the elements or partial with one or two components. HELLP occurs in 0.5 to 0.9 of all pregnancies and in 20% of all cases with severe pre-eclampsia.

The Mississippi Triple class system classifies this syndrome based on platelet counts (Joshi, 2010).

- Class I< 50,000/mm^3
- Class II50,000 to 1,00,000/mm^3
- Class III1,00,000 to 1,50,000/mm^3

In our study of 21 women with PIH, 7 women had HELLP, 5 belonging Mississippi Class I and 2 to Class II. Abruption was found in 2 and eclampsia was found in 4. HELLP, abruption and eclampsia require immediate termination irrespective of the gestational age. All our patients were terminated before 38 weeks of pregnancy, most of them were early or late preterm. Only one patient expelled at 26 weeks. M Sibai et al also states the same in his analysis of 442 pregnancies with HELLP syndrome [9]. In a study of 437 women who had 442 pregnancy with HELLP syndrome, serious maternal morbidity including DIC (21%), abruption 16%, ARF 8%, Pulmonary edema 6%, liver haematoma 1%, retinal detachment 1%. 55% of patients required blood component therapy and 2% required laparotomy for bleeding. Maternal mortality was 1%. Of 21 patients with low platelets with PIH, transfusion was done only in 11 patients, 9 of them had counts <50,000/mm^3 and only 2 had counts >50,000/mm^3 - one had 55,000/mm^3 and other had 62,000/mm^3, since LSCS had to be performed platelet transfusion was done as per British guidelines. Platelet count of > 80,000/mm^3 is recommended for epidural anesthesia by the British committee for the standards in hematology [10]. The count that was aimed in our patients was 50,000/mm^3 for vaginal delivery and 80,000/mm^3 for LSCS.

Dengue with super added PIH was seen in 3 patients. 2 of these patients in addition had HELLP-one complete and another partial. These patients had extremely low platelet counts (7,000/mm^3). The counts were much lower than those seen in severe pre-eclamsia. All of them had bleeding tendencies and all required transfusions. 24 units were given for the patient with 9000/mm^3, 22 units for a patient with twins and a count of 7,000 cells and 7 units for a patient with partial HELLP and previous caesarean. The rise in platelet count was very slow in this group, it took 10 days for platelet count to stablise. Dengue is a common tropical disease in our country. All our 3 patient had secondary dengue with super added pre-eclampsia and presented with bleeding tendencies. No reports of dengue with pre-eclampsia have been reported so far. The compounded effect of pre-eclampsia and dengue lead to very low platelet count and massive platelet transfusion was required in these women. The interval between the diagnosis and delivery was within 2 to 3 days. Termination was done immediately for all case of abruption, eclampsia, renal failure and HELLP after platelet correction to the desire level. In preterm mothers steroid administration was done for lung maturity and subsequently induction or LSCS was resorted to based on other parameters.

Haematological disorders must always be borne in mind especially when the clinical situation rules out pregnancy related conditions like PIH. In cases of severe anemia, megaloblastic anemia must always be thought of as was done in our case. In case of megaloblastic anemia the patient was referred as severe anemia with hemoglobin of 4.3gm/dl, platelet count showed 60,000cells/mm^3 . Anemia was more profound in this case and peripheral smear and bone marrow confirmed the diagnosis. A patient with known ITP presented at 28 weeks with PROM. She was on steroids. After delivery she developed hemothorax. She was treated as per ASH guidelines (The American Society of Hematology, 2011) Since she did not respond to steroids, Anti Rh immunoglobulin was given. She received a total of 44 units of platelets. Splenectomy was done as a last resort. A normotensive woman was referred as severe anemia with low platelet count. Dengue and drug history were ruled out. ITP was initially thought of, but inspite of transfusion the platelet count never raised. The expected rise was 5000cell/mm^3 after the single unit of transfusion but in this patient even after 4-5 units the counts did not raise. Further evaluation was done and ultimately a bone marrow confirmed aplastic anemia. We had to delivery her for fear of abruption or bleeding elsewhere and planned to refer her for bone marrow transplant. The patient was delivered under cover of single donor platelet.

However following delivery the counts fell to <2000/mm^3, she developed huge vulval haematoma, multiple bleeds, cerebral bleed and could not be resuscitated. Sometimes massive bleeding as in PPH may result in dilution coagulopathy as seen in our patient. This patient was referred from outside with abdominal distention after caesarean section, was found to have hemoperitoneum with platelet count of 60,000cells/mm^3, hemoglobin of 5gm/dl, fibrinogen of 150mg/dl, INR 1.6, she was diagnosed as DIC. NIH consensus conference report noted that pathological haemorrhage in a patient receiving massive transfusion is caused more frequently by thrombocytopenia than by depletion of coagulation factors. This may be due to hemodilution using crystalloids or using only packed cells. In such a situation it is always worthwhile to serially check for platelet count, PT & INR to see if dilution coagulopathy has occurred, since unless it is corrected bleeding would not stop (Platelet Transfusion Therapy, 1986). Still birth and IUD were seen in 6 women all in the PIH group. The high perinatal mortality was due to prematurity and IUGR. Similar reports are quoted by Kubilay Ertan (A Kubilay Ertan, 2002). However thrombocytopenia was not related to the preterm birth.

Factors to be considered in thrombocytopenic patients in the last trimester are

- When to terminate?
- What is the mode of termination?
- What is the ideal count to be obtained?
- What is the type of transfusion to be given?

Termination needs to be thought of only for maternal conditions like PIH, HELLP or abruption. The severity of thrombocytopenia directly correlates with the severity of the lesion[(14)]. Patient with severe PIH need to be serially monitored and a drop in platelet count may heralds the onset of HELLP. Careful surveillance is necessary. Vaginal birth is the preferred mode delivery. The chance of bleeding is less when trauma is minimal. Even episiotomy need to be given only where necessary because 1 patient with aplastic anemia had huge vulval haematoma after delivery. Both British and American guidelines suggest a platelet count >50,000/mm^3 is safe for vaginal delivery. British guidelines suggest aiming at a platelet count >80,000/mm^3 for a caesarean section. The count that was aimed in our patients was 50,000/mm^3 for vaginal delivery and 80,000/mm^3 for LSCS.

A single unit of platelet transfusion rises the platelet count by 5,000/mm^3. A unit obtained by apheresis of a single donor (SDP) contains an equivalent of 5 to 6 units raising the platelet count by around 30,000 to 60,000/mm^3. Platelet should be ABO and Rh compatible. Since stored platelets have a very short shelf- life, procuring many units may be a problem as the blood bank may not have that many bags. When requirement of platelet is large SDP is preferred as the risk of blood born pathogenesis is low, as also alloimmunisation. Where aphaeresis unit is not available, obtaining one required a lot of effort and co-ordination. Since the presentation varied interdepartmental assistance was often required. Good co-ordination with blood bank was required for procuring blood and blood products. In addition consultation with intensivist, haematologist, nephrologist, anesthetists and pediatrician was required. Team approach was the secret of success of survival of these patients.

Conclusion

Unlike in the antenatal period, moderate to severe thrombocytopenic patients near term are in a grave situation – one because the diagnoses has still to be made and secondly due to limited time constraints as delivery is imminent. A detailed history & physical examination is necessary in evaluating a patient with thrombocytopenia. Timely administration of platelets and discrete use of SDP especially when massive platelet transfusion is required helps prevent risk of infection and alloimmunisation. A platelet count of above 10,000cells/mm^3 must be maintained even after delivery to prevent spontaneous bleeding. Delivery should be as atraumatic as possible, avoidance of episiotomy to be practiced. Any pregnancy with a low platelet count less than 50,000cells/ml requires to be shifted to a tertiary centre, since etiology is varied and treatment is multidisciplinary.

RESEARCH ARTICLE

Labor Pattern in South Indian Population

Chitra Bhat[1], Seetha Panicker[2]

Abstract

Aim: Labor dystocia is one of the commonest indications of lower segment cesarean section (LSCS). Recent studies have shown a dramatic change in the rate of cervical dilatation and labor progress. There are no large studies to assess labor in this ethnic group and hence this study has been done to find out labor behavior in women with spontaneous labor in South India.

Materials and methods: A retrospective study was done in our teaching hospital. Labor was managed as per protocol and a partogram was maintained. Data were extracted from case-records and analyzed.

Results: Labor progress was much slower than what was thought of. There was wide variability in the duration of labor.

Conclusion: Many women took time up to the 95th percentile and some even crossed three times the median time to deliver.

Clinical significance: Though many women will deliver in the expected time, it is important to know the maximum time or the 95th percentile for each dilatation so that sufficient time can be allowed before labeling a case as prolonged labor.

Keywords: Labor curve, Labor duration, Rate of cervical dilatation, Slowest rate of dilatation.

Journal of South Asian Federation of Obstetrics and Gynaecology (2020): 10.5005/jp-journals-10006-1839

Introduction

Cervical dilatation is one of the key determinants of the progress of labor and may be dependent on many factors. There have been many attempts to define the norms for the progress of labor that have yielded variable results.

This is not an easy task as there are many challenges to accurately measure the duration of labor. The labor norms are also dependent on a woman's ethnicity, age, parity, BMI, use of epidural analgesia, and may vary among population groups. Despite all these difficulties, it is important to arrive at a proper understanding of labor norms and identify the slowest acceptable rates of cervical dilatation.

The rates of cervical dilatation in the active phase of labor largely stem from the data published by Friedman in 1950.[1] The Friedman's labor curve and the active management of labor pioneered by O'Driscoll et al.[2] where the lowest acceptable rate of dilatation is 1 cm/hr has influenced obstetric practice worldwide. WHO partogram[3] is practiced all over the world and the expected rate of dilatation is 1 cm/hr in the active phase. Any shift to the right and if the curve crosses the action line, labor is labeled as prolonged labor or non-progression of labor, and lower segment cesarean section (LSCS) is performed.

Dystocia characterized by a delay in progression of cervical dilatation is one of the most common indications for primary cesarean sections, ACOG Bulletin states it is the leading cause contributing to around 50% of all primary LSCS being performed.[4]

Zhang et al. reassessed Friedman's curves.[5] They studied the electronic records of 62,416 parturients and found the rates of cervical dilatation to be much slower. Data from this study formed the basis of the new guidelines for the active phase of labor. Labor may take even 6 hours to progress from 4–5 cm and more than 3 hours to progress from 5–6 cm. Only after 6 cm was the progress faster.

Due to ethnic differences, it is important to have insight regarding labor in our population that is critical in diagnosing labor dystocia and making a decision regarding the mode of delivery

Aims and Objectives

- To determine the duration of labor and the rates of cervical dilatation in low-risk primigravida and multigravida women with spontaneous onset of labor.
- To determine the slowest acceptable rates of cervical dilatation.
- To create a labor curve for this population.

Materials and Methods

This was a prospective observational study done in a teaching hospital in South India between 2017 and 2018.

The study population included both primigravida and multigravida who were admitted with spontaneous labor.

The inclusion criteria were term gestation, singleton pregnancy, and vertex presentation with spontaneous onset of labor who delivered either normally or by assisted vaginal delivery. The exclusion criteria were induced labor, pre-term labor, mal-presentations, and patients who were delivered by cesarean section.

The institutional protocols for monitoring of labor were followed. Maternal and fetal monitoring was done in the usual way. The progress of labor was assessed by monitoring uterine contractions per 10 minutes for every half an hour, cervical

dilatation, and descent of the head was assessed by vaginal examination every 3–4 hours in the first stage of labor.

The rate of cervical dilatation was plotted on a partogram with time in hours on the x-axis and cervical dilatation on the y-axis.

Ethical clearance was obtained from our institutional human ethical committee.

Statistical Analysis

The data was entered on an Excel spreadsheet and analysis was done using SPSS STATA13.1 software.

The data were analyzed concerning maternal demographic characteristics. The cumulative labor duration from cervical dilatation on admission (i.e., at 1, 2, 3, 4, 6, 7) to reach 10 cm was assessed. Data were extracted according to two parity groups nulliparous and parous women.

With each starting dilatation, the mean rate of dilatation was calculated for primigravida and multigravida. Taking the value of 2SD, the slowest rate of dilatation was also calculated.

A non-regression model was used to plot the labor curve with cervical dilatation against time in hours.

Results

The total number of deliveries during the study period was 4150.

A total of 2558 women were delivered by cesarean section. The number of women with spontaneous onset of labor who delivered vaginally was 1196. A total of 152 patients who had incomplete data and 21 patients who were admitted at more than 8 cm were excluded. So, only 1023 deliveries were analyzed.

Primigravida were 556 in number and multigravida were 467 in number. The age, cervical findings on admission, and mode of delivery are shown in Table 1.

The cumulative time taken for each dilatation starting from 1 to reach 10 cm was analyzed in both primigravida and multigravida.

In our study, the median duration of labor was chosen, as the mean duration may be skewed by a few laborers of very short or long duration. If the labor duration is positively skewed, the mean duration will be longer than the median duration as shown in this study thus at 2 cm the mean duration was 7.7 hours and the median duration was 7 hours.

Table 2 shows the cumulative mean time taken for each dilatation to reach 10 cm in primigravida and multigravida, respectively. It shows that multigravidae took a shorter time to progress to 10 cm when compared to primigravida. Primigravida took a median time of 9 hours to reach 10 cm from 1 cm, whereas it was 8 hours in multiparous women. At 2 cm it was 7 and 6 hours. At 3, 4, 5, 6–10 cm it was 5, 3, 3, and 2 hours in primigravida and 4, 3, 2, and 2 hours in multigravida.

Table 2 also shows the 5th and the 95th percentile, the number of women who crossed the 95th percentile, and the maximum time allowed for labor to continue that resulted in normal vaginal delivery.

At 2 cm though the meantime was 7.7 hour in primigravida, 16 women crossed the 95th percentile and 10 patients had a vaginal delivery after almost three times this mean-ranging from 18–26 hours. In six multiparous women at the same dilatation, labor was prolonged to 16–27 hours and 15 women crossed the 95th percentile.

At 3 cm dilatation, although the mean duration of labor was 5.5 hours, four primigravida women had a vaginal delivery after 19, 17, 16, and 13 hours, respectively. Correspondingly three multigravidas had taken 21, 15, and 13 hours to deliver from 3 cm dilatation for a mean of 4.7 hours.

At 4 cm against a mean of 3.8 hours, five primigravidas had taken between 8 and 11 hours to deliver, and in multigravida for a mean of 2.9 hours four had taken between 6 and 9 hours. At 7 cm a multiparous woman took 6 hours to reach full dilatation.

With each starting dilatation, the mean rate of dilatation was calculated for primis and multis. Taking the value of 2SD, the slowest rate of dilatation was also calculated as shown in Table 3.

The labor curve obtained was hyperbolic and not a sigmoid curve. There was no definite point of acceleration seen (Figs 1 and 2).

Table 1: Demographics

Details	*Primigravida*	*Multigravida*
Number of cases	556	467

Discussion

A total of 1023 patients were analyzed, out of which 556 were primigravida and 467 were multigravida. We found the following in our study:

- In the active phase, the average time taken was more than that described by Friedmann.[6,7] In his study, he has stated that from 2.5 cm to reach 10 cm the average time is 4.6–4.9 hours, and once they reach 4 cm half of them deliver in 2.6 hours. Our corresponding figures were 7.7 hours to reach 10 cm from 2.5 cm and the mean duration at 4 cm was 3.8 hours against 2.6 hours. Peisner and Rosen[8] found that 75% of women at 3 cm, 50% at 4 cm, and 25% at 5 cm do not dilate at the indicated rates associated with active labor.

However, recent studies have shown a longer first stage of labor with slower acceptable rates of dilatation. Zhang et al. derived the average labor curves from 27,170 nulliparous women in the US population with spontaneous onset of labor. The curve had a slower progression of 1.1 cm/hr with no definite inflection point. The slowest acceptable rate was 0.6 cm/hr.

Albers et al.,[9] Albers,[10] and Jones and Larson[11] found that labor progression takes a longer time than the thought of earlier. These investigators have reported that in the active phase of labor from 4 cm to reach 10 cm the time ranges from 6.2–7.7 hours on average. In Albers's study, the time taken was 7.7 hours since there was no use of oxytocin and labor was spontaneous.

- The second derivative was that there was a wide difference in time taken between individuals. When women were admitted at 2 cm, the median time taken to reach 10 cm was 7 hours in primigravida and 6 hours in multigravida. However, 2SD at this dilatation was 4.5 hours extending labor to 11.5 hours. Many women crossed the 95th percentile and also, ten primigravidas delivered normally after a duration that was almost three times the median ranging from 18–26 hours indicating wide variability in the duration of labor are still associated with normal outcomes. The same was seen at all dilatations. Our findings were similar to that quoted by Oladapo et al.[12] as part of WHO BOLD PROJECT (better outcome in labor difficulty) where he says median cumulative duration of labor indicates that nulliparous women admitted at 4, 5, and 6 cm reached 10 cm within an expected time, but their corresponding 95th percentile shows that labor could last up to 14, 11, and 10 hours.
- It was found that the rates of cervical dilatation accelerate as labor progresses and for each dilatation, an acceptable slow rate of progress exists. This is comparable to the study by Zhang et al. who found that the slopes of cervical dilatation progressively steepen with each passing centimeter. In his study, he also found that the median rates of dilatation between 3–4, 4–5, 5–6, 6–7, 7–8, 8–9, and 9–10 cm were 0.4, 0.6, 1.2, 1.7, 2.2, 2.4, and 2.4 cm, respectively. At the 5th percentile that is used to define the slowest normal dilatation rates the rates were 0.1, 0.2, 0.3, 0.5, 0.7, 0.8, and 0.7 cm/hour, respectively.
- Finally, the labor curve that was obtained showed a smooth hyperbolic curve, there was no point of acceleration. A similar labor curve pattern is seen in other studies. Suzuki et al.[13] studied the labor patterns in 2369 low-risk nulliparous Japanese women with spontaneous onset of labor and derived the labor curve for that population. It showed that the curve had a smooth shape with an active phase duration of 5.1 hours with slower progression than that of Friedman's curve. The deceleration phase was not observed and the rate of dilatation started to double from 5–6 cm onwards. A study done in South India by Pitchaimuthu and Bhaskaran[14] showed the same pattern

of slower dilatation, a smooth labor curve, and no point of inflection.

The limitations of this study include interpersonal variations in the assessment of cervical dilatation. The effect of ARM and oxytocin were not analyzed since many patients were subjected to either both or one of them.

Conclusion

In low-risk women, both primigravida and multigravida with spontaneous onset of labor, there is wide variability in the duration of labor with normal maternal and fetal outcomes. Our study showed that in low-risk women admitted in early spontaneous labor, half of them took more than the meantime and a significant number of women took even three times the mean. The rate gradually increased with dilatation and in nulliparous women at 6 cm of dilatation the rate was much higher. It is worthwhile to note that many women despite crossing the 95th percentile delivered normally, hence, revision of the expectations of the rate of cervical dilatation would reduce both unnecessary interventions in labor and cesarean sections for slow or abnormal progress of labor. Labor should be more patient-centered and the same pattern will not fit all.

Acknowledgments

I sincerely thank both of the statisticians Dr. Varun and Dr. Karthikeyan who took great efforts in analyzing the data and deriving the labor curve. I thank all the staff involved to retrieve the case sheets and the junior residents who helped me with data entry.

Efficacy of intermittent iron versus daily iron in antenatal women

Dr. TV Chitra, Dr. Seetha Panicker and Dr. Grace Wesley

DOI: https://doi.org/10.33545/gynae.2020.v4.i4a.614

Abstract
Aim: This study was done to determine if alternate day oral iron as effective as daily oral iron in antenatal women including those with mild anemia.
Methods & Material: A prospective randomised trial was done in 215 antenatal women attending a tertiary centre in South India. Group 1 received 100mg of elemental iron daily and group 2 received 100mgs of elemental iron on alternate days. Haemoglobin was estimated in all the trimesters and change in Haemoglobin from baseline and at 32-34 weeks were estimated. Side effects and neonatal outcomes were analysed. Further analysis were done within groups depending upon the Haemoglobin levels.
Results: There was no difference in Haemoglobin levels between the two groups. The response was better in patients with mild anemia in both groups, however when iron was given daily in mildly anemia women the increase in Haemoglobin was better than alternate iron therapy.
Conclusion: Intermittent iron is as effective as daily iron.

Keywords: Haemoglobin, daily iron, intermittent iron, iron therapy in pregnancy, anemia in pregnancy

Introduction

Anaemia complicating pregnancy is one of the most common medical disorders of pregnancy. The WHO [1] has defined anaemia as a Haemoglobin less than 11gms/dl in the first and third trimester and a Haemoglobin of less than 10.5gms/dl in the second trimester. Any Haemoglobin less than the 5th percentile for a given gestation is defined as anaemia by CDC [2]. Globally about 58.25 million women are found to be anaemic during pregnancy and 95% of them belong to the developing world [3]. In India as per the population based survey in 2016 it was found that about 50% of pregnant women were anaemic [4]. Anaemia is a direct and an indirect cause of maternal mortality and causes around 13% of all maternal deaths and about 20% in South East Asia [5].

As part of a global strategy to prevent anaemia, WHO has recommended that all pregnant women be given 60mgs of elemental iron with 400mgs of folic acid every day prophylactically[6]. However in the event of iron deficiency anaemia, higher doses are prescribed. Oral iron is associated with many undesirable side effects causing poor compliance. An ideal dosing schedule is yet to be found, which patients will not default and yet give the desired results.

There has been lot of research in iron metabolism over the past two decades.

First is the presence of protein Hepcidin which regulates iron absorption [7], second is the mucosal turn over time which is said to occur once in 3 to 5 days. Thus after a given dose, further supplementation with iron until turn overtime is completed might lead to impaired absorption since the cells are already saturated [8]. Excess iron may cause oxidative stress and other side effects [9]. This has changed the thinking that intermittent iron might work as well. Subsequent to this there are many studies which state that iron two or three times per week or even once a week might be all that is required. Most of these studies have been done in pregnant women who had normal haemoglobin levels.

The WHO in a recent guideline has suggested administration of weekly iron of 120mgs with 2.8mgs of folic acid in pregnant women in areas where the prevalence of anaemia is less than 20% [10].

In India, the practise is still to administer daily iron during pregnancy. Being an area where the prevalence of anaemia is high, it would be worthwhile to know the efficiency and advantages of intermittent iron and hence this study was conducted to determine the usefulness of intermittent iron in both mildly anaemic and non anaemic pregnant women.

Materials and Methods

This was a prospective observational study conducted at a teaching hospital in South India. 215 pregnant women attending the antenatal OPD were randomly recruited for this study. 105 pregnant women from Unit 1 were assigned to daily iron and formed group 1 and 110 pregnant women from Unit 2 were given alternate day iron and were assigned as group 2. During the first visit between 10 to 14 weeks investigations like CBC, Peripheral smear and serum ferritin were done. This helped to rule out thalassemia which is not very uncommon in this area. Ferrous tablets containing 100mgs of elemental iron and 500mgs of folic acid was used after completion of 13 weeks and continued till delivery.

Exclusion criteria: Were Haemoglobin less than 9gms in the first trimester, history of haemtological disorders like sickle cell or thalassemia and history of autoimmune disorders.

Inclusion criteria: All patients attending OPD from at least 12 weeks of pregnancy. The patients were asked to take iron at night before food or at least one hour after food. They were asked to report if they had any side effects like vomiting, diarrhoea, heart burn or constipation. Repeat Haemoglobin was done in the second trimester and around 32 to 34 weeks to assess the Haemoglobin status of the individual. If the Haemoglobin fell to less than 8gms they were advised parenteral iron. Haemoglobin was done using Coulter LH 780 Haematology Analyser method. The maternal and fetal outcomes were noted.
Patients who did not have their delivery in our institution and if the Haemoglobin levels were not done in the third trimester, were excluded from the final analysis and two patients who were given parenteral iron were also excluded from final analysis.

Statistical Analysis

The categorical variables were analysed using chi square test and the continuous variables were analysed using test and ANOVA. P value of .005 was taken as significant. Both groups were compared in regard to mean change from baseline Haemoglobin to Haemoglobin at the 2nd and 3rdtrimester.
The groups were further subdivided into three groups based on Haemoglobin levels. Group A had Haemoglobin level between 9 to 11gms, Group B had Haemoglobin levels between 11.1 to 13gms and Group C had Haemoglobin levels more than 13gms and analysis done within the subgroup with regards to the change in Haemoglobin levels in the first and last trimester.

Results

Total of 215 pregnant women were included in this study 105 in the daily group and 110 in the alternate group. A total of 173 women, 80 in group 1 (daily Iron) and 93 in group 2 (alternate day Iron) were analysed and the attrition was mainly due to change of place for delivery, or incomplete data and investigations. Table 1 shows the age distribution in both groups and Table 2 shows the parity.

Table 1: Age

Age Yrs	Daily Regimen	Alternate Iron
<20	1	3
	1.3%	3.2%
21-25	34	31
	42.5%	33.3%
26-30	36	48
	45.0%	51.6%
>30	9	11
	11.3%	11.8%
Total	80	93

Table 2: Parity

	Daily Regimen	Alternate Iron
Primi	53	62
	66.25%	66.66%
Multi	27	31
	33.75%	33.33%
Total	80	93

The distribution of age and parity were similar in both groups. Table 3 shows the mean Haemoglobin levels in all trimesters in both groups which showed that the mean Haemoglobin levels were almost identical in both groups. The levels were higher in the first trimester and third trimester and slightly lower in the second trimester as expected due to haemodilution.

Table 3: Mean Hemoglobin in all trimester

Trimester		Daily regimen (N=80)	Alternate regimen (N=93)
1st trimester	Mean Hb	11.553	11.983
	SD	(1.2447)	(1.1462)
2nd trimester	Mean Hb	11.138	11.271
	SD	(0.9611)	(0.8489)
3rd trimester	Mean Hb	11.3065	11.382
	SD	1.1487	1.1218

The relationship between the Haemoglobin level and the ferritin level is shown in Fig1.

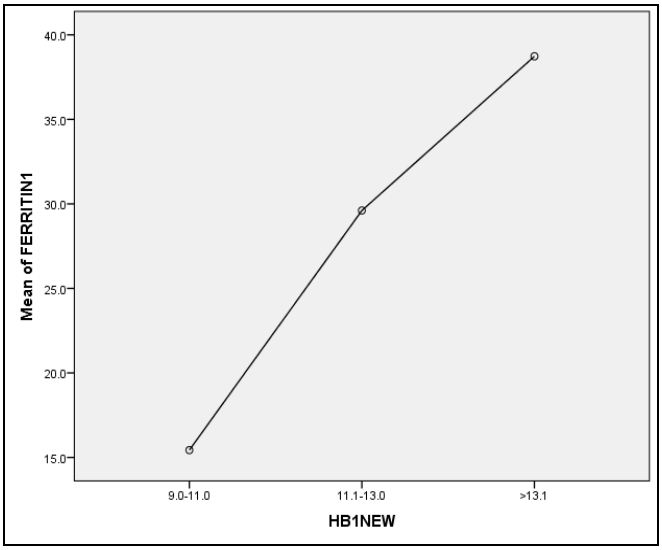

Fig 1: Relationship between the Haemoglobin level and the Ferritin level

38 women had ferritin levels less than 12ngm/dl. 24 in the daily group and 14 in the alternate group had ferritin less than 12 ngm/dl.
Table 4 shows the side effects of oral iron in both groups. Side effects were much lesser in the alternate iron group and so also was the compliance, which was found to be significant statistically with a P value of <001.

Table 4: Side effects

Side effects	Daily regimen (N=80)	Alternate regimen (N=93)
Vomiting	38	5
Constipation	30	8
Diarrhoea	2	1
Metallic taste	5	2
Bloatedness	10	2

Both groups were analysed as subgroups with the Haemoglobin levels in each trimester as shown in Table 5. This table shows that the response and Haemoglobin rise was better in women with mild anemia in both groups and the rise in Haemoglobin was better in the daily group.

Table 5: Analysis of haemoglobin in different sub groups in all trimesters

Hb gm/dl		1st trimester	2nd trimester	3rd trimester
9.0-11.0	Daily regimen N=26	10.085	10.872	11.1960
	Alternate regimen N=22 cases	10.395	10.629	10.9719
11.1-13.0	Daily regimen N=45 cases	11.996	11.107	11.2500
	Alternate regimen N=55 cases	12.169	11.375	11.3611
>13.1	Daily regimen N=9 cases	13.578	12.033	11.9625
	Alternate regimen N=16 cases	13.525	11.756	12.0333
Total	Daily regimen N=80 cases	11.553	11.138	11.3065
	Alternate regimen N=93 cases	11.983	11.271	11.3823

There were no preterm deliveries and the birth weight of babies was similar as shown in Table 6.

Table 6: Birth weight

	Hb	Number	Mean birth weight
Daily regimen (N=80)	9.0 – 11.0	25	3.0548
	11.1 - 13.0	45	2.9983
	>13.1	9	3.2938
	Total	80	3.0487
Alternate regimen (N=93)	9.0 – 11.0	22	3.0514
	11.1 - 13.0	55	2.9898
	>13.1	16	2.9106
	Total	93	2.9908

Discussion

In our study 80 women with a mean Haemoglobin 11.5gms/dl were given daily iron and 93 women with a mean Haemoglobin of 11.93gms/dl were given alternate iron. The third trimester Haemoglobin was 11.30gms/dl in the daily group and 11.38gms/dl in the alternate group showing that in both the treatment groups the Haemoglobin was almost the same.

WHO recommends 30-60mgs of elemental iron for all pregnant women depending on the prevalence of anaemia. This lower dose of 30mgs by WHO supersedes the previous recommendation of 60mgs taking into account the side effects and iron pharmokinetics [11].

The National iron plus initiative of India recommends iron folic acid [IFA] supplementation of 100 mg elemental iron and 500 mgs of folic acid every day for at least 100 days starting after the first trimester at 14–16 weeks of gestation for all non-anemic pregnant women followed by the same dose for 100 days postpartum [12].

Currently intermittent iron supplementation has been accepted for prophylaxis except in antenatal programmes for which debate is still ongoing.

In the past few years many studies have proven the hypothesis that intermittent iron is as effective as daily iron in terms of Haemoglobin change with the added advantage of having less side effects and being cost-effective. In spite of this information the change to intermittent therapy has not yet been implemented, maybe, since the prevalence is so high and further studies are warranted.

Cochrane in 2015 reviewed 21 trials of daily iron versus intermittent iron and stated that while there was no difference between groups for any maternal or fetal outcomes, the intermittent groups had less side effects [13].

Pena-rosa [14] suggested that women receiving intermittent iron had similar maternal and fetal outcomes. Study by Mukhopadhyay [15], Goonewardene [16] and ZInatossadaat [17] in have all suggested that intermittent iron is as effective as daily dosing.

Our study also proved that intermittent iron was as good as daily iron.

The second observation was that in patients who were found to have Haemoglobin between 9 to 11gms/dl, the rise in Haemoglobin was better in these patients with mild anaemia than non-anaemia and a mean increase of 1.1gm/dl was noted in daily group and 0.60gms/dl in the alternate group. The patients in the group with Haemoglobin between 11.1 to 13gms/dl and more than 13gms/dl did not show an increase, but showed a slight fall in Haemoglobin level from baseline.

There were two observations different in our study when compared to many studies. The first observation was that post treatment Haemoglobin did not show an increase from baseline as many studies have shown. However Adaji [18] in his Nigerian study between once and twice daily dosing has shown a fall in baseline Haemoglobin from 11.1gms/dl and 11gms/dl to 10.2gms/dl and 10.5gms/dl respectively in both arms. Similar fall in Haemoglobin has been noted by Okwara [19] who showed a fall from 11.2gms/dl in the first trimester to 10.4 gms/dl in the third trimester. In our study too, in the daily group the fall in Haemoglobin level was 0.2gms/dl and was 0 .6gms/dl in the alternate day group which was not statistically significant.

The second observation was that Haemoglobin improvement was better in women with anaemia in both groups. Although the final Haemoglobin was not very different in both groups, daily iron proved to be slightly better than alternate iron. The maximum oral dose per day is only 160mgs/day. Hence doubling the dose to twice daily is not beneficial, anaemic women would do well by just once daily dosing

Intake of iron is generally associated with untoward side effects like vomiting, constipation, dark stools, diarrhoea and a metallic taste in the tongue. A few rare myths discovered during the study was the belief that babies might be darker or be heavier which lead to women refraining from taking the medications. Side effects were less when given on alternate days, making women more compliant. According to a study by Khalafalloh [20] the side effects of oral iron include gastro intestinal disturbances characterised by colicky pain, vomiting, diarrhoea and constipation which occurred in about 50% of patients. Many patients taking more than 30mgs of iron per day have side effects causing them to discontinue the medication. In our study two women had to be given parenteral iron both belonging to the daily iron group since they experienced severe nausea and vomiting with oral iron.

Slon [21] *et al.*, Shatrugnaan [22] and Beard [23] and Souxa [24] have all corroborated the fact that increasing dose frequency also increases the side effects.

Preterm labour and low birth weight are common when Haemoglobin is less than 9gms or more than 13gms. Haemoglobin above the upper limit can give rise to decreased plasma expansion and is associated with poor pregnancy outcomes. In our study there was no preterm babies and no difference in birth weight in both groups, neither was there any growth restricted babies.

Conclusion

Intermittent dose seems convenient compared with daily dosing. There was no difference in Haemoglobin levels when administered daily or on alternate days. This regime was more cost effective and had less side effects and better compliance. Intermittent iron can also be practised for anaemic pregnant women since the absorption is better, however the improvement is better with daily iron. There is no benefit in increasing the dose to twice or thrice daily since required benefit was seen even with a daily dosing

[illegible]

[illegible]r[illegible]d It is essential to intervene pregnancy for safety of mother, fetus or both. Successful labor induction is clearly related to the state of the cervix. Women with an unfavorable cervix who have not experienced cervical ripening phase before labor present the greatest challenge with regard to labor induction. Therefore, it is necessary to use optimal technique for cervical ripening and safe confinement. One of the common methods includes use of PGE2 gel for cervical ripening. The rationale of this study is to compare the safety and efficacy of Iso-sorbide mononitrate as pre-induction cervical ripening with PGE2 gel induction.

M[illegible]d After attaining ethics approval [PSG IHEC], a prospective randomised, case-controlled study was conducted on 182 women undergoing elective induction of labour. They were allocated to either Study or Control group by computer generated random number table method. ISMN was used vaginally prior to labour induction in the study group whereas PGE2 gel induction was used in the control group. Change in bishop score and Induction to delivery interval was assessed in both the groups.

[illegible]There was a significant reduction in induction to delivery interval in the study group (ISMN) 15.2 hours when compared to 23.2 hours in the control group (PGE2 gel) with p=0.000. Need for augmentation of labour was reduced in the study group significantly with p=0.003. Cost of induction was less when compared to the control group. ISMN had less side effects hence can be used as OP basis.

[illegible]Vaginal Isosorbide mononitrate when used as a cervical ripening agent significantly reduces induction to delivery interval. Use of Isosorbide mononitrate was associated with very less side effects and it is a cost-effective drug. Thus, ISMN can be used safely and effectively in term patients for pre-induction cervical ripening when compared to PGE2 gel.

[illegible]rd Cervi prime gel, safety, Induction delivery interval, Induction of labour, Iso-sorbide mononitrate

[illegible]

Induction of labor is indicated when the risks to either the mother or the fetus of continuing the pregnancy outweigh the benefits. The conditions which commonly necessitate induction of labor include preeclampsia, postdatism, prelabor rupture of membranes, maternal medical disorders, fetal growth restriction and intrauterine fetal demise (Hibbard et al). The success of labor induction largely depends on the `favorability' of cervix.[1] Various methods like insertion of extra amniotic self-retaining catheter, hygroscopic cervical dilators and prostaglandins have been tried in an effort to ripen the cervix prior to induction (Hibbard, Vengalil, Owen).

Prostaglandin E2 or dinoprostone administered intracervically, has been shown to improve bishop score and induction to delivery times in comparison to untreated controls (Owen). However, use of prostaglandins is associated with complications like uterine tachysystole and rupture of uterus and fetal cardiac rhythm abnormalities (Keller, Vaisanen).[2] Besides, more caution is advocated when these agents are used in women with a scarred uterus.[3]

Nitric oxide (NO) has been recently postulated to have a regulatory role in the myometrium and cervix during pregnancy and parturition, and an endogenous NO system is documented in the human cervix.[4] The present study was planned to evaluate the effects of NO donor isosorbide mononitrate (ISMN) on cervical ripening at term, to compare its efficacy and safety with that of dinoprostone gel and to evaluate the maternal and fetal outcome after use of these agents for cervical priming.

M□□□□□□

This prospective study was carried out on 182women with singleton live pregnancy (between 37 to 42 weeks of gestation) and an unfavorable cervix (modified Bishop score of 0-6), posted for induction of labour during the period between June 2014 to May 2015, in the Department of Obstetrics and Gynaecology at PSG, Coimbatore. Women with malpresentations, multiple pregnancy and those with history of epilepsy, hypertension or bronchial asthma were excluded from the study.

After a thorough history, general physical and obstetric examination (including assessment of Bishop Score) all women underwent admission NST to assess the fetal condition. Randomization was done, Women of group I were administered 40 mg ISMN vaginally 2 doses 12 hours apart while those of group II received dinoprostone gel (0.5 mg in 3 gm base) intracervically which was repeated after 6 hours, if the bishop score remained below 6. Bishop score was reassessed after 24 and 6 hours in group I and II respectively. EFM was used in labour.

All women were monitored for pulse rate, blood pressure, fetal heart rate, uterine contractions, any adverse effects and maternal and neonatal outcome.

□□□□□□□

The majority of women (39 in group I and 44 in group II) in the study were in the age group of 20-24 years. A total of 63 (78%) women in group I and 43 (57%) in group II were between 40-42 weeks of gestation, the remaining being at 37 weeks. Indications of induction in the study were postdated fetal growth restriction, decreased fetal movements, oligohydramnios or maternal medical disorders. Table 1 shows the change in bishop score in the study. The change in bishop score after 6 hours of instillation of the ripening agent in both groups was not significant. In group II, 80% (24 out of 30) women with an initial score of 0-3 and 20% (4 out of 20) of those with initial score of 4-5 needed a repeat dose of dinoprostone.

Post score	4.1±1.91	3.6±2.1	0.134
P value	0.08	0.144	

In group I- as ISMN was used as a pre-induction cervical ripening agent, induction of labour was done with PGE2 gel after 2 doses of ISMN. In group II- PGE2 gel not only ripens the cervix but also initiates labour, hence maximum of 3 doses PGE2 gel were instilled 6 hrs apart depending upon the bishop score. Further augmentation of labour was done with misoprostol, ARM and oxytocin as indicated. Induction to delivery interval was calculated from time of first PGE2 gel dose to delivery in both the groups. 24 hours of ISMN was excluded from group I as it was used only as a pre-induction ripening agent.

Mean±SD	15.2±9.08		23.2±9.14	
Inference	The difference between both is statistically significant			

The mean duration of induction to delivery is more with PGE2 gel 23.2 hours and mean duration in ISMN group was 15.2 hrs. In PGE2 gel group 11% had induction delivery interval <12 hrs whereas 39% had less than 12 hours in ISMN group. This was statistically significant. Similarly, duration of labour from 36-48 hrs was 7.7% in PGE2 gel and 3.2% in ISMN group this was not statistically significant. Overall, In ISMN group 86.8% had delivered within 24hrs whereas in PGE2 gel group only 53.3% delivered within 24hrs.

Required	62	67.3	76	87.4
Total	92		90	
Inference	Cases which required acceleration were significantly reduced in ISMN group p=0.003			

None of the patients went into labour after administration of ISMN, as it had no action on myometrium. In PGE2 gel group apart from ripening of cervix patients also had onset of uterine contractions even with a single dose. In group I, requirement of drugs such as misoprostol, PGE2 gel and oxytocin for acceleration is less (67%) when compared to group II (87.4%).32.6% of the patients did not require acceleration of labor in the study group when compared to 15.5% of the patients in PGE2 gel group did not require acceleration. Patients with spontaneous rupture of membranes were augmented with oxytocin and others had ARM and oxytocin.

Mean±SD	285.3±123.9		463.3±256.8	
Inference	There was a significant reduction in cost of induction when ISMN was used as number of PGE2 gel used was less.			

The mean cost of ISMN used is Rs. 12, each ISMN 20mg tablet cost Rs. 3 each PGE2 gel cost Rs. 375. Average cost of induction in PGE2 gel was Rs. 463, and this was reduced by 50% when ISMN was used prior to induction as number of PGE2 gel used was significantly reduced.

[illegible]

NO is a common product of arginine metabolism in many tissues. It appears to be an important paracrine vasodilator and may be involved in cell death and nerve transfer.[5] NO is also released from several vasodilator drug molecules. It is released from important medications such as nitroprusside, nitrates, and nitrites.[6] This substance is a potent vasodilator in all vascular substrates and a powerful relaxant in most smooth muscle cells. Its performance mechanism in this case is activation of guanylyl cyclase and production of cyclic guanosine monophosphate (cGMP) which causes dephosphorylation and disables the light chains of myosin and causes relaxation of smooth muscle. It also has a physiological role in erectile tissue function.[7]

As mentioned earlier, several studies have tried to show the effect of NO on cervical pre-induction ripening.[8,9] Findings of previous studies indicated that delivery length from the onset of intervention in the misoprostol group was shorter and the need for induction in this group was lower.[10,11]

The results were comparable to other studies like Bollapragada et al who concluded that clinical utility of IMN as a pre-induction cervical ripening agent was minimal.[12] Though in their study, IMN had a significant effect on the change in cervical Bishop score (mean difference of 0.65, p=0.013), they could not demonstrate a significant change in their primary outcome measure which was admission to delivery interval (mean difference-1.03 hours, p=0.68).

Bishop score appeared to be an important predictor for induction to delivery interval in the study. Of the women with an initial score of 0-3, only 3.71% (1 patient) from group I and 16.67% (5 patients) from group I delivered vaginally within 12 hours. While 66.67% (18 patients) of women with an initial bishop score of 0-3 delivered between 12-24 hours in group I, only 40% (12 women) did so in group II. Of the women with bishop score of 4-5, 34.78% (8 women) women of group I and 40% (8 women) of group II delivered in the first 12 hours and another 47.83% (11 women) and 30% (6 patients) woman delivered between 12-24 hours in group I and II, respectively. The mean induction to delivery interval was 15.2±9.08 in group I and 23.2±9.14 hours in group II (p=0.00). Oxytocin was required in (38 of group I and 33 of group II) women in the study.

The mean difference in cervical scores at 24 hours was 0.01 with a p = 0.983 and there was no significant change in drug insertion to delivery time. Osmanet al also concluded in their study that isosorbide mononitrate was less effective as a cervical ripening agent, though they used prostaglandins (PGE2) as the comparator. In contrast, Agarwal et al attested to the effectiveness of IMN as cervical ripening agent by showing a significant change in Bishop scores after 2 doses of 40 mg IMN (3.17±2.02; p < 0.001) and a reduction in admission to delivery interval (p < 0.001).[13,14]

There was no case of hyper stimulation in the IMN group in the study done by Habib et al, but a higher incidence of tachysystole (1.96%) was observed in the IMN group.[15] Most of the other studies have reported headache as the most common side effect of IMN, although it was treatable with simple analgesics like paracetamol. Maternal hemodynamics, like blood pressure or pulse rate was also not affected. In a study conducted by Ekerhovd et al, significant changes were recorded in maternal hemodynamics which however did not prove to be of any clinical importance (at 180mins, change in maternal PR, p < 0.01, SBP, p < 0.001, DBP, p < 0.0001).[16]

Fetal distress formed the indication of CS for 8 (out of 36) patients of group II and 7 (out of 27) patients of group I (p<0.05). 4 patients of group I and 6 of group II underwent abdominal delivery for failed induction. Bollapragada et al did not report any differences in the number of women going into labour within the first 24 hrs (9% in IMN; 4% in placebo, p = 0.09).[12] However, in the study conducted by Bullarbo et al more women went into labour within 24 hours in the IMN group than in the placebo group.[16]

Most of the studies such as those conducted by Agarwal et al and Habib et al have shown lower incidence of

caesarean deliveries in IMN group albeit statistically insignificant.[14,15] Though the number of caesarean deliveries were more in IMN group than placebo in present study, it was not statistically significant. Most of these were done for fetal distress following PGE2 and failed induction of labour after 2 doses of PGE2 and maximal doses of oxytocin infusion.

Headache was the most common adverse effect observed in group I 31 women (33%). 9 women of group II had uterine hyperstimulation, in comparison to none from group I. Two women of group I had atonic postpartum hemorrhage (PPH). One woman of group I had cervical tears. NICU admissions and APGAR scores were not significantly different in both the groups. There was a significant reduction in cost of induction when ISMN was used as number of PGE2 gel used was less.

□□□□□□□□□□

Induction of labour is a challenge to all obstetricians. Various drugs were used for labour induction, among which PGE2 gel was most widely accepted. ISMN has been studied as a pre-induction cervical ripening agent in recent times.

Advantage in this group was that cervix became soft and responded well to induction with other drugs. Side effect was only headache which subsided with analgesics. There was no evident change in bishop score following ISMN induction. Whereas induction to delivery interval in this group was significantly reduced. There was no case of hyper stimulation recorded in any of the studies as it does not cause myometrial contractions.

It is a cost-effective method of cervical ripening does not require monitoring during the period of ISMN induction. Hence patients do not require admission. It can be safely used at home.

Hereby authors conclude that ISMN is an effective drug when used as a pre-induction cervical ripening agent.

CASE REPORT

Supraventricular tachycardia in one of the twins: The ethical dilemmas involved in treatment

Vinoth Doraiswamy[1], Lalitha Natarajan[2], Chitra TV Venkatesh[3]

[1]Department of Cardiology, PSG Institute of Medical Sciences and Research, Coimbatore, Tamil Nadu, India, [2]Department of Fetal Medicine, PSG Institute of Medical Sciences and Research, Coimbatore, Tamil Nadu, India, [3]Department of Obstetrics and Gynaecology, PSG Institute of Medical Sciences and Research, Coimbatore, Tamil Nadu, India

ABSTRACT

The pediatric cardiologist now has an important role to play in fetal medicine. They are often called upon to manage fetal cardiac problems such as arrhythmias or perform fetal cardiac interventions such as balloon valvuloplasty or atrial septostomy. In these scenarios, it becomes very important for the pediatric cardiologist to understand the concepts of "fetus as a patient," "viability," etc., and their implications in management. We try to shed light on these principles through our case scenario of managing supraventricular tachycardia in one of the fetuses of a twin pregnancy.

Keywords: Beneficence, fetal arrhythmia, fetus as a patient

INTRODUCTION

Fetal arrhythmias are detected in 2% of unsuspected pregnancies during routine obstetric ultrasound. Majority of them are benign. However, serious arrhythmias such as supraventricular tachycardia (SVT) and atrial flutter are common and can lead to fetal hydrops, premature delivery, and death if not aggressively treated.[1] SVT in one of the fetuses of a multiple gestation is uncommon.[2-4] In the treatment of fetal arrhythmia, there is no consensus on the regimen of drugs, and the protocol varies from institution to institution.[1,5] We describe such an unusual case and the ethical dilemmas involved.

CASE REPORT

A 23-year-old primigravida with 25 weeks' gestation presented to us with a dichorionic-diamniotic twin pregnancy. She conceived by *in vitro* fertilization resulting in a triplet pregnancy. Triplet reduction was done at 16 weeks' gestation. Her obstetric ultrasound showed twin 1 having intermittent atrial ectopics and persistent SVT [Figure 1a and b]. Twin 2 was normal. After obtaining informed consent, the mother was loaded with oral digoxin (1 mg/24 h) followed by 500 μg/day in two divided doses. After 36 h, twin 1 developed pericardial effusion [Figure 1c] and cardiomegaly. In view of impending fetal hydrops, oral sotalol was started at 160 mg/day in two divided doses. It was increased to 240 mg/day in three divided doses due to persistent SVT. Twin 1 reverted to sinus rhythm on day 4 of admission [Figure 1d] and twin 2 was healthy. The patient was discharged on day 7 of admission.

On follow-up after 2 weeks, both twins and mother were healthy, and pericardial effusion resolved in twin 1. Digoxin was stopped and the dosage of sotalol was tapered gradually to 80 mg/day and continued till delivery. She was delivered by elective cesarean section at 36 weeks' gestation, twin 1 and 2 weighing 2.16 kg and 2.1 kg, respectively. At present, they are 3 months of age with no recurrence of arrhythmia.

DISCUSSION

The concept of "fetus as a patient" was mainly the work of McCullough and Chervenak who opposed the word "unborn child." "Unborn child" was used by opponents of abortion to confer independent moral status to the fetus, meaning that parents and practitioners had a moral obligation to protect and promote the interests of the fetuses above everything.[6] The authors, however, emphasized more on the dependent moral status where the fetus could not be seen as a separate entity.[6] Hence, the physician had beneficence-based obligations to the mother and fetus which had to be balanced against autonomy-based obligations to the mother. The fetus, of course, being neurologically immature, there was no question of fetal autonomy.[7,8]

"Beneficence" simply means that clinical benefit should outweigh harm, based on sound evidence-based treatment. It would be common for the physician's recommendations to sometimes go against the mother's autonomy.[7,8]

In our situation, we had three patients and three possible treatment options. They included giving transplacental antiarrhythmics, no treatment, or urgent delivery. Our team opted for therapy. Here, we could justify our beneficence-based obligations to twin 1, but twin 2 and mother were exposed to side effects of the drugs with unknown consequences and harm.

The mother initially opted for no treatment. Her reasoning being, she could at least save twin 2. This resulted in conflict with our recommendations. Due to the scarcity of similar case reports, lack of treatment guidelines,[2-4] and unpredictable side effects, sound evidence-based recommendations were difficult. Based on the limited literature available, our experience, and constant counseling, the mother eventually made an informed decision to treat. If conflict still persisted, would legal methods have to be sought? If the court ruled in our favor, wouldn't the decision be in conflict with the mother's autonomy?

The third option involved urgent delivery. Here lies the importance of the concept of "viability." A fetus is said to be viable if it is of sufficient maturity to survive in the neonatal period and attain independent moral status given the available technological and professional support.[7,8] In high-income countries, this is generally between 24 and 25 weeks.[9] In India, it has been fixed administratively at 28 weeks,[10] but there is a wide interregional variation of technological support available. Hence, the issue of viability becomes

[Downloaded free from http://www.annalspc.com on Monday, August 9, 2021, IP: 103.224.34.2]

many times institution based.[11] If urgent delivery was resorted to, both the twins of questionable viability would be exposed to the problems of extreme prematurity.

The role of pediatric cardiologists is expanding in the field of fetal cardiac interventions (FCIs). The FCI of early years was primarily for pharmacological therapy of arrhythmias, heart block, and heart failure. Then came the era of direct FCI with the advent of valvuloplasty and balloon atrial septostomy.[12] All the above interventions were aimed toward improving fetal cardiac function, survival, and/or achieving a biventricular circulation to improve postnatal outcome. It is difficult to put forth guidelines in the above scenarios due to inability to conduct randomized control trials, uncertainty of the natural history of the disease, risk/benefit ratio of the intervention to both the mother and fetuses, etc. Especially in hypoplastic hearts, many fall in the gray zone between univentricular and biventricular circulations.[12] Decision-making becomes even more difficult when you have a multiple gestation where the fetuses are discordant for the problem, as the nonaffected fetus in addition to the mother becomes an innocent bystander.

The management of such patients should always involve a multidisciplinary team. When it comes to counseling for/against an FCI, the team should understand the concepts of beneficence, autonomy, viability, and their ethical implications. In any event, should there arise a conflict between the mother and healthcare giver, it should be resolved through constant knowledge sharing and counseling, respecting the mother's autonomy and beliefs.

Declaration of patient consent

The authors certify that they have obtained all appropriate patient consent forms. In the form the patient(s) has/have given his/her/their consent for his/her/their images and other clinical information to be reported in the journal. The patients understand that their names and initials will not be published and due efforts will be made to conceal their identity, but anonymity cannot be guaranteed.

□□□□□□□□□

□□□r□d□□□□□□□Selective fetoscopic laser photocoagulation (SFLP) for twin-to-twin transfusion syndrome (TTTS) is challenging for new surgeons at the start of their learning curve. We described an approach utilising telementoring and team-based training to facilitate rapid attainment of the skills required for safe and efficient practice with a limited caseload.□

M□□□□d□□□We conducted a prospective observational study of SFLP performed by the novice primary surgical team in three stages: under direct on-site supervision from an expert mentor (Group 1), with remote tele-guidance from that mentor (Group 2) and independently (Group 3), at an academic tertiary hospital in Singapore. The primary team undertook regular training on high-fidelity tissue models to accelerate skills acquisition and complement the surgical performance. □

□□□□□□□□Nine patients diagnosed with Stage 2 TTTS were assessed for procedural characteristics, surgical outcomes and perinatal survival following SFLP. There were no significant differences in operative duration, anastomoses ablated, gestational age or birth weight at delivery. The complications observed were: recurrent TTTS (22.2% of pregnancies), twin anaemia polycythaemia sequence (33.3%), preterm prelabour membrane rupture (22.2%) and delivery at < 32 weeks (44.4%). At least one twin was live-born in 88.9% of cases, while postnatal survival to six months of at least one twin occurred in 77.8%.

□□□□□□□□□□Systematic mentoring and specialised skills training are useful in aiding new surgeons to negotiate the steep learning curve and achieve good outcomes at the start of a new practice, particularly in the setting of low patient numbers. This is best paired with dedicated model training to achieve and maintain surgical dexterity for this complex procedure.

Keywords: fetoscopic laser photocoagulation, fetoscopy training, learning curve, surgical mentoring, twin-twin transfusion syndrome

□□□□□□□□□□□□□

Monochorionic twinning affects 30% of multiple pregnancies, while twin-to-twin transfusion syndrome (TTTS) occurs in 10%–15% of monochorionic diamniotic (MCDA) pregnancies with an untreated mortality of 70%–100%.[1,2] TTTS results in unilateral blood transfusion from the donor to the recipient twin, mostly via arteriovenous anastomoses (AVAs), causing oligohydramnios from the hypovolaemic and oliguric donor, and polyhydramnios from the hypervolaemic recipient. This can progress eventually to cardiac failure and the eventual death of one or both twins.[2] Of the various treatments offered for TTTS, only selective fetoscopic laser photocoagulation (SFLP) of causative AVAs at the inter-twin vascular equator is potentially curative and permits the rescue of both twins (compared to selective reductive techniques which cause the demise of one twin), and in experienced centres, is associated with 75% survival of both twins.[3,4] Twin anaemia polycythaemia sequence (TAPS), caused by slow blood transfusion through a few small-calibre (< 1 mm) placental AVAs, may complicate SFLP and result in anaemia and polycythaemia of the donor and the recipient twins, respectively.[5] SFLP has been available in Singapore at two tertiary maternity units since 2011 and 2015; both have published perinatal outcomes from their initial experiences that were comparable to international reports.[6,7] Prior to this, patients with affected pregnancies were offered palliative therapies or referral to a regional fetal therapy centre for SFLP, options that both delay the institution of definitive treatment and substantially inflate expenses. The initiation of this advanced fetal therapy service at two Singapore hospitals has ensured that SFLP is accessible to local and foreign affected patients for whom it is the best therapeutic option.

SFLP is a complex procedure that has been associated with a steep learning curve and significant maternal and fetal morbidity.[8-10] As with the majority of complex surgeries, the

acquisition of skills in SFLP usually follows the traditional path of surgical apprenticeship vis-a-vis close observation followed by progressive hands-on performance under direct supervision.[11,12] This classic training model is less time- and cost-efficient for new fetal therapy centres, and may limit patient access to SFLP.[13] We have experienced similar challenges as other low-volume fetal therapy centres in terms of negotiating the long surgical learning curve while achieving procedural aptitude, maintaining competent and safe practice with a limited number of patients (not meeting the suggested minimum of 25 annual procedures)[10] and providing rapid access to SFLP to an underserved population.[7,13] This is a common experience, given that 48% of fetal laser surgery centres, mostly situated in Asia, Australia and South America, perform under 20 procedures annually.[14]

To overcome these limitations, a 'collaborative surgical services' model has been proposed, in which personnel and resources are pooled and shared to improve timely access to surgery and quality care in low-volume centres.[13] New models of surgical training are designed to emulate the benefits of traditional surgical apprenticeship, especially the skills-focused training supervised by a surgeon-mentor, while minimising the cost of specialist surgeons spending time away from their primary clinical practice, including expenditures incurred in temporary relocation and lost manpower. These models utilise teleconferencing advances to bring the expert to the surgical team across geographical barriers, employing the mentoring process in the primary clinical setting to assist the surgical team in adopting new procedures successfully.[15-18] Continued off-site mentoring after the initial training phase, combined with skills practice on high-fidelity models and competence-based assessments, can be an effective strategy to overcome the aforementioned situational limitations and ensure that procedural competence is maintained beyond the period of formal training.[19-22]

We have previously described our team-based approach to implementing SFLP, which relied on model practice and stepwise skills learning with an on-site ('hands-off') proctor for the first three cases performed at our institution.[7] We herein discuss a natural extension of this arrangement to include continued off-site mentoring for the second phase of cases, leading to independent surgery without a stand-by mentor, updating the 'see one, do one, teach one' approach.[23-25] We compared the outcomes and complications of our first nine cases to determine the utility of this collaborative approach as an alternative to the lengthy and costly surgical apprenticeship model.

M□□□□□□□

Patients diagnosed with MCDA twin pregnancies at booking visits were monitored fortnightly from 16 weeks' gestation for TTTS, which was diagnosed and staged using the Quintero criteria (Fig. 1).[1,26-29] All patients were offered combined first trimester screening at 11.0–13.9 weeks or non-invasive prenatal testing according to clinical protocol, followed by early anatomic survey at 18 weeks. Inter-twin discordance in nuchal translucency of > 20%, crown-rump length > 10%, nuchal translucency > 95th centile, or cardiac dysfunction in one twin were taken as early indicators of TTTS based on meta-analyses of MCDA biomarkers.[30,31] Patients with Stage 1 TTTS were monitored at least twice weekly for clinical progression, including cardiac failure in the recipient twin,[29] and were offered SFLP based on the following criteria: (a) at least Stage 2 TTTS; (b) gestational age < 26 weeks; and (c) the absence of perinatally lethal structural or genetic anomalies in either fetus. Patients were extensively counselled regarding the diagnosis, alternative therapeutic options and potential complications of SFLP.[3] The multidisciplinary team consisted of fetal therapists, maternal-fetal medicine specialists, obstetric anaesthetists, nurse specialists and

administrative support staff, who had prepared for this clinical service together with workflow drills and training on high-fidelity models.[7,19] Patients were informed upfront about the relative inexperience of the surgical team and the on-site or telepresence of the overseas-based surgeon-mentors for support and supervision. All patients provided written informed consent for the SFLP, video recording, photography and placental dye studies, and agreed to the mentoring arrangement. Preprocedure planning involved placental and vascular equator mapping to determine the point of fetoscope entry.[7,19] Surgery was scheduled as soon as the mentor could travel to our centre; when this was not possible, real-time telementoring was arranged via multiple-user internet teleconferencing applications Skype (Skype Technologies SARL, Palo Alto, CA, USA) and WhatsApp (WhatsApp Inc, Mountain View, CA, USA) over fourth-generation (4G) broadband cellular networks, as the operating room was not equipped for formal videoconferencing. Fetoscopic images were captured directly from the screen and transmitted to the mentor, who was able to follow the entire surgery and advise on the proceedings. Patients diagnosed with TTTS who underwent SFLP were assigned into Groups 1–3 chronologically. The first cases were performed with a mentor on-site (Group 1) and the last cases were performed by the primary surgical team independently (Group 3). Cases 5 and 6 (Group 2) were performed by the team with the mentor observing remotely (i.e. telementoring) to assist with technical difficulties.

All procedures were performed under general anaesthesia in anticipation of a potentially lengthy surgery. Patient position and choice of fetoscope (curved or straight; Karl Storz Endoskope Berlin GmbH, Berlin, Germany) were determined by placental location, and surgical team members performed specific roles, as previously described.[7,19] Selective ablation of all identified AVAs along the vascular equator was achieved using a 400-μm or 600-μm diode laser at 15–30W (Medilas D Multibeam; Dornier MedTech Asia, Singapore), followed by ablation of residual

superficial anastomoses across the vascular equator from one placental margin to the other (Solomon technique), if technically feasible, to minimise the risk of post-SFLP TAPS.[32] Bleeding from ablated AVAs was handled using coagulation of feeder vessels and by applying transabdominal pressure to achieve a tamponade effect. Amnioreduction was performed at the end of the procedure from the recipient twin sac in all cases until the deepest vertical pocket reached ~4 cm. Cervical length and dilatation were assessed using transperineal ultrasonography (US). After the procedure, patients were observed in the ward for 48 hours, followed by repeat US before discharge. All patients were placed on a short course of prophylactic oral antibiotics and tocolytics (nifedipine and indomethacin) to maintain uterine quiescence.

Patients were followed up with weekly US monitoring for resolution of TTTS features such as re-accumulation of donor twin amniotic fluid and improved recipient twin cardiac function. Umbilical artery and middle cerebral artery Doppler studies were performed to assess placental function, developing anaemia and cardiac dysfunction. US surveillance for procedure- and monochorionicity-related complications continued once to twice weekly, particularly for persistent TTTS, TAPS and selective fetal growth restriction. Placental dye injection was performed, as previously described, to assess completeness of laser ablation.[33]

Ethical approval for collection and use of human data was granted by the National Healthcare Group Domain Specific Review Board (reference no. DSRB/2017/01128). Statistical analysis was performed using GraphPad Prism version 6.04 (GraphPad Software Inc, La Jolla, CA, USA). Data was expressed as median and range. Groups were compared using two-way analysis of variance with Tukey correction for multiple comparisons. Statistical significance was set at $p < 0.05$.

□□□□□□□

Between 2015 and 2017, nine pregnancies that were complicated by Stage 2 TTTS were treated with SFLP (Table I). Cases 1–4 were performed under on-site supervision by the surgeon-mentor (Group 1), Cases 5 and 6 were performed under off-site supervision via real-time videoconferencing (Group 2) and Cases 7–9 were performed independently with the expert proctor available by telephone for troubleshooting (Group 3). There were no demographic differences between the groups. The median gestational age (GA) at TTTS diagnosis was 20.1 (range 19.1–20.7) weeks. SFLP was performed at a median GA of 20.7 (19.4–21.6) weeks (Table II). The median diagnosis-to-procedure time was 4.0 (2.0–7.0) days with lower intervals in Group 2 (2.0 [range 1.0–3.0] days) and Group 3 (5.0 [range 1.0–6.0] days) compared to Group 1 (7.0 [range 5.0–12.0] days).

Group 1 had on-site mentoring, Group 2 had remote mentoring, and Group 3 had independently performed surgery. *Data presented in median (range). †Measurement available in only one case. ‡Selective feticide by radiofrequency ablation for cerebellar aplasia in ex-donor twin. AF: amniotic fluid; GA: gestational age; PPROM: preterm prelabour rupture of membranes; SFLP: selective fetoscopic laser photocoagulation; sIUGR: selective intrauterine growth restriction; TAPS: twin anaemia polycythaemia sequence; TTTS: twin-to-twin transfusion syndrome

The mentor's advice on team and equipment organisation (Fig. 2a), fetoscope entry, identification and photocoagulation of individual AVAs at the vascular equator (Fig. 2b) assisted the primary surgical team in completing the surgery and troubleshooting complications (e.g. placental-site bleeding). Residents recorded the locations of AVAs within the recipient twin amniotic sac during the initial fetoscopic end-to-end examination of the vascular equator (Fig. 2c). Detailed evaluation was performed after each surgery with critical feedback on the team's performance and improvements required. When telementoring arrangements were required on challenging cases, real-time images were continuously provided to the remote mentor using a mobile smartphone and 4G Internet connection (Figs. 2d & e). The image quality provided was generally satisfactory for the mentor to confirm the correct anastomoses (if the appearance raised doubts) and to advise a suitable approach for large vessels at risk of rupture. The mentor stayed online throughout the surgery.

The median duration of surgery was 96.5 (67.0–145.5) minutes (Table II). 5–11 AVAs were ablated in each patient. Large vessels were carefully ablated by 'shaving' the girth of the vessels from the periphery inwards and by coagulating the smaller feeder vessels to achieve satisfactory cessation of blood flow.[19] The main complications were brisk bleeding from uterine vessels that were lacerated upon entry; haemostasis was achieved by applying pressure with the fetoscope under direct vision. The Solomon technique was performed under direct supervision in

Cases 3 and 6, and in all cases in Group 3 to minimise the risks of TTTS recurrence and TAPS. It was not performed in Cases 1, 2, 4 or 5 because the primary team decided it would have been too technically demanding. No other adverse outcomes (e.g. placental abruption or hysterectomy) were encountered. Transient donor hydrops was observed in Case 8 within the first week after SFLP and resolved spontaneously.[34]

Cases 5 and 9 had persistent oligohydramnios and absence of the urinary bladder in the donor twin following satisfactory AVA ablation, with eventual re-accumulation of polyhydramnios in the recipient twin, and were classified under recurrent TTTS (incidence 22.2%, Table II). Both cases required amnioreduction from the recipient sac within a week of SFLP, which in Case 5 preceded preterm membrane rupture and emergency Caesarean delivery at 27.1 weeks, approximately 1.9 weeks post SFLP. In Case 9, post-SFLP sonographical surveillance showed rapidly progressing Stage 3 TTTS, with abnormal placental blood flows in the donor fetus and evidence of cardiac strain in the recipient fetus, requiring repeat SFLP. This was performed at another regional fetal centre that was better equipped to perform the complex surgery. Two large central anastomoses that had originally been ablated had recannulated causing recurrence and were successfully re-ablated. The patient was eventually delivered for progressively abnormal placental blood flows. Three cases of TAPS that were diagnosed sonographically (Cases 2, 7 and 8, incidence 33.3%) were managed expectantly.[5]

Selective intrauterine growth restriction (sIUGR) was diagnosed in Cases 2, 4, 5, 7 and 9 based on > 25% intertwin discordance from the estimated fetal weight (range 25.3%–46.8%).[35] Case 2 was complicated by TAPS, while in Case 4, intrauterine demise of the growth-restricted twin occurred at approximately 32 weeks. The incidence of sIUGR was 55.6% (n = 5) out of nine patients. The incidence of preterm prelabour membrane rupture (PPROM) was 22.2%. One sibling

twin (Case 7) was selectively terminated post SFLP upon diagnosis of a serious structural anomaly by radiofrequency ablation.[36] The prenatal loss rate of at least one fetus was 33.3% (n = 3) and the loss rate of both fetuses was 11.1% (n = 1; Table III).

Group 1 had on-site mentoring, Group 2 had remote mentoring, and Group 3 performed surgery independently. *Data presented in median (range). †Stillbirth of ex-donor twin diagnosed just before delivery. ‡Does not include Case 7, in which selective feticide of the ex-donor was performed for inferior vermian agenesis by radiofrequency ablation. §For anaemia of prematurity and twin anaemia-polycythaemia syndrome. EFW: estimated fetal weight; GA: gestational age; ICH: intracranial haemorrhage; NA: not available; US: ultrasonography

There were no significant differences in postnatal outcomes between groups. There were trends towards lower GA at delivery, shorter procedure-to-delivery intervals and lower birth weight in both twins in Group 3 compared to Group 1 (Table III). Survival of at least one twin to birth was 88.9% (n = 8), with double survival in 55.6% (n = 5) of all pregnancies treated. All were born preterm at < 37 weeks, with 44.4% delivered at < 32 weeks. Median ages at delivery were similar: 36.2 (range 27.1–36.9) weeks (Group 1), 32.7 weeks (Group 2, single survivor) and 28.6 (range 27.3–29.4) weeks (Group 3). Median procedure-to-delivery interval was 8.9 (8.9–14.7) weeks with a trend towards shorter intervals in Groups 2 and 3 (Table III).

Placental dye injections were performed in every case in which patients gave consent to identify arteries and veins from donors and recipients. Six placentas were examined after birth for

residual anastomoses (Figs. 3a–d), excluding Case 7 (declined consent), and Cases 6 and 9 (delivered overseas). A partially recannulated AVA between the proximately sited cords was observed in Case 5 (recurrent TTTS, white star in Fig. 3a & b), while the remaining AVAs were successfully coagulated (yellow stars in Figs. 3a & c). The other placentas showed no obvious residual anastomoses (yellow stars in Fig. 3d) and satisfactory Solomon ablation (broken line in Fig. 3d).

Infant survival of at least one twin was observed in 77.8% of pregnancies at both 28 days and six months, and 33.3% of pregnancies had both twins survive at six months (Table III). One twin pair and one ex-recipient died at seven days and 49 days respectively from prematurity-related respiratory distress syndrome. Neonatal complications included spastic cerebral palsy (7.7%, one out of 13 infants) and benign intraventricular changes (66.7%) in six infants who had normal neurological outcomes at 8–35 months of age.□

□□□□□□□□□□

This report illustrates the usefulness of a collaborative effort to introduce a new complex surgery while maintaining safety and producing satisfactory outcomes. Prior to establishing SFLP locally, patients with treatable TTTS were referred to regional centres; these arrangements, commonly self-funded, result in delayed treatment and represent an unsustainable solution, particularly when surgery is needed urgently. The conventional apprenticeship model requires resources for surgical training and a minimal case-load (25–75 procedures) to attain proficiency.[8,10] Outcomes reflect individual and institutional learning curves that are influenced by the clinical team working collectively to manage the patient.[37] While achievable in high-volume centres, successful adoption of SFLP is a real challenge in a low-volume clinic servicing a much smaller

population.[13] We thus adapted a collaborative model utilising on-site mentoring and telementoring with model practice to achieve these goals. This review of our initial outcomes in the early part of the learning curve is important to validate the safety and efficacy of this approach.

We worked closely with two regionally based fetal surgeon mentors who were able to travel quickly and teleconference easily across negligible time differences. The primary team acquired basic fetoscopy skills through model training, as no local surgeon had undergone a full fetoscopy apprenticeship.[19] These arrangements proved particularly helpful in the first cases that presented technical challenges (i.e. anterior placentas, large vessels), which were overcome with much greater efficiency under direct supervision of the mentor,[7] and in post SFLP management for recurrent TTTS and TAPS.[19] There were greater procedural delays for Group 1 as travel arrangements had to be made for the overseas mentor, and these first cases predictably took the primary team longer to organise. Duration of surgery was the longest for Group 2, as these cases were complicated by anterior placentae and significant intrauterine bleeding. Placental dye injections enabled reflection and continuous learning from the unsuccessful cases.

Survival rates in our preliminary series are comparable to those in the published literature, including survival rates for pregnancies with at least one live birth (88.9% vs. 70%–88%),[4,14] two survivors (55.6% vs. 35%–74%) and no survivors (11.1% vs. 9.5%–27%),[1,38] respectively. Rates of PPROM, perinatal survival and neonatal death in our cohort were similar to published outcomes.[1,38] Incidences of recurrent TTTS (22.2%) and TAPS (33.3%) were higher than the reported rates of 0%–16% and 2%–13%, respectively.[5,39] This data reflects the primary team's inexperience in identifying and ablating smaller or more peripheral anastomoses, and in dealing with large AVAs, as well as the small patient numbers in this series.

The approach we used illustrates the prerequisites for a mentoring system to work effectively: the primary team operating efficiently as a single unit (performing all cases together to improve operating efficacy) with each member fulfilling specified functions,[7,16,19] immediate feedback from the mentor, and specific skills reinforced by model practice.[19,40] The proximity of regional centres allowed us to coordinate the entire team, including the overseas mentor, within days. The main limitation to the timely growth of a new fetal therapy centre is a caseload that is insufficient to attain and maintain proficiency in the traditional sense.[41] As our centre services a small population with a low birth-rate, it will not easily meet the conventional numeric requirements for institutional competence in uncommon procedures.[42] This solution gives the primary team the confidence to proceed with service provision without compromising patients' rapid access to SFLP within the existing healthcare system, and can be adapted to provide accessible advanced therapies at similar low-volume centres.

While surgical apprenticeship is the accepted practice,[11] it is inadequate in itself to meet the increasing demand for SFLP at low-volume centres.[43,44] Skills acquisition as a surgical team and effective mentor-mentee communication were the critical factors in the success of the collaborative model driven by patient and institutional needs and can be applied to other complex surgical therapies.[13,45] Mentoring beyond the apprenticeship period provides continued benefit,[18,46] resulting in fewer clinical errors, complications and mortality.[47,48] We acknowledge that although this is a promising approach to skills acquisition for new techniques, our numbers are small and hence further studies with larger numbers are required to reinforce our conclusions.

Abstract

Background: To evaluate the placental morphology and perinatal outcome in patients with gestational hyperglycemia on diet and medication.

Methods: Placental examinations performed at the Department of Pathology between August 2016 to August 2018 were retrospectively reviewed. Of the received 140 placentas, 35 of gestational diabetes (GDM) and pre gestational diabetes were identified and segregated into hyperglycemia on diet and on medication. The clinical details, placental findings and perinatal outcome of patients in both the groups (gestational hyperglycemia on diet and medication) were collected and analyzed.

Results: Among the 35 cases, there were 24 cases of mild gestational hyperglycemia controlled with diet and 11 cases of hyperglycemia on medication (oral hypoglycemic drugs ± insulin).

Most of the placentae in both the groups weighed less than tenth centile. The cord abnormalities such as hyper coiling, velamentous /marginal insertion and furcate cord were observed more in women with GDM on diet. There was no significant gross placental lesion in those on medication. Placental histological features most consistently associated with both the groups include, disturbances of villous maturation (DVM), Derangements in uteroplacental / foetoplacental circulation and villous capillary lesions. Small for gestational age and intrauterine foetal death were found in both the groups, but more commonly in patients with hyperglycemia on medication.

Conclusions: Villous maturation defects, uteroplacental / foetoplacental malperfusion are the essential placental changes which can result in adverse perinatal outcomes in women with hyperglycemia irrespective of the diabetic control.

Keywords: Gestational diabetes, Gestational hyperglycemia, Perinatal outcome, Placental malperfusion, Placental pathology

Introduction

India has the second largest diabetic population in the world after China,with 8.7% of the total population in the age group 20-70 years being diabetic.[1] A cross sectional study among 15 states showed an estimated prevalence of 7.3%.[2] Diabetes in pregnancy is a growing health concern among the antenatal mothers in India. A recent meta-analysis shows the pooled estimate for mean prevalence of gestational diabetes to be 10.1% with a rising trend from 0.53% to 27.3%.[3-5]

Gestational diabetes is defined as glucose intolerance with onset or first recognition during pregnancy and is associated with a multitude of maternal and foetal complications.[6] There is a higher incidence of spontaneous miscarriages, congenital malformations, macrosomia, intrauterine death, operative deliveries, birth injuries, neonatal respiratory distress, neonatal hypoglycaemia in diabetic pregnancies and increased incidence of type 2 diabetes in offspring. Maternal complications include a higher incidence of preeclampsia, polyhydramnios, obstructed labour, caesarean sections, postpartum haemorrhage and infections.

Placenta is the organ which serves as a means of communication at the maternal foetal interface, meanwhile acting as a selective barrier between both the circulations. Changes in the glycemic status are known to affect the placenta and the resulting histopathological findings are categorised based on the time of onset of hyperglycemia.[7,8] Earlier onset of altered glycemic profile results in structural alterations whereas later onset causes functional impairment. Common changes observed include villous immaturity, villous fibrinoid necrosis, chorangiosis, and increased angiogenesis.

Hence the placenta may be regarded as a route map guiding us in our understanding of the pathological basis of the foetal complications encountered in diabetic pregnancies.

We sought to determine the placental morphological changes in diabetic pregnancies and to correlate them with neonatal outcome.

M□□□□□□

In this retrospective study, 35 singleton placentas from mothers with altered/abnormal glucose profile were studied. Institutional ethical committee approval was obtained. The study materials were archived from the departments of Pathology, Obstetrics and gynaecology and from medical record department. The study period was between August 2016 to August 2018 (2 years).

Inclusion criteria

- Placentas from patients with the clinical history of gestational diabetes / hyperglycemia on diet and medication irrespective of associated comorbidities

Exclusion criteria

- Unfixed/poorly fixed placental specimen and Placentas with no clinical details will be excluded

Clinical data collected were patient's age, gestational age, obstetric score, co-morbidities and types of glucose intolerance. All the antenatal women were routinely screened for gestational diabetes during 24 to 28 weeks of gestation by the DIPSI OGCT (75 grams glucose load in non-fasting state followed by a 2-hour plasma glucose).[9] Women with 2 hour plasma glucose more than 140mg/dl were categorized as gestational diabetes. They were categorized into 2 groups: Mild gestational hyperglycemia (on diet), diabetes on medication (pregestational /gestational).

Perinatal factors observed were mode of delivery, pregnancy outcome [intrauterine foetal death (IUD), neonatal death], birth weight, Apgar scores and NICU (neonatal intensive care unit) admission. According to the birth weight, the babies are classified as small for gestational age/ foetal growth restriction (SGA/FGR), appropriate for gestational age (AGA) and large for gestational age (LGA).

The placental tissues were fixed in 10% buffered formalin. The gross parameters observed were trimmed disc weight, measurements, cord (color, length, diameter, number of vessels, twists, insertion site, true/false knots), membranes (color, insertion and rupture site), foetal surface, maternal surface and parenchyma (color, sponginess, location & size of any lesion, calcification, etc.).[10]

After taking photographs of the foetal and maternal surfaces, 2 bits were taken each from the membrane roll and umbilical cord. The placental parenchyma was then cut into thin slices with the interval of 1.0cm (bread loaf method). Picture of the parenchyma was taken for all the placentas. 3 bits were taken from the normal looking central parenchyma and few more from the lesional area (if present grossly). Haematoxylin and eosin stained slides were reviewed, and significant changes were noted.

Since it was a descriptive study with limited numbers, statistical analysis for comparison was not attempted.

□□□□□□□

The 35 cases were identified with hyperglycemia in pregnancy. There were 24 cases of mild gestational hyperglycemia controlled with diet and 11 cases of hyperglycemia on medication, which included gestational and pre gestational diabetes.

Mild gestational hyperglycemia on diet (n=24)

Clinical characteristics

The age distribution of the patients whose placentae were examined ranged from 23 to 40 years with the mean age of 30.83 years. The earliest gestational age was 25 weeks and the maximum was 40 weeks. Fourteen patients were primigravida and ten were multigravida. Half of the placentas were from preterm pregnancies and half from term pregnancies. Associated maternal conditions were analysed with few cases showing comorbidities such as oligohydramnios (n=3),hypertension /preeclampsia (n=2),

antiphospholipid antibody (n=2), anemia (n=2), abruption (n=2) and one each of familial hypercholesterolemia, placenta previa, polyhydramnios and hypothyroidism.

Foetal outcome

The birth weights of nine (37.5%) of the neonates were appropriate for gestational age (AGA). Among the remaining, 8 (33%) were small for gestational age (SGA), 3 (12.5%) were large for gestational age (LGA) and 4 (16.6%) of the pregnancies resulted in intrauterine foetal demise (IUFD). Table 1 highlights the perinatal outcome in both the groups.

Placental findings

Weight: Of the 24 studied placentas, 11 weighed less than the 10th centile (11/24). This is in correlation with the growth restriction in 6 foetuses (6/11) and IUD in 1 case (1/11). The remaining small placentas (4/11) were of foetuses with normal weights.

The weights of nine of the placentas(9/24) were in the normal range

Gestational and pre gestational diabetes on medication (n=11)

Clinical characteristics

The age distribution of the patients whose placentae were examined ranged from 25 to 42 years with the mean age of 32.9 years.

The earliest gestational age was 30 weeks and the maximum was 39 weeks. Four patients were primigravida and seven were multigravida. Three of the placentas were from term pregnancies and eight from preterm pregnancies. Associated maternal conditions included were three cases each of gestational hypertension/preeclampsia and hypothyroidism and one each of anemia and immune thrombocytopenic purpura.

Foetal outcome

Five (45%) of the neonates were SGA, 2(18%) were AGA and 1(9%) was LGA. The remaining 3 (27%) were IUFD (Table 1).

Table 1: Perinatal outcome in GDM on medication and GDM on diet

Perinatal outcome	SGA	AGA	LGA	IUFD
GDM on diet (n=24)	8	3	9	4
GDM on medication (n=11)	5	1	2	3

Placental findings

Weight: 7/11 placentas weighed less than 10th centile. Four of them were associated with small foetuses and 2 each were associated with AGA and IUD respectively.

Gross features

Table 2 highlights the gross placental findings including umbilical cord.

Microscopic findings

Table 3 displays the microscopic features of placenta in both the groups.

Apart from the tabulated findings, calcification, perivillous fibrin deposition, increased NRBCs, subchorionic cysts and mild focal villitis were also observed.

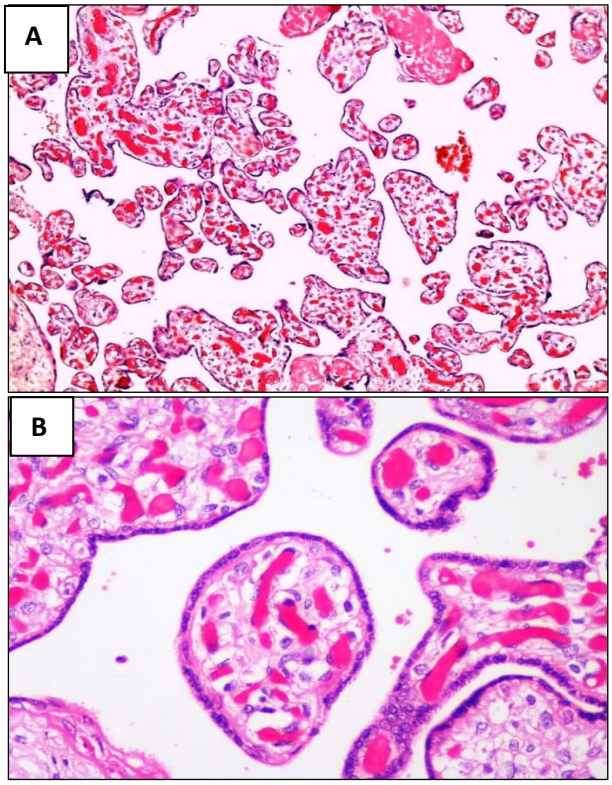

Table 2: Gross placental findings in GDM on medication and GDM on diet

Gross placental findings	GDM on diet (n=24)				GDM on medication (n=11)			
	SGA (n=8)	AGA (n=3)	LGA (n=9)	IUFD (n=4)	SGA (n=5)	AGA (n=1)	LGA (n=2)	IUFD (n=3)

[illegible]

[illegible]

In the present study, we analyzed the placental morphology and clinical outcome in pregnant women with mild hyperglycemia on diet and Gestational and pre-gestational diabetes on medication.

[illegible]

[illegible] 10 [illegible]

There have been studies on placentas of diabetic women which have reported large babies and higher placental weights.[11-15] In contrast to that, we encountered more number of small placentas which belonged to small to normally grown babies and was comparable with Edu et al.[16]

Risk of foetal loss is increased in diabetic pregnancy irrespective of glycemic control.[17] Similarly, incidence of intrauterine death was higher in women in both the groups.

There was no significant increase in gross placental lesions among GDM on medication.[18] The cord abnormalities such as hypercoiling, velamentous/marginal insertion and furcate cord were observed more in women with GDM on diet.[19] Single umbilical artery is generally associated with gestational diabetes, but there were no such instances in our study.

Placental histologic changes

Disturbances of villous maturation (DVM)

DVM also known as distal villous immaturity were found in more than half of the cases in both groups. In contrast to the findings of Huynh et al, we did not find any differences between the two groups.[20]

Generally, in the last trimester of pregnancy, there is accelerated differentiation into terminal villi with increase in vasculosyncytial membrane formation. However, in pregnancies complicated by diabetes, this terminal differentiation is inhibited due to growth factor like activity of foetal insulin. Additionally, this is amplified by coexistent hypercoiling of the cord as seen in our study.[21]

As a result of defective villous maturation, there is reduced placental reserve leading to poor tolerance to acute hypoxia resulting in late intra uterine foetal loss. Since, this entity has a 10% risk of recurrence in subsequent pregnancies, it has been recommended to rescue the foetus by early delivery.[22]

Derangements in uteroplacental circulation/Maternal vascular malperfusion (MVM)

In our study, we observed greater incidence of features of MVM such as, infarcts, intervillous thrombus and increased syncytial knotting in both the groups. As described in literature, decidual vasculopathy was the prominent finding in women with coexistent preeclampsia/APLA as compared to isolated GDM.[23] Retroplacental hematoma with blood dissecting into the intraparenchymal villous space and subsequent haemorrhagic necrosis was also noted in few cases of GDM on diet.

Derangements in foetoplacental circulation/foetal vascular malperfusion (FVM)

FVM frequently goes undetected antenatally and is commonly diagnosed with pathologic examination of placenta. Among the multitude of factors associated with FVM, maternal hyperglycemia plays a significant role.[24]

Pregnancy per se is a thrombogenic state. When it is combined with maternal hyperglycemia (prothrombotic tendency) and hypercoiling of the cord (thereby causing vascular stasis and ischemia), it results in thrombosis in the foetal vascular tree, leading to foetal growth restriction and increased perinatal mortality and morbidity.[25,26]

The following findings were seen as part of FVM in our study population: chorionic plate/ stem villous vessel thrombi, vascular ectasia, groups of avascular, fibrotic to hyalinized villi and villous stromal karyorrhexis.

Villous capillary lesions

A gamut of villous capillary lesions encompassing chorangiosis, chorangiomatosis and chorangiomas believed to be caused by preplacental hypoxia.[27]

GDM in pregnancy is commonly associated with chorangiosis, which is hypothesized to be caused by insulin/IGF-1 receptor mediated angiogenesis.[25]

In our series, we predominantly encountered chorangiosis and an occasional case of microscopic chorangioma, but none of the cases showed chorangiomatosis.

Inflammatory lesions

Acute chorioamnionitis was detected in a few cases of maternal hyperglycemia, of which more than half were complicated by preterm labour /preterm rupture of membranes. Severe maternal inflammatory response and early foetal inflammatory response were noted.[28]

Mild chronic villitis and chronic histiocytic intervillositis (CHIV) were also observed in some cases. Both the lesions have strong association with maternal autoimmune diseases.

Chronic histiocytic intervillositis is an uncommon placental lesion, characterized by a dense lymphohistiocytic infiltrate confined to the intervillous space. CHIV has a tendency for causing recurrent pregnancy loss due to the presence of persistent increase in memory T cells in subsequent pregnancies.[29,30]

Subchorionic pseudocysts, increased cell islands, foetal nucleated red blood cells and vascular ectasia are a known histologic sign of hypoxic lesions and found more in cases of GDM on diet.[31]

The strengths of our study include that all the women were booked at our hospital, the investigations, follow up and delivery was in the same institution and there was no loss to follow up and hence no attrition of data.

The limitations of our study include, smaller sample size and retrospective nature. Not all placentas with GDM were sent for pathological examination. Only those cases with maternal clinical conditions warranting special attention and those with adverse perinatal outcomes were sent for examination.

To summarize, Villous maturation defects, uteroplacental / fetoplacental malperfusion and villous capillary lesions are the essential placental changes which can result in adverse perinatal outcomes in women with hyperglycemia irrespective of the diabetic control.Further prospective studies with large sample size including all GDM placentas with exclusion of confounding factors would help in better characterization of placental lesions in different levels of glycemic control. Understanding the placental pathogenesis will help to develop protocols for prevention and treatment strategies to improve perinatal outcomes.

Abstract

Background: This study was designed to evaluate the institutional Maternal Mortality Ratio (iMMR) in our institution, a tertiary private medical college hospital and to suggest recommendations and possible interventions to reduce it.

Methods: This retrospective descriptive study was conducted by reviewing the hospital records over a period of ten years from January 2009-December 2018. The case records were reviewed for maternal demographic characteristics and complications.

Results: The total number of deaths during the study period was 21, giving an iMMR of 85.268 per 100000 live births. Most of the maternal deaths (>80%) occurred postpartum. Obstetric causes contributed to 57% of the deaths with hypertension and hemorrhage topping the list. Other causes were sepsis and non obstetric causes including one case of maternal suicide. 52.38% of the women died more than 48 hours after admission to the hospital, while 28.57% succumbed in less than six hours. Secondary complications noted were ICU admission, extended intubation, massive transfusion, operative intervention and multi organ dysfunction.

Conclusions: The classical triad of Hypertension, Hemorrhage and Sepsis continues to be the major determinant of maternal mortality and are potentially preventable by promoting universal access to quality health care, strengthening of health services and ensuring accountability.

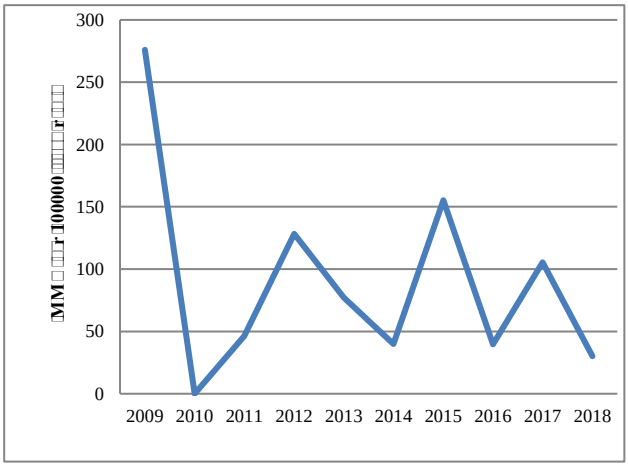
Keywords: Hemorrhage, Hypertension, Maternal mortality, MMR, Multi organ dysfunction, Suicide

INTRODUCTION

In the year 2000, the United Nations adopted the Millennium Development Goals (MDG) out of which MDG 5 was targeted on reducing the Maternal Mortality Ratio (MMR) by three fourths between 1999-2015.[1] By the year 2015, Sustainable Development Goals (SDG) were introduced and SDG 3 aimed at Good Health and Well-Being.[2] Under this, the aim is to bring down the global maternal mortality to below 70 per 100000 by the year 2030.

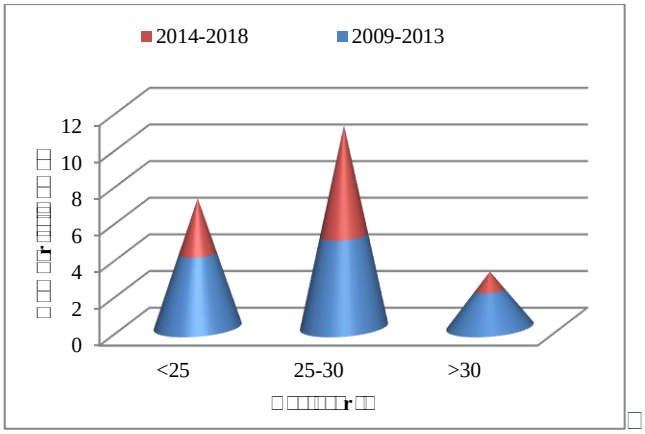
At an MMR of 130 per 100,000 live births in 2016,India is ranked 128 in the world.[3,4] WHO commended India for its groundbreaking progress in reducing maternal mortality by 77% to the present rate.[3] Strategies responsible for this achievement include (i) Increased coverage of maternal health services and promoting institutional deliveries (ii) Incentives and financial support for women delivering in the public health system (iii) Improving literacy among women and increasing the average age at marriage (iv) promotion of public-private partnerships in the care of pregnant women.[3]

To put the country on track to achieve the SDG targets, Government of India established the NITI (National Institution for Transforming India) in the year 2015 to monitor, coordinate and ensure implementation of the SDGs.[2]



This study was designed to evaluate the MMR in our institution, a tertiary private medical college hospital and to suggest recommendations and possible interventions to reduce the institutional Maternal mortality ratio (iMMR). Continued and focussed efforts to end preventable deaths due to pregnancy and childbirth will help our country reach the SDG.

M□□□□□□



This retrospective descriptive study was undertaken in the Department of Obstetrics and Gynecology at the PSG Institute of Medical Sciences and Research, Coimbatore, India during the period from January 2009- December 2018. The approval of the Institutional Human Ethics Committee was obtained. Informed consent was not required since it was a retrospective study and there was no direct patient contact. The case records of all the women who died during pregnancy or within 42 days of delivery due to complications of pregnancy or other causes were reviewed for the following factors: age, obstetric history, antenatal complications and co morbidities, gestational age at onset of symptoms (if any), ICU admission, the need for ventilator support, blood transfusion, multidisciplinary management, cause of death and admission death interval. The number of live births during the study period was obtained from the parturition register. MMR was calculated as number of maternal deaths per 100000 live births.

□□□□□□□

There were a total of 24628 live births in our institution during the study period. Data regarding the socioeconomic status, urban/rural divide were difficult to ascertain from the case records.

The total number of deaths during the study period was 21, giving an iMMR of 85.268 per 100000 live births. The annual trend in iMMR has been pictorially represented in Figure 1. The age of the women ranged from 20-32 years (mean-25.9±3.6 years). The age distribution of the women is graphically represented in Figure 2.

Blood transfusion>5 units	6	3	42.87
Operative intervention	1	2	14.28

Majority of the women died postpartum, except for three. Two of the women who died antenatally were referred to our facility in a moribund state and died within two to three hours of admission despite intensive resuscitative measures. Ten of the women were multiparous and eleven of them were primiparous. Referrals from outside facilities were predominant in the first five years. Obstetric causes dominated the scenario in the first five years (6/11), whereas deaths during the next five years were mainly due to medical disorders (Table 1).

52.38% of the women died more than 48 hours after admission to the hospital, while 28.57% succumbed in less than six hours of admission (Figure 3).

Secondary complications noted were ICU admission, extended intubation, massive transfusion, operative intervention and multi organ dysfunction. Commonest among the above was ICU admission (71%) and the least common was operative intervention (14.28 %) (Table 2).

Maternal mortality is considered an index of the quality of healthcare services in a society. MMR of Tamil Nadu (a state in South India) at 66 per 100,000 live births is low as compared to most of the states in India.[4]

The lower rates are due to a higher proportion of institutional deliveries, effective healthcare delivery system and high quality emergency obstetric care provided by CEmONC (Comprehensive Emergency Obstetric and Newborn Care) centres.

In the present study, the highest mortality rates were in the age group 25-30 years, which is comparable to those of similar studies from South India.[5,6] This may be explained by the fact that the highest proportion of the pregnant population belongs to this age group.71.43% of the women were primiparous as against other studies where multiparous women formed the majority.[7] Both vaginal deliveries and cesarean sections were encountered equally in our series.

A fluctuating trend in iMMR was observed during the study period with peaks during the years 2009, 2012 and 2015. This was a chance observation since the women were referred from maternity units from the surrounding areas and there was a modest but steady increase in the number of deliveries over the years.

Major proportion of the deaths occurred in the postpartum period (80.95%).[6,8] One perimortem caesarean section was done on a patient with peripartum cardiomyopathy (PPCM) who had a cardiac arrest on table.

Two thirds of the women who died were referred from other hospitals.[5] Increased mortality was seen in patients who were referred from other hospitals, due to the bad general condition in which they were received and the time delay. The type of delay could not be assessed in the referral cases as the primary care was given elsewhere.

Obstetric causes of maternal mortality include those resulting from obstetric complications of the pregnant state (pregnancy, labour and puerperium). Non obstetric causes result from pre existing diseases or those that develop during pregnancy and which is not due to direct obstetric cause, but was aggravated by the physiological effects of pregnancy.[9]

Interestingly, 57% of the deaths were due to direct obstetric causes in contrast to those by Sowjanya kumari et al (85%), B. Paul et al (76.7) %, Murthy et al (72.5%) and similar to Khandale SN et al (61%).[6,10-12]

The leading causes of death were hypertensive disorders (23.8%) and haemorrhage (23.8%) comparable to the study by Paily et al. The major cause of death in women with hypertension in our series was hepatic dysfunction (60%).[13]

Severe preeclampsia is associated with high rates of maternal mortality and morbidity. The major contributors to maternal mortality in preeclampsia are eclampsia, HELLP, cerebral haemorrhage, renal dysfunction and coagulopathy. The two pronged approach to management of preeclampsia, i.e., control of hypertension with Labetalol and seizure prophylaxis with Magnesium sulphate has to be adopted to minimise complications.[14] Standard protocols have to be in place for early detection, referral, appropriate treatment and timely delivery.[15]

80% of the women who succumbed to obstetric haemorrhage were referred from other hospitals in a critical condition and died within few hours of admission despite intensive resuscitative measures including obstetric hysterectomy. Atonic postpartum haemorrhage (PPH) was the cause of death in four cases while one patient died due to rupture uterus. Rupture uterus followed a second trimester termination in a woman with two previous cesarean sections with an inappropriate dose of misoprostol.

Active management of third stage of labour (AMTSL) and oxytocin as the first line uterotonic has been advocated as the gold standard in preventing complications due to PPH.[16] In health care settings without facilities like access to blood and blood products and specialist care, early referral will play a pivotal role in preventing mortality. Women at high risk for PPH could be appropriately managed antenatally and delivered in a tertiary centre so that complications arising henceforth could be anticipated and prevented. Staff in the tertiary centres have to be trained in protocols for management of PPH with frequent mock drills.

Since our institution is an urban centre, the prevalence of cases of severe anaemia was less.[13] This could be attributed to early identification of women with anaemia and institution of appropriate treatment. Still anaemia was a contributory factor in five women in our series. Blood transfusion for moderate anaemia close to delivery was the trigger for deterioration of the maternal condition in three instances. Two of the three women were diagnosed with transfusion reaction which led to acute renal failure requiring dialysis.[6,8] The importance of early detection of anaemia, its correction and the need for raising the threshold for transfusion is reiterated by these cases.

Two women in our study had a diagnosis of PPCM (9.52%) as compared to Creanga et al (10-15%).[17] One of them was diagnosed antenatally at 29 weeks and the other followed a normal vaginal delivery.

Four women had hepatic dysfunction and jaundice, out of which three were due to preeclampsia and one was due to viral hepatitis. All patients with hepatic dysfunction were referred from other hospitals due to availability of good intensive care facilities and were directly referred to the gastroenterology unit. The incidence of pulmonary embolism, hepatitis and sepsis in our series were similar to that of Singh et al.[8]

One death in our study was due to suicide. According to the ICD-MM guidelines published by the WHO all antepartum and post partum suicide deaths should be included as direct obstetric deaths even if it is not possible to establish the diagnosis of depression or puerperal psychosis.[18] This is a major deviation in maternal mortality reporting and has the potential to increase the MMR since hitherto unreported deaths will be accounted for henceforth.[13,19]

The commonest complications encountered by these women were prolonged ICU stay and ventilator support. Multidisciplinary care was required in more than 50% of our cases, commonest being the involvement of nephrologist, gastroenterologist and cardiologist. 29% of the women died within six hours of admission, whereas 52% succumbed to complications after 48 hours, the longest being 33 days.[5,7,8,12]

The only operative intervention performed was obstetric hysterectomy which was required in three women-two following failed medical management of atonic PPH and one following rupture uterus. 50% of our patients required multiple transfusions since obstetric haemorrhage was a leading cause of mortality, and coagulopathy due to hepatic dysfunction was also seen in a few cases.

More than 50% of deaths in our study were due to obstetric causes, which are largely preventable. This could be achieved by intensive monitoring with incorporation of early obstetric warning tools.[20] Early warning tools include monitoring of maternal vital parameters such as blood pressure, heart rate, temperature, oxygen saturation, respiratory rate and altered sensorium; and notification to the physician in case of any abnormality.

As with all retrospective studies, our study also has limitations. Our institution being a private medical college in a city with many other well equipped hospitals, we reported a lesser number of maternal deaths. Fewer numbers preclude adequate statistical analysis and hence reduce the power of the study. Higher proportions of cases were referred from far-off areas and hence details regarding the initial management could not be accessed. In addition, autopsy was not performed routinely and therefore, the exact cause of death could not be verified in many of the cases.

□□□□□□□□□□

Though the iMMR has shown a fluctuating trend, it has remained at acceptable levels in comparison to the state and national averages. The classical triad of Hypertension, Haemorrhage and Sepsis remains the major determinant of maternal mortality in our institution and most of them are preventable. By promoting universal health coverage, access to quality health care, strengthening of health services and ensuring accountability, we can strive to reduce deaths due to pregnancy and childbirth.

Abstract

Background: Ectopic pregnancy (EP) is a common, life threatening emergency during the first trimester and a significant cause for maternal morbidity and mortality. In any woman of reproductive age presenting with abdominal pain and vaginal bleeding, ectopic pregnancy should be considered. The objectives of the present study is to determine the incidence, risk factors, clinical presentation, type of ectopic pregnancy, treatment, morbidity and mortality.

Methods: Retrospective analysis of case sheets of patients admitted with ectopic pregnancy at PSGIMSR, Coimbatore during the period July 2011 to June 2016 was done. The details noted were age, parity, risk factors {previous abortion, previous EP, previous pelvic surgery, intrauterine contraceptive device, tubectomy, history of pelvic inflammatory disease}, treatment for infertility, clinical presentation, ultrasound findings, investigations including beta HCG value and hemoglobin level, treatment offered, need for blood transfusion, operative findings and morbidity.

Results: During the five year, there were 12,407 deliveries at our hospitals and 88 cases of ectopic pregnancies were managed. The incidence is 6.6/1000 deliveries. Among them 44% belonged to the age group of 25-30 years and multi gravida were 73.8%. Most common risk factors were previous abortion (23.8%) and previous surgeries including caesarean section, tubectomy, appendicectomy, tubal microsurgery (23.8%). Most common presentation was pain abdomen (85.2%). Out of the 88 cases, 73 patients were managed surgically (82.9%) and 11 cases were managed successfully with methotrexate (12.5%). Three of them underwent conservative management and one had Uterine Artery Embolization.

Conclusions: Early diagnosis based on risk factors and timely intervention plays a main role in reducing morbidity and mortality associated with ectopic pregnancy.

Keywords: Beta HCG, Ectopic pregnancy, Methotrexate, Risk factors, Salphingectomy Transvaginal USG

Introduction

An ectopic pregnancy is implantation of fertilized ovum outside the normal endometrial cavity i.e, fallopian tube, ovary, caesarean scar, cervix and peritoneal cavity.[1] In the first trimester, ectopic pregnancy is the most common cause for maternal morbidity and mortality.[2] It has also been shown that EP reduces future fertility and increases the chance of subsequent EP.[3] The incidence of EP is increasing since the last decade, but the incidence of complications like rupture and morbidity are declining due to early diagnosis with serial Beta-HCG(human chorionic gonadotrophin) monitoring, transvaginal USG(ultrasonogram) and minimally invasive surgery.[4] Early diagnosis not only reduces the risk of tubal rupture but also allows for conservative and medical management.[5] Prior damage to the fallopian tube due to PID(pelvic inflammatory disease), tubal surgeries, pelvic adhesions are the major risk factors for ectopic pregnancy.[6] The other identified risk factors are,

advanced maternal age, previous EP, previous pelvic surgeries, IUCD (intra uterine contraceptive device) insertion and infertility treatment.[7-12] Identifying these risk factors among high risk mothers helps in early diagnosis and reduces the morbidity related to this condition.[13] Unfortunately, most of the patients presenting with EP do not have risk factors.

M□□□□□□

This was a retrospective analysis of case records of patients admitted with ectopic pregnancy, done at PSG IMSR Hospital, Coimbatore from July 2011- June 2016.

Inclusion criteria

We included all the patients with suspected ectopic pregnancy who were confirmed by βHCG and transvaginal ultrasound.

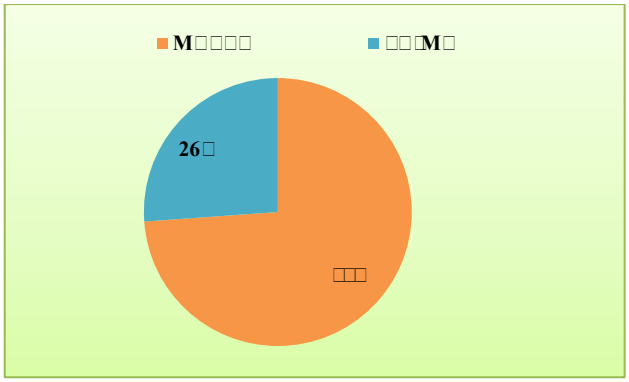
Exclusion criteria

None

Methodology

The case sheets were retrieved from medical record department and the details such as age, parity, risk factors like previous abortion, previous EP, previous pelvic surgery, contraception in the form of IUCD and tubectomy, history of PID, infertility treatment, clinical presentation, investigations including beta HCG value, hemoglobin level, treatment offered, need for blood transfusion, operative findings and morbidity were collected and analyzed.

Statistical analysis



No statistical tool used.

□□□□□□□

During the 5-year period, there were 12,407 deliveries at our institution and 88 cases of ectopic pregnancies were managed. The incidence was 6.6/1000 deliveries. Among the patients most of them belonged to the age group of 25-30 years (Table-1). 26% of patients were primigravida, 73.8% of patients were multigravida (Figure -1).

Twenty-one patients were fit into medical management, among them 12.5% of patients were managed medically with methotrexate successfully.

10 cases failed to medical management which were subsequently managed with either laparoscopic or laparotomy and salphingectomy.

3 cases were managed conservatively by observing the declining trend of Beta-HCG.

Other types of ectopic

Caesarean scar pregnancy was diagnosed in 3 patients, among them 2 patients underwent surgical excision. One patient was managed with UAE (uterine artery embolisation) followed by methotrexate. Heterotopic pregnancy following ovulation induction which resulted in twin intra uterine gestation and tubal ectopic was noted in one patient and she underwent emergency laparotomy and salpingectomy. Two patients were diagnosed as having ovarian ectopic and surgical excision was offered to both of them. Most common morbidity noted was anemia in 42%, out of which severe anemia (4-7gm) was seen in 5.6% (Table 8). Among them 28.4% of patients received blood and blood products. No surgical site infection or mortality was noted.

[illegible]

The incidence of ectopic pregnancy among women attending emergency department with first trimester abdominal pain, bleeding or both is between 6-16 %(14). A study conducted by Shraddha Shetty et al had incidence of 5.6/1000 deliveries.[15] In our study the incidence is 6.6%/1000 deliveries which is comparable. Majority of patients were between 25-30years which is similar to the above study and Khaleeqe et al.[15,16]

As in Karki et al (17), we had similar higher incidence of ectopic pregnancies (73.8%) in multigravida. In our study, the commonest predisposing factors were previous abortion either spontaneous or induced, previous pelvic surgeries including caesarean section, history of IUCD insertion, tubectomy, history of PID and infertility treatment, which are similar to various other studies.[17,18] As in the studies by Porwal Sanjay et al, Shraddha Shetty et al, the most common symptom in our series was pain abdomen which is comparable.[15,18]

Urinary beta HCG, serum beta HCG, transvaginal USG are the diagnostic tools for diagnosing EP. USG should be the investigation of choice for symptomatic women. In asymptomatic women, serial monitoring of serum beta HCG should be done. As in the study by Shraddha Shetty et al, we also had more number of right sided EP and involvement of the ampullary portion of the tube.[15]

Heterotopic pregnancy is rare in natural conception which is around 1 in 30,000 pregnancies. But the incidence is more in case of ovulation induction or with

assisted reproduction techniques. In our study, we had a case of triplet heterotopic pregnancy following ovulation induction with clomiphene citrate. It is recommended that even patients shown on ultrasound to have intrauterine pregnancy should be given comprehensive pelvic ultrasound so that possibility of synchronous heterotopic pregnancy can be excluded, particularly in pregnancies following fertility treatment.[19]

In our study, ruptured EP was noted in 53% of cases, 43.9% of cases had an unruptured ectopic gestation. In Latchaw G et al study, the same were 59% and 41% respectively.[20]

Laparoscopy and medical therapy have now emerged as the widely used therapeutic modalities with great success in terms of reduced morbidity, shorter hospital stay and conservation of fertility.[21] However choice depends upon early identification of ectopic pregnancy and hemodynamic status of the patients.[22] In our study, 11% of patients responded well to single dose of methotrexate.

Surgery should be the treatment of choice in unstable patient.[19] In our study 13.6% were unstable and all of them were managed surgically. Commonest surgery performed was partial/total salpingectomy. We did bilateral total salpingectomy for patients who had undergone tubectomy previously and were not desirous of future childbearing. It has been extensively studied and reported that conservative management does not increase the risk of future ectopic.[15] In our study, three patients were managed conservatively by observing the declining trend of Beta HCG. Morbidity included anemia, blood transfusion and wound infection. In our study, we had 42% of patients with hemoglobin level of less than 10grams. Among them 28.4% of patients received blood and blood products. No surgical site wound infection was noted.

No maternal mortality was noted in our study which is consistent with the study by A Abbas et al.[23] Early identification of the patients with EP by a multipronged approach including high index of suspicion, risk prediction, serum beta HCG and transvaginal ultrasound helps in improving the prognosis as far as morbidity, mortality and future fertility are concerned.[24]

□□□□□□□□□□

Identification of underlying risk factors, early diagnosis with essential investigating modalities like beta-HCG, transvaginal USG, timely intervention with medical or surgical method will definitely reduce morbidity and mortality and improve the future reproductive outcome.

Fetal medicine as a part of early clinical exposure

Lalitha Natarajan, Darshana Srinivasan[1], Dhakchenya C. Sekar[1], Punithavathi Krishnamoorthi[1], Pananghat A. Kumar[2]

Abstract:

CONTEXT: Clinical relevance of basic sciences is not well appreciated by the preclinical students. In an effort to remedy this, Medical Council of India has introduced the program of early clinical exposure. Although broad guidelines are provided, institutions have been bestowed with the responsibility of conducting this important program depending on the available resources and local logistics.

AIMS: The aim of the study is to create an awareness of correlation of fetal medicine with the participants taught during preclinical year, particularly embryology.

SETTINGS AND DESIGN: Preclinical students were posted in the Division of Fetal Medicine in the Department of Obstetrics and Gynecology, as observers. The program enabled the students to appreciate the procedures performed in the clinics and to interact with the consultants and health-care staff during their posting. They interacted with the patients as well.

SUBJECTS AND METHODS: Preclinical students observed the clinical procedures performed in the clinics. Tests were conducted before and after the intervention, and their results were compared to evaluate the effectiveness of the program. Open-ended feedback was also taken to assess the impact of this program on the students.

STATISTICAL ANALYSIS USED: Fisher's exact test was used to evaluate the test scores.

RESULTS: Test scores revealed that this program improved the general awareness about the scope of fetal medicine and its direct relevance to the fetal developmental events; they learn in embryology. Feedback comments reiterated this fact.

CONCLUSIONS: Posting of preclinical students in fetal medicine during ECE program has observed the desired effect of them realizing the clinical significance of subjects; they are learning during their preclinical year of study. It has also impressed upon them the scope of fetal medicine as a subject.

Introduction

Medical Council of India had mandated a program of "Early clinical exposure" (ECE) to be implemented during the preclinical training period of undergraduate training, which has now been endorsed by National Medical Council as well.[1] This program aims at bringing out clinical relevance of preclinical participants and link it to patient care. Implementation of this program was made easy in our institution, since we had initiated a unique program of "Clinical Observership" earlier on 2001 itself, the learning objectives of which matched very much with that of ECE.[2] During the 1st year of the MBBS course, students were posted in selected clinical departments, wherein they had the opportunity of being in the hospital surroundings, observing a few clinical procedures such as blood transfusion, cardiac catheterization, and dialysis. They also had the opportunity of interacting with the patients as well as the clinical consultants. At present, ECE is being held in

two rotations of five clinical departments each. Clinical departments for this important program have been identified, based on their direct clinical relevance and the willingness of the faculty to be part of this program. Section of fetal medicine, within the Department of Obstetrics and Gynecology, was one such department, where students got posted as part of ECE, during the past academic year.

Significance of introducing preclinical students to live clinical scenarios in the hospital environment has been reported from quite a few European countries and also from South Africa, as well.[3-5] There seems to be a paucity of information regarding the conduct and content of ECE from our country. Students of our institution have reported their experience of exposure to ECE in the departments of cardiology, neurology, and nephrology and the clinical simulation laboratory.[6-9] To our knowledge, there has been no report of fetal medicine, as a component of ECE and hence this report.

Subjects and Methods

First-year medical students divided into groups of ten were posted in the Fetal Medicine Unit of the Department of Obstetrics and Gynecology as observers for half a day, as part of the ECE program. This study was approved by the Institutional Human Ethics Committee at our institution (No: 17/335).

Design of the program

The program was designed such that it enabled the students to observe, assimilate all the proceedings in the clinic during their postings, and to interact with the consultants and health-care staff during their posting. Students could interact with the patients as well. A questionnaire related to the core content of the program was administered as a pretest and posttest to assess the impact of the program on the students.

The students got the opportunity to observe ultrasound examinations of antenatal cases during 11–14 weeks of pregnancy, which included nuchal translucency scan and the midtrimester (18–22 weeks) target scans. They were briefed on the normal appearance of each organ system in the first and second trimester, in correlation with the embryology that is being taught to them as part of their 1st year curriculum. In addition to observation of the ultrasound examinations, students had the opportunity to go through one of the following four basic modules, prepared for this program: central nervous system, gastrointestinal system, urogenital system, and the face and limbs. Two short videos on the development of the fetal CNS and the fetal circulation were added to integrate the knowledge of embryology into the program. The modules contained the normal appearance and a few common major anomalies of all the organ systems that are commonly encountered in current practice [Table 1].

Selection of the video graphs and modules depended on the clinical case, available for the program on that particular day. Anomalies, if any, encountered in the patient were discussed with reference to the underlying fetal pathology.

Results

Program evaluation

The program was evaluated quantitatively based on the pre and posttest scores. The test covered questions to assess their awareness of events during normal development, particularly of cardiovascular, pulmonary, and nervous systems and the possible congenital

Table 1: Content of the early clinical exposure course in fetal medicine

System	Topics included
CNS module	Normal appearance of:
	The spine, lateral ventricles, corpus callosum
	Cerebellum and vermis in the first and second trimesters
	These were compared to encephalocele, meningomyelocele/spina bifida, lateral ventriculomegaly, agenesis of corpus callosum
	Arnold Chiari malformation and vermian agenesis
	Dandy-Walker malformation
Gastrointestinal system	Normal appearance of the fetal stomach and bowel in comparison to diaphragmatic hernia, bowel dilatation in intestinal atresia/obstruction
	Physiological bowel herniation of the first trimester was shown as against omphalocele and gastroschisis
Urogenital system	Fetal kidneys and bladder
	Abnormalities such as renal agenesis, hydronephrosis, enlarged echogenic kidneys of infantile polycystic kidneys, cystic dysplastic kidneys, and bladder outlet obstruction as in posterior urethral valve were also brought out in this module
Face and limbs module	Normal appearance of the fetal face in three cardinal planes and the abnormalities encountered in each plane - absent nasal bone, cleft lip and palate, and frontal bossing
	Hands and feet were compared to anomalies such as club foot, syndactyly, polydactyly, and abnormally shaped long bones

CNS=Central nervous system

[Downloaded free from http://www.ijhas.in on Tuesday, November 30, 2021, IP: 103.224.34.2]

anomalies. Qualitative assessment was performed based on their feedback comments.

Test scores

The test scores revealed that the students have improved their comprehension regarding the content of the program. Fisher's exact tests on the test scores proved that the postactivity responses have registered significant improvement regarding their awareness of fetal anatomy and physiology. The program has helped them to understand the general aspects of fetal medicine and the relevance of embryology to this clinical participant.

Feedback

Students have expressed their appreciation of the content of the modules presented to them. It was, in general, amazing experience for them to have visualized the events during embryonic development in a pregnant lady, who underwent the regular mandatory antenatal checkup. A few of their remarks have been appended to illustrate the students' response [Table 2].

Discussion

ECE as an effective and interesting learning program has been brought out in earlier observations.[6-12] ECE posting in fetal medicine becomes important, since the undergraduate medical student does not have the opportunity of getting exposed to the practice of fetal medicine, as a specialty in spite of their rather long postings in the Department of Obstetrics and Gynecology. The departments, selected for ECE, are the ones where an intern/compulsory rotatory residential intern does not get posted. Feedback analysis of the present batch of students reveals that the program in fetal medicine has provided them the rich opportunity of monitoring fetal growth and intrauterine events. Even though basic details of human development are expected to be learned in their embryology course, during the 1st year of MBBS, they do not have access to witness the intrauterine events in the conventional academic schedule. Embryology remains as a standalone purely theoretical. They tend to memorize the facts, without appreciating the intricacies of amazing embryological events. Exposure of the students to the field of fetal medicine has given them the opportunity to connect the abstract science with clinical medicine and reality. Analyzing their experience in fetal medicine, the observations indicate that they had gained practical insight into the human fetal development and some of its complications. A 1st year medical student finds embryology a tough subject, mainly because the events that happen *in utero* are not easy to imagine and comprehend. It is true that embryological events are depicted with varying clarity in three dimensions, in video graphs and youtube presentations. Yet, very many intricacies are left to the sheer imagination of the students. In the department of fetal medicine, students got to observe the routine ultrasound scans of pregnant ladies and to interact with the clinicians. They visualize position of the fetus during different trimesters and the ultrasound images of the developing organ systems. They also got the first-hand opportunity to appreciate that embryological events happen simultaneously with events interacting with parallel developments. This program has provided them the unique opportunity of getting an overall idea of the general behavior of the fetus in *utero* and eventually to consider the fetus as a patient.

Table 2: Selected comments about the course from the student feedback

The whole idea of early clinical exposure fascinated us, and in the department of fetal medicine, being able to see the ultrasonography appliances understand how the imaging correlates with the embryology we learn in anatomy was a fantastic experience
Fetal medicine and the idea of ultrasounds did not sound very appealing at the first. ECE in fetal medicine made all the difference. It was a very interesting session that made us want to learn more of diagnostic imaging and maternal-fetal health
Made us realize the significance of the intrinsic process of embryological events, which we had found tough to imagine, during our embryology classes. This session made the essential connect of the facts

ECE=Early clinical exposure

Students realized that fetal medicine is a specialty which calls for maternal-fetal interventions, which basically involve two patients – the mother and the fetus, demanding extremely thoughtful and careful approach. They witnessed the routinely conducted anomalies scans and appreciated the significance of identifying congenital anomalies, early during pregnancy.

Fetal medicine makes use of ultrasonography for routine screening procedures. It has been well documented that ultrasonography training equips a student for diagnostic skills. Students had the opportunity of realizing the value of this very important diagnostic modality, right during the preclinical year of their training itself.

Conclusion

Posting in fetal medicine has remarkably helped them to realize the role of ultrasound examination in patient care.[13,14] The experience has enhanced their awareness of contemporary medical practice, which happens to be one of the goals of ECE. New specialties are evolving in the practice of medicine, and this program has helped the students to realize one such specialty, during the very 1st year of their career in medicine itself. This exposure to the specialty could develop an interest in fetal medicine in the young medico's mind, early in his career. ECE provides an avenue to know recent advances and emerging specialties. It does not involve extra resources

[Downloaded free from http://www.ijhas.in on Tuesday, November 30, 2021, IP: 103.224.34.2]

to implement an interesting and beneficial session of ECE in fetal medicine. The routine clinical material coming up in the clinic could provide the core content of such sessions. Our experience of posting the students for ECE in fetal medicine has been very encouraging and enriching, since it has contributed immensely to achieving the goals of successful ECE.

Acknowledgments

Authors wish to thank the faculty members of Obstetrics and Gynecology of our institution, who actively took part in the program to make it a success. We acknowledge the help rendered by Dr. Merlyn Veronica, for her help in the statistical analysis of the test results.

SUMMARY

We report a rare case of hyperreactio luteinalis (HL) which developed in association with triplet pregnancy in a 27-year-old woman who underwent assisted reproductive technology treatment for primary infertility. She had undergone frozen embryo transfer 2 months after ovarian retrieval. She presented in the first trimester with abdominal pain and distension associated with ovarian enlargement and did not respond to conservative management. Fetal reduction was done from triplets to twins which resulted in good symptomatic relief for the patient. Fetal reduction may be an effective approach in such situations when conservative strategies fail in HL.

BACKGROUND

Hyperreactio luteinalis (HL) is a rare condition occurring during pregnancy, associated with multiple theca lutein cysts causing bilateral ovarian enlargement. It is caused by elevated β-human chorionic gonadotropin (β-hCG) levels or an abnormal response to normal levels due to heightened sensitivity of the ovarian tissue to β-hCG receptors.[1] HL is commonly seen in association with gestational trophoblastic disease, multiple pregnancies, fetal hydrops, fertility treatment and isoimmunisation.[1] Generally, HL is benign, typically resolving postpartum and hence managed conservatively. Rarely HL can present as acute abdomen due to ovarian torsion or haemorrhage necessitating intervention.[2]

We describe a rare occurrence of HL following frozen embryo transfer (FET) which required intervention in the form of fetal reduction for symptomatic relief of the patient.

CASE PRESENTATION

A 27-year-old woman presented with primary infertility after 6 years of marriage. She had regular menstrual cycles, normal ovaries and uterus and normal hormonal profile (Follicle stimulating hormone (FSH): 5.4mIU/mL, LH: 4mIU/mL, Anti Mullerian hormone (AMH): 4.3mIU/mL). Her partner had severe oligoasthenozoospermia with sperm count of 2.5 million/mL and a total motility of 15%. Considering the severe male factor, they were advised artificial reproduction with intracytoplasmic sperm injection (ICSI). She reported on the second day of menstrual cycle with normal hormonal levels (E2: 2:5 pg/mL, Luteinising hormone (LH): 1.7mIU/mL; FSH: 5.4mIU/mL) and was started on 150 IU of recombinant FSH and 75 IU of human menopausal gonadotropin for ovarian stimulation. Follicle growth was monitored. She was started on a gonadotropin-releasing hormone antagonist 0.25 mg s.c from the sixth day of stimulation. She was maintained on the same dose of gonadotropins for 9 days as growth rates were normal. On the 10th day, she was triggered with recombinant human chorionic gonadotropin (Ovitrelle) 250 μg given subcutaneously. Estradiol levels on the day of trigger was 4200 pg/mL. Twenty oocytes were retrieved followed by ICSI which was done on 19 mature oocytes. This resulted in fertilisation of 15 embryos which were cryopreserved. Embryo transfer was deferred for fear of ovarian hyperstimulation. Post retrieval, she was monitored for signs of ovarian hyperstimulation and was asked to review after 2 months for FET.

Two months later, she was prepared for FET. Her hormonal assay on the second day of menstrual cycle and pelvic ultrasound was normal. She was started on oral estradiol valerate 2 mg two times a day for 14 days. Endometrial assessment on day 14 showed a triple line endometrium measuring 9 mm. Both ovaries appeared normal with follicles less than 5 mm in size. She was started on intramuscular progesterone 100 mg daily for 3 days followed by embryo transfer. Oral estradiol was maintained at 2 mg two times a day. Three embryos were transferred. After 14 days of transfer, her β-hCG was 2228 mIU/mL. Ultrasound done at 6 weeks of gestation showed triplet pregnancy with cardiac activity in all the three sacs. Both ovaries were normal in size. She was continued on intramuscular progesterone for luteal support. At 8 weeks of gestation, ultrasound showed trichorionic triamniotic pregnancy with normal cardiac activity in all sacs (figure 1A). Both ovaries were enlarged with right ovary measuring 7.4×4×4 cm and left ovary measuring 6.4×4.1×4.8 cm with multiple cysts in both ovaries (figure 1B,C).

INVESTIGATIONS

At 9 weeks, the patient developed nausea and vomiting with abdominal distension and pain. Ultrasound showed normally developing triplet gestation with bilateral enlarged ovaries (right: 15.8 cm × 7.7cm × 12.2 cm; left: 12 cm × 5.8 cm × 7.3 cm) with a 'spoke-wheel' appearance and minimal free fluid in the pelvis and pleural space bilaterally (figure 1D–F). At 10 weeks, her symptoms became worse and she could not sit or walk. She was admitted with a diagnosis of hyperreactio luteinalis. She had mild hypoproteinaemia and hypoalbuminaemia with no haemoconcentration (haemoglobin: 109 g/L; haematocrit: 33.7%). Her β-hCG was 200 000 mIU/mL.

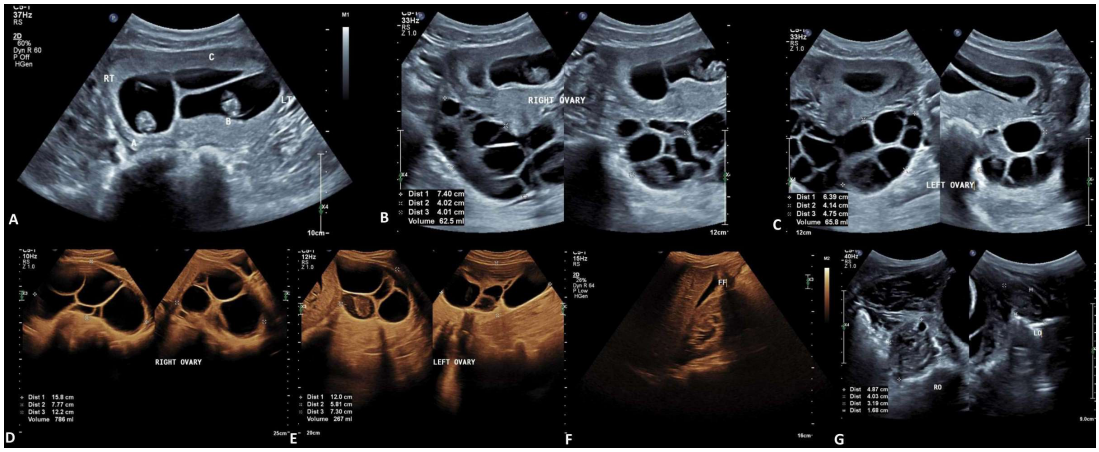

Figure 1 Ultrasound at 8 weeks of gestation showing triplets (A) and enlarged ovaries with multiple cysts (B and C). Ultrasound around 10 weeks showing increased enlargement of ovaries with a 'spoke-wheel' appearance and minimal free fluid in the pelvis (D, E and F). Both ovaries gradually decreased in size and returned back to normal size by 4 weeks of gestation (G).

TREATMENT

She was administered 20% 100 mL albumin every 4 hours and initiated on prophylactic heparin. The patient was offered medical termination of pregnancy or fetal reduction to singleton so as to decrease the β-hCG and give her symptomatic relief. After detailed counselling regarding the procedure, she opted for fetal reduction to twin gestation. Fetal reduction is beneficial in higher order multiples since it provides a reduction in the rates of miscarriages and preterm births. Reduction from triplet to a twin pregnancy in our patient would result in a reduction of pregnancy loss from 15% to 3.5%.[3] All the three fetuses were screened for aneuploidy with Nuchal translucency (NT) and markers such as nasal bone, tricuspid and ductus venosus flow and structural abnormalities were ruled out. The fetus with the highest NT and the one that is farthest from the cervix was chosen for reduction. The procedure was performed at 11 weeks of gestation under local anaesthesia with the transabdominal insertion of a 20 G × 15 cm needle. Under continuous ultrasound guidance, potassium chloride was instilled into the fetal thoracic cavity and the needle withdrawn after cardiac asystole was confirmed.

OUTCOME AND FOLLOW-UP

Post reduction, she improved symptomatically and the β-hCG level dropped to less than a lakh mIU/mL in 3 days. She could sit and walk now and was discharged to home with twin pregnancy. Pregnancy was closely monitored as per protocol for twin gestation. Both ovaries gradually decreased in size and returned back to normal size by 4 weeks of gestation (figure 1G). There were no signs of virilisation. At 34 weeks of gestation, one of the fetuses had abnormal Doppler findings showing low resistance flow at middle cerebral artery with reversal of cerebroplacental ratio. In view of the abnormal Doppler, the patient underwent caesarean section and delivered a healthy baby boy and a baby girl of 2 kg weight each with Apgar scores of 9 at 1 min and 5 min.

DISCUSSION

Our case of HL is unique in many ways. First, there are only two such reported instances in the literature of this condition developing after FET.[4 5] Second, HL in the first trimester is very rare in contrast to its more common occurrence in the third trimester and postpartum. This makes it difficult to differentiate it from spontaneous ovarian hyperstimulation syndrome (OHSS).[6] Third, the deviation from the more commonly advocated strategy of conservative management for HL in our patient. Progressive ovarian enlargement resulted in the patient becoming bedridden at 10 weeks. In such a scenario, conservative approach is not an option and we proceeded with fetal reduction. Ours is only second such instance in the literature of fetal reduction being employed for the management of HL.[7]

The ovarian enlargement occurring in the first trimester of pregnancy following assisted reproductive technology (ART)

Table 1 Outline of differences between hyperreactio luteinalis (HL) and ovarian hyperstimulation syndrome (OHSS)

Characteristics	OHSS	HL
Pathophysiology	1. Defect of the aromatase gene and FSH receptor 2. Abnormal sensitivity to vascular endothelial growth factor	1. Constantly elevated hCG levels 2. Increased β-hCG receptor sensitivity of the ovaries
Common association	Fertility treatment, commonly ovarian stimulation with exogenous gonadotrophins	Nulligravida and multigravida
Relationship to pregnancy	With or without pregnancy	Only with pregnancy
Time of occurrence	First trimester	Late trimesters and post partum
Main clinical feature	Ascites	Ovarian enlargement
Extra ovarian symptoms	Virilisation is rare	Virilisation in 25% of patients
Clinical course	More acute	More indolent
Life-threatening complications	More frequent—includes fluid shifts resulting in hypovolemia and thrombosis	Less frequent—misdiagnosis as ovarian tumour is possible
Pregnancy-related complications	Preterm labour	Pre-eclampsia and fetal growth restriction

hCG, human chorionic gonadotropin.

BMJ Case Rep: first published as 10.1136/bcr-2020-236455 on 2 March 2021. Downloaded from http://casereports.bmj.com/ on December 16, 2021 at PSG Institute of Medical Science and Research. Protected by copyright.

would make one consider OHSS as the closest differential diagnosis. The differences between the two entities are subtle rather than distinct and are detailed in table 1. Since there are many things in common between them including aetiology, clinical features and the predominantly conservative management, they may be considered as entities in continuum.[8] More important is the other differential of HL, which is ovarian malignancy. In a review of 96 cases of HL, malignancy was suspected in 38% of patients with many inadvertently undergoing oopherectomy.[9] The bilaterality of involvement along with morphological regularity suggests more of functional abnormality rather than malignancy. The spoke-wheel appearance suggests theca lutein cysts without solid component. The rapid resolution of ovarian enlargement and free fluid along with reduction in the β-hCG levels following fetal reduction seen in our case suggests HL due to raised β-hCG.

Following ART, HL has been reported both with ovulation induction with gonadotrphins as well as FET.[4 5 10] Cases of HL following fresh cycles of IVF have not been reported. Increased β-hCG receptor sensitivity of the ovarian tissue may be more important than simple raise in β-hCG, since multiple pregnancies following fertility treatment, though common do not seem to predispose the individual to HL. Though majority of cases of HL are managed conservatively, more aggressive approach is suggested when the condition becomes life threatening as happened in our case. Fetal reduction may be one such approach which by decreasing the placental production of β-hCG reduces the ovarian enlargement bringing symptomatic relief to the patient. Also, it is a safe procedure since it neither interferes with the maternal health nor affects the prospects of future fertility.

Learning points

- Hyperreactio luteinalis (HL) is a rare condition in pregnancy associated with bilateral ovarian enlargement caused by elevated β-human chorionic gonadotropin (β-hCG) levels or increased sensitivity of the ovarian tissue to β-hCG receptors and commonly seen in association with gestational trophoblastic disease, multiple pregnancies and following fertility treatment.
- HL can also be seen in association with assisted reproductive technology procedures including frozen embryo transfer.
- Ovarian hyperstimulation syndrome and ovarian malignancies are the important differential diagnoses for HL and conservative strategies are the mainstay of management.
- In selected cases of multiple pregnancies presenting with HL in the first trimester, fetal reduction can bring symptomatic relief by decreasing β-hCG levels.
- The rare self-limiting entity of HL should be remembered while encountering ovarian enlargement in pregnancy so that unnecessary surgical procedures including oopherectomy are avoided.

Background: First trimester bleeding is one of the common complications during pregnancy which affects almost 16-25% of all pregnancies. To evaluate and ascertain the adverse maternal and perinatal outcomes in pregnant women presenting with first trimester vaginal bleeding.

Methods: Prospective case-control study. A case control study involving 60 pregnant women with vaginal bleeding in the first 13 weeks + 6 days of gestational age with 60 matched controls. The study period was from March 2015 to March 2016 and conducted at PSG Institute of Medical Sciences and Research, Coimbatore, Tamil Nadu.

Results: The complications seen in the study group were: first trimester abortion (16.7%), second trimester abortion (6.7%), preterm labour (25%), abruption (6.7%), neonatal intensive care admission (25%), ectopic (6.7%), IUGR (10%), IUD (1.7%) and PROM (8.3%). When compared with the parity matched controls there was statistically significant increase in first and second trimester abortions, preterm labour, abruption, NICU admission and ectopic pregnancy whereas there was no significant difference between the two groups with regard to intrauterine growth restriction (IUGR) and intrauterine death (IUD).

Conclusions: Women with first trimester vaginal bleeding had several adverse outcomes in both the mother and the fetus, and it is very important to explain about the possibility of these outcomes and ensure proper follow up with close antenatal surveillance.

Keywords: Adverse maternal outcome, Adverse fetal outcome, First trimester threatened abortion, First trimester vaginal bleeding, Sub chorionic hematoma, Threatened miscarriage

Introduction

First trimester bleeding is one of the common complications during pregnancy which affects almost 16-25% of all pregnancies.[1,2]

The presumptive symptom of threatened miscarriage is the history of vaginal bleeding in early pregnancy with closed cervix. Meta-analysis indicates that vaginal bleeding increases the risk of pregnancy complications by twofold.[3] Vaginal bleeding may herald the initiation of spontaneous abortion, or it can be a sign of implantation of pregnancy, or it can be a pathological sign indicating gestational trophoblastic disease or ectopic pregnancy.

Vaginal bleeding during early pregnancy needs further evaluation to identify normal or abnormal pregnancy or any pathological condition which requires immediate intervention.[4,5] It is hypothesized that vaginal bleeding in first trimester may be an indication of an underlying placental dysfunction, which may manifest later on with adverse outcomes like first or second trimester abortion,

pre-eclampsia, preterm delivery, premature rupture of membranes, intrauterine growth restrictions and intra uterine death.[6]

This study aims to evaluate maternal and perinatal outcomes in women with first trimester vaginal bleeding.

M□□□□□□

This study was approved by the institutional Human Ethics Committee (IHEC), PSG Institute of Medical Sciences and Research, which has been recognized by the Strategic Initiative for Developing Capacity in Ethical Review (SIDNER). This study was conducted among 120 subjects in PSG Hospitals. Among the 120 patients studied, 60 pregnant women who had first trimester vaginal bleeding were compared with 60 matched controls, over one year from March 2015 to March 2016.

All pregnant women who attended antenatal clinic with first trimester vaginal bleeding (<12 weeks) were included in this study. Women with multiple pregnancies, bad obstetric history, congenital uterine abnormality, known case of any bleeding disorders, chronic medical complications including diabetes and hypertension were excluded from this study. Informed consent was obtained and they were put under surveillance till delivery. Ultrasonography was performed for all these women as routine and serum beta-HCG was done in indicated cases. They were followed up once a month for the first six months, once a fortnight during seventh and eighth month and weekly during the last month of pregnancy. The data collected was analyzed and significant outcomes were reported.

Statistical analysis

Data collected from the patients were initially entered into Microsoft Excel-sheets analyzed using SPSS. Pearson's chi-square was used to compare the association between the first trimester vaginal bleeding and the adverse maternal and fetal outcomes. A predictive value of less than 0.05 was taken as statistically significant.

□□□□□□□

In this study 120 women were included (those who met the inclusion criteria) among which 60 women were in control group and 60 in study group. The study and control group were selected based on the following demographic characteristics. The demographic data in each of these groups are represented in Table 1. There was no statistically significant difference between the two groups with respect to the baseline characteristics as age, height, weight, BMI and parity.

The maternal and perinatal outcomes of the women with first trimester vaginal bleeding were compared among the study and the control groups and represented in Table 2. There was significant difference between two groups in the following primary outcomes such as first and second trimester abortions, pre-term labor, abruption, NICU admission, ectopic pregnancy and nil complications. The results were statistically significant.

□□□□ □ □□□□ □ □

Vaginal bleeding is one of the most common and alarming early pregnancy symptoms. The aim of this study was to evaluate the risk factors associated with first trimester bleeding and the various adverse outcomes. Several studies had reported the association between vaginal bleeding in first trimester and the adverse maternal and perinatal outcomes which include abortion, preterm labor, low birth weight, intra uterine growth restriction. Most of these studies were retrospective.

This study was a randomized, prospective case - control study.

In this study, the amount of blood loss and its effects in pregnancy outcomes was also evaluated as it is important in predicting the risk of miscarriage. In the study group 8 among 10 women who had a first trimester miscarriage had heavy bleeding (quantified by the pictorial charts).

From this study it is clear that more than 80% of the women with first trimester miscarriage had heavy bleeding. Further analysis also suggests that pain associated with this heavy bleeding is also significant.

Whereas women with spotting per vaginum had comparatively good outcome. This result is similar to other studies which also indicate greater risk with heavy bleeding.[7]

This study showed that there was statistically significant difference in the first and second trimester miscarriage between the study and control groups. Many other studies have also documented that the rate of first and second trimester abortions in women with first trimester vaginal bleeding were approximately 20% and 18% respectively.[8-10]

Preterm labor and delivery are one of the most leading cause of neonatal death. This study showed that women with first trimester bleeding have significantly increased risk of having preterm labor in study group (25%) when compared to control group (6.7%) and premature rupture of membranes in study group (8.3%) when compared to control group (5%). This result is similar to the previous studies.[10,11]

A study by Saraswat et al which was a meta-analysis also suggested a higher incidence of preterm labor and premature rupture of membranes, but a similar study done by Strobino et al did not show any significant association between first trimester bleeding and preterm labour.[12,13] Placental abruption occurs in approximately 2% of all the pregnancies and the most common cause is first trimester bleeding. The hematoma that collects in between the chorionic plate and the uterus gradually increases in size and separates the placenta and causes heavy bleeding and eventually leads to abruption.

In this study the abruption rate in the study group was 6.7% whereas there was no abruption in control group. Hence this study suggests that women with threatened miscarriage have a very high risk of abruption hence close monitoring in very essential. The results of this study are similar with the findings of Weiss et al and Ananth et al, which also showed a significant incidence in abruption in women associated with first trimester bleeding, but on the contrary studies done by Wijesiriwardana and Jihn's et al did not show any significance in the relationship between the two.[14-16]

The incidence of IUGR (10%) and IUD (1.7%) in the study group was not statistically different from the control group (3.3% and 0% respectively). A similar outcome was seen in a study done by Amirkahani Z which also had an incidence of 1.7% (IUD) and 12% (IUGR) in women with first trimester vaginal bleeding.[8]

To our surprise some women also had a positive outcome by delivering a live baby without any complications such as preterm labour, placental abnormalities, PROM, IUD, NICU admissions or intra uterine growth restriction.

In this study about 16.7% of women in the study group had a good outcome with none of the above-mentioned complications when compared with the control group where 83.3% women had no complications. This result was statistically significant.

This result suggests that women who had first trimester threatened miscarriage, if given proper antenatal care and by routine ultrasound and regular follow up and specific

management, could deliver a live term baby without any complications.

□□□□□□□□□□

Considering the outcome of this study, women with first trimester vaginal bleeding had several adverse outcomes in both the mother and the fetus, and it is very important to explain about these outcomes and ensure regular close care antenatal surveillance.

Further, intervention by the clinicians has an important role in not only helping the women to continue the pregnancy but also help in reducing the maternal and fetal complications in high risk pregnancies. Hence precise treatment and planning is essential.

Abstract

Background: Adnexal torsion is one of the gynecologic emergency conditions requiring prompt diagnosis and surgical treatment to save the ovarian function. This retrospective study is intended to analyze the clinical manifestations and treatment in a tertiary care center.

Methods: This is a retrospective study Case records during five-year period of February 2012-2017 in PSG Institute of Medical Sciences and research, Coimbatore, India.

Results: Adnexal torsion was seen in all age groups and commonly in reproductive age. It was seen in few pregnant patients also. Lower abdominal pain of acute onset associated with nausea and vomiting was the commonest clinical feature. Ovarian cyst and PCOD were the common risk factors predisposing torsion. Though ultra sound was the common modality used, the diagnosis was done based on strong clinical suspicion with surgical confirmation. The ovaries were preserved in some patients of reproductive age group.

Conclusions: Adnexal torsion is one of the gynecologic emergencies. The symptoms and signs are nonspecific and may not have a confirmatory lab or imaging study. Hence a strong clinical suspicion followed by prompt surgical management in both pregnant and non -pregnant patients of any age group saves the ovary and further complications.

Keywords: Abdominal pain, Ovary, Torsion, Ultrasound

Introduction

Adnexal torsion is one of the gynecological emergencies affecting females of all ages. Ovarian torsion is defined as rotation of ovary or adnexa with the vascular pedicle on its axis resulting in arterial, venous,or lymphatic obstruction.[1]

It often presents as intermittent acute abdominal pain exacerbated by positional shifts.[2] Approximately 70% have symptoms of nausea and vomiting mimicking other surgical causes of pain like acute appendicitis or renal colic. So, the clinical scenario can lead to misdiagnosis.[3]

In addition, the conventional ultrasound may not be conclusive and the diagnosis can become difficult. Delay in diagnosis and treatment leads to necrosis of the affected ovary.

The aim of the study was to analyze the clinical manifestations and management done during the past five years.

Methods

A Retrospective analysis of 47 medical records with surgically confirmed cases of adnexal torsion was done. The clinical parameters taken for analyses taken were age, medical history, clinical manifestations and examination findings. In clinical presentation the type of abdominal pain with associated clinical findings were noted.

Additionally, whether the condition was associated with fever and leukocytosis was also noted. The imaging performed with its findings, operative details and histopathological reports of the specimens were also analyzed.

[illegible]

Clinical findings

The total number of patients with ovarian torsion were 47 in number. The median age of our patients was 22 years (18days-66years). There were 5 (10.6%) patients in premenarchal age group, 41 patients (87.2%) in reproductive age group and 1 (2.1%) in postmenopausal group. Acute onset of pain was the common symptom present in all patients (100%). The abdominal pain was diffuse and nonspecific in 21patients (44.6%), localized to right side in 19 patients (40.4%), and on the left side in 7 patients (14.8%). The next common symptom was nausea and vomiting seen in 37 (78.7%) patients followed by fever in 5 (10.6%) patients. A mass was palpable in 14 (29.7%) and tenderness elicited in 17 (36.17%) of the cases.

There were 3 (6.3 %) patients in early pregnancy with torsion.

Lab investigations revealed leukocytosis in 18 (38.2%) and anemia in 4 (8.5%) cases.

In all cases ultrasound along with Doppler was performed and torsion was reported in 25 patients (53.19%). 11 cases (23.4%) had minimal free fluid in pouch of Douglas. Ovarian cyst was reported in 31 cases (65.9%) in ultrasound. Of that 16 patients (51.6%) had cyst size of 5- 10cms, 11 patients (35.4%) had cyst size of more than 10cm and 4 patients (12.1%) had cyst size of less than 5cms. The contralateral ovary showed features of PCOD in 5 (10.6%) patients.

Operative findings

Of 47 patients with adnexal torsion, right adnexa was involved in 27 (57.4%) cases followed by 20 (42.5%) cases on left side. The risk factors like tubal ligation was noted in 3 (6.3%) cases, previous surgery adhesions in 1 (2.1%) patient.

Isolated fallopian torsion was seen in 3 (6.3%) in patients.

Detorsion with oophoropexy was done in 8 (17%) patients, ovarian cystectomy was done in 20 (42.5%) patients, unilateral salpingectomy in 3 (6.3%) patients, unilateral salphingo oophorectomy in 11 (23.4%) cases and total hysterectomy with bilateral salphingo oophorectomy in 5 (10.6%) patients. The patients with conserved ovaries were found to have normal ovarian function and asymptomatic on follow-up.

[illegible]	[illegible]	[illegible]
Serous cyst adenoma	6	12.77
Serous cyst adenofibroma	1	2.13
Serous cyst adeno carcinoma	1	2.13
Mucinous cyst adenoma	2	4.26
Teratoma	2	4.26
Follicular cyst	1	2.13
Corpus luteal cyst	4	8.51
Paraovarian cyst	5	10.63
Endometriotic cyst	1	2.13
Total specimens with haemorrhagic necrosis	17	36.17

Histopathological examination was done in all excised specimens and results are shown in Table 1. The common finding seen in specimens was hemorrhagic necrosis (36.1%) and the common benign tumor noted was serous cyst adenoma in 6 patients (12.7%).

[illegible]

Adnexal torsion is the reported to be the fifth most common gynecological emergency condition encountered with a prevalence of 2.7%.[4] Though it is fifth most common emergency it poses difficulty to diagnose clinically due to nonspecific presentation. The lower quadrant abdominal pain described in adnexal torsion is of sudden onset usually following exercise or jerky movement. It is described as sharp, stabbing or less frequently crampy.[5] The ultrasound findings of ovarian torsion may change depending on the duration and degree of torsion (Complete or incomplete) and the presence or absence of ovarian mass.[6,7] The other adnexal pathologies like endometriosis, hemorrhagic cysts, ectopic pregnancy, pelvic inflammatory disease form complex adnexal mass and make it difficult to differentiate sonographically.[4,8,9]

All age groups are susceptible to develop adnexal torsion though it is commonly seen in reproductive women.[3,10-12] Majority of our cases in this study also were in younger reproductive age group (Table 2). It commonly occurs in normal ovaries in young children.[13] Torsion was seen in 5 (10.6%) of our cases in premenarchal age group. Our youngest patient was 18 days neonate, prenatally diagnosed to have an ovarian cyst. Oltmann SC et al reports occurrence of 16% in infant population.[14] It was less common in post-menopausal women in this study.

The most common symptom seen in all our cases (100%) was acute onset of abdominal pain. Other studies also reported the increased incidence of acute abdominal pain.[12,15] In respect to site of pain 21 (44.6%) cases had diffuse pelvic pain, 19 (40.4%) cases had pain on right flank and 7 (14.8%) cases on the left flank. The site of pain may not always denote the site of torsion because twisted adnexal masses are often midline, positioned cranial to the uterine fundus of abdominal pain.[1] The next

common symptom in this study was nausea and vomiting seen in 37 (78.7%) cases similar to other studies.[11,14] In this study palpable mass was seen in 14 (29.7%) cases and tenderness was demonstrated only in 17 (36.1%) cases and was similar to another study.[12] Other symptoms like vaginal bleeding and urinary symptoms reported in other studies were not noted in this study.[11,16]

Table 2: Comparison of clinical presentation and management in various studies

Parameters	Present study	Comparison study	Comparison study
Number of patients	47	70	30
Age	18 days-66y	11y-91y	2 months-18 y
Premenarchal age	10.60%	2.90%	
Reproductive age <45yrs	87.20%	82.60%	
Parity	31.90%	50.00%	
Pregnancy	6.30%	2.90%	
Menopause	2.10%	17.00%

Nausea/Vomiting	78.70%	65.70%	56.70%
Fever	10.60%	12.90%	20.00%
leukocytosis	38.20%	44.00%	63.30%
Palpable mass	29.70%	42.90%	
Tenderness	17.00%	25.70%	
USG diagnosed torsion	53.19%	25.70%	63.00%
USG Free fluid POD	23.40%	23.80%	26.70%
Right side	57.40%	55.70%	70.00%
Left side	42.50%	42.90%	30.00%
Size 5-10cm	51.60%	71.40%	
Size > 10cm	35.40%	11.40%	
Serouscystadenoma	12.70%	15.70%	
Mucinouscystadenoma	4.20%	7.10%	3.30%
Teratoma	4.20%	22.80%	16.70%
Hemorrhagic necrosis	36.10%	30.40%	
Conservative surgery	59.50%	54.30%	46.70%
Radical surgery	40.30%	45.70%	53.30%

Adnexal torsion can occur rarely in pregnancy. The incidence reported is 1 in 5000 and occurs more frequently in the first trimester in patients that underwent treatment for infertility with in vitro fertilization or ovarian stimulation.[17] Present study had 2 cases of adnexal torsion in first trimester and one case in second trimester of pregnancy. Similar case series also reports torsion common in first trimester and less common in second and third trimesters.[18] The diagnosis of torsion in pregnancy becomes more challenging and also there is tendency to go for conservative approach. Adnexal torsion requires surgical intervention in pregnancy with preservation of corpus luteum. Organ preservation is important for the continuity of the pregnancy and a study by Oelsener et al reports performing detorsion in all 40 cases of torsion regardless of the macroscopic appearance.[19]

Fever and leukocytosis was seen in 5 (10.6%) and 18 (38.2%) cases respectively. Nurith et al reports incidence of fever in 20% and leukocytosis in 43 % of cases.[15] Fever and leukocytosis occurs due to adnexal mass necrosis. Four patients had anemia, and of that one had 6gm%, 2 cases had 7gm% and one had 8gm% which is similar to another study.[11] Anemia is usually rare in cases with ovarian torsion and may be seen in few patients due to occurrence of hemorrhagic necrosis.

Ultrasound as a modality to diagnose torsion is found to have a senstivity of 63%-95% due to difficulty in interpretation.[1,14,20] Normal adnexal appearance is common in 69% of premenarchal patients.[21] Some studies[9,20] show enlarged ovary with multiple peripheral follicles as sign of torsion with a sensitivity of 64-74%. So, to improve the detection rate further studies have focused on blood flow using doppler.[22] Since there is possibility of arterial flow in cases of partial type or early adnexal torsion it led to further studies to improve detection rate to 88-95% by focusing on twisted pedicle described commonly as whirlpool sign.[1,23] In present study torsion was diagnosed using ultrasound with doppler in 53.19% of our cases. The ultrasound finding showing presence of ovarian cyst in 31 (65.9%) cases suggests that it is the common risk factor in most of our

cases, especially if the size was 5-10cm in 16 (51.6%) followed by size >10cms in 11 cases (35.4%) and size of <5cm in 4 (12.9%) cases. Ovarian cyst as common risk factor was reported by Oltmann SC et al.[24] It was noticed polycystic ovary in 5(10.6%) cases as the next common risk factor. In young women polycystic ovary is reported to be a common risk factor for adnexal torsion.[11]

Regarding the side of torsion our study showed right side was involved in 27(57.4%) cases and on left side in 20 (42.5%) cases. Other studies also similar findings. This could be because of long right ovarian ligament or presence of sigmoid on the left side.[12,14] Isolated tube torsion was seen in three (6.3%) cases. No specific risk factors like hydrosalpinx was seen in our cases.

Previously oophorectomy or salphingo oophorectomy was the preferred procedure fearing the possibility of gangrenous transformation and sepsis. Now recently the studies show preserved ovaries maintains its function on follow up.[25] In present study 8 (17%) cases had undergone detorsion and oopheropexy, 20 (42.5%) had ovarian cystectomy, 3 cases (6.3%) had unilateral salphingectomy, 5 cases (10.6%) had hysterectomy with bilateralsalphingo oophorectomy, and 11(23.4%) cases underwent unilateral salphingo oophorectomy. In total, conservative surgery was done in 59.5% of patients and radical surgery in 40.3% of patients (Table 2). Removal of adnexa was performed in patients having a gangrenous mass and ovarian preservation was done in cases having edematous or bluish black ovaries. On follow up patients with preserved ovaries were comfortable, was asymptomatic and showed evidence of ovarian function.

Histopathology examination (Table 1) showed benign conditions in most specimens and were associated with hemorrhagic necrosis commonly. The common benign tumor was serous cyst adenoma followed by mucinous cyst adenoma and teratoma. One of patients diagnosed as malignancy had torsion following the completion of third cycle of presurgical chemotherapy. But the pain was misdiagnosed as ureteric colic and was treated conservatively before taking up for surgery. There are other case series reporting the rarity of malignant tumour undergoing torsion.[24]

□□□□□□□□□□

Diagnosis of adnexal torsion is a challenge to both clinician and radiologist due to its nonspecific clinical and radiological findings. So, it requires strong clinical suspicion and radiological expertise. Early diagnosis and surgical management saves the ovary, thereby preserving its function.

Abstract

Background: Our goal was to find association between first trimester fasting blood sugar value compared with the second trimester oral glucose tolerance test value (75gm DIPSI criteria) for diagnosis of GDM. To find the efficiency of FBS and BMI as a screening test for GDM.

Material and Method: 270 antenatal patients having antenatal follow up from 1st trimester of pregnancy between June 2014 – May 2015. The study period was 12 months. Their fasting blood glucose levels was measured in first trimester. The patients were followed up during second trimester and 75 grams OGTT was done. Correlation between first trimester FBS, BMI versus second trimester OGTT were done. Screening property of both fasting blood sugar and BMI were calculated and compared using receiver operating characteristic (ROC) curves.

Result: Out of 270 patients, 14 patients developed GDM, 1 patient developed overt diabetes. With threshold of FBS>90 yielded sensitivity of 86%, specificity of 52%. FBS >90mg/dl can be considered as a threshold value for predicting GDM. With a threshold of BMI>24 yielded sensitivity of 60%, specificity of 67.5%, hence BMI >24 is a good predictor of GDM. Receiver operating characteristic curve shows FBS(AUC-0.69) has little more discriminatory power in identifying GDM than BMI(AUC=0.63**)**. P value <0.05 was considered statistically significant.

Conclusion: In conclusion, FBS measurement at first prenatal visit or at first booking will be useful to screen for previously undiagnosed pre-existing diabetes mellites and also help to predict the development of GDM earlier.

Keywords: Gestational, Diabetes mellites, Fasting, Blood, Sugar, BMI

Introduction

GDM is defined as ―glucose intolerance of variable degree with onset or first recognised during pregnancy. GDM has been recently reported to affect approximately 18% of pregnancies. According to World Health Organisation India has the largest number of cases of Diabetes in the world. As estimated 31.7 million people with diabetes in 2000 in India are projected to increase to 79.4 million in 2030.[(1)] Women who are diagnosed with gestational diabetes have an increased chance (35% to 60%) of developing diabetes in the next 1-2 decades and the predicted health care expenses are definitely going to be high.

Many of these women were amenorrhoeic and only about 2% of diabetic patients conceived. The diabetic patients who conceived had an increased risk of morbidity and mortality.

Poor sugar control in mother lead to poor maternal and perinatal outcomes. There is approximately 42.9% chances of perinatal mortality. With proper diagnosis and treatment of GDM, the perinatal and maternal outcome can be increased.

Intrauterine exposure of increased sugar levels has a negative impact on the pregnancy and also lead to glucose intolerance in the offspring latter period of life.

No uniform guidelines for the management of GDM exist on a local, national or global level. Given the high rate of hyperglycaemia in pregnancy, selective testing based on known risk factors has poor sensitivity for detecting GDM, universal rather than risk factor-based testing seem to be more practical. Universal testing is recommended by several organizations including International Association of Diabetes and Pregnancy study Group (IADPSG), Diabetes In Pregnancy Study group India (DIPSI). Asian Indian women are considered to be at the highest risk of GDM and therefore require universal testing.

In India, approximately 27 million births occur annually requiring at least 27 million OGTTs annually; considering a 10% average prevalence of GDM, the number of GDM pregnancies would be around 2.7 million, a huge burden to deal with for any health system. Any recommendation for testing women for hyperglycaemia during pregnancy must, therefore, be pragmatic, feasible, convenient and cost-effective. FBS in first trimester will help in establishing this.

Our aim is to find association between first trimester fasting blood sugar value compared with the second trimester oral glucose tolerance test value (75gm DIPSI criteria) for diagnosis of GDM. To find the efficiency of FBS and BMI as a screening test for GDM.

Early diagnosis and early intervention of diabetes is useful for improving pregnancy outcomes. FBS measurement at first prenatal visit or at the time of first booking will be useful to screen for previously undiagnosed pre-existing diabetes and also help to predict the development of GDM earlier.

Materials and Methods

The study was conducted in the department of Obstetrics and Gynaecology, PSG Hospitals, Coimbatore from June 2014 – May 2015. The study period was 12 months.

Study Design: Prospective Observational Study

Study Population: 270 antenatal patients having antenatal follow up from 1st trimester in the department of Obstetrics & Gynaecology, PSG IMSR & Hospitals, Coimbatore.

Inclusion Criteria: All antenatal patients from first trimester of pregnancy, Singleton pregnancy

Exclusion Criteria: Pre gestational diabetes mellitus

Patient who lost follow up for OGTT testing during 2nd trimester.

Patients with first trimester FBS more than 105mg/dl.

Antenatal patients on long term steroids for medical disorder.

Methodology

The study was initiated after obtaining approval from the ethics committee in PSG IMSR.

The patients selected were according to the inclusion criteria- antenatal patients from first trimester without having pre-existing diabetes mellitus and oral and written consent were obtained.

Patients who had not turned up for OGTT during the second trimester or who were not willing to participate in the study were excluded.

Basic assessment of their risk factors was already done in the first antenatal visit along with detailed family history. Their height and weight was measured. Weight was noted at the time of first visit. BMI was calculated form the first visits data. Gestational age was noted for both the tests during first and second trimester.

About 270 antenatal mothers were selected during their first trimester from Obstetrics & Gynaecology department OPD during June 2014-May 2015 were explained about the study after excluding other women who were not eligible for the study and fasting blood glucose levels were measured and documented. The patients were followed up during the second trimester and a 75 grams OGTT was done and the levels were noted.

All the patients were asked to follow unrestricted carbohydrate diet and not to change the diet pattern and fasting blood glucose was tested during the first trimester with overnight fast of atleast 8 hours.

During second trimester, when the patients entered the hospital for second trimester OGTT irrespective of the last meal given, 75gms oral glucose mixed in 150 ml of water and blood test taken 2 hrs later according to the DIPSI criteria. All the patients were instructed not to have meals after the 75gm glucose ingestion.

If the patient experienced nausea during the drinking procedure a pinch of fresh lime was added. If she had vomited after glucose ingestion then the testing is done at the further time of the day or asked to come on the following day for re-testing and the same procedure is followed. The patient is requested not to have meals in between and venous blood was collected 2 hrs later.

Two ml of venous blood was collected in sterile fluride vial. These samples were centrifuged at 3500 rotation per minute for 10 minutes. Plasma was used for estimation. Blood test should be done within 3 hours of collection using autoanalyser, Cobas Integra 400 plus-Roche diagnostics by glucose hexokinase method using spectrometric assay. It has analytical sensitivity of 0.59mg/dl and test range of upto 720mg/dl.

Test Principle:

Hexokinase catalyses the phosphorylation of glucose by ATP to form glucose 6 phosphate and ADP. To follow the reaction, a second enzyme glucose 6 phosphate dehydrogenase is used to catalyse oxidation of glucose 6 phosphate by NAD+ to form NADH

D Glucose+ ATP $\xrightarrow{HK}$ Glucose 6 phosphate + ADP

D Glucose 6 phosphate + NAD $\xrightarrow{G6PD}$ D-6-Phosphogluconate + NADH + H+

The concentration of NADH formed is directly proportional to glucose concentration. It is determined by increase in absorption at 340nm.

Patients with first trimester fasting blood glucose levels were categorised as <92 mg/dl, 92-105 mg/dl were included, >105 mg/dl were excluded from the study. Patients with FBS <92 mg/dl were subjected to second trimester 75 gms OGTT. Patients with FBS between 92-105 mg/dl were subjected to diabetic diet, FBS and PPBS was done after 2 weeks of diabetic diet and if it was found to be normal, they were subjected to second trimester 75 OGTT DIPSI criteria. If FBS, PPBS after 2 weeks of diabetic diet were high they were not subjected to second trimester OGTT and were excluded from the study. Patients with FBS of >105 mg/dl were excluded from the study.

First trimester FBS value and second trimester 75 gms GTT values were analysed and the results were tabulated. Correlation between first trimester FBS, BMI versus second trimester OGTT were done. Women diagnosed as GDM were managed appropriately.

Screening property of both fasting blood sugar and BMI were calculated and compared using receiver operating characteristic (ROC) curves.

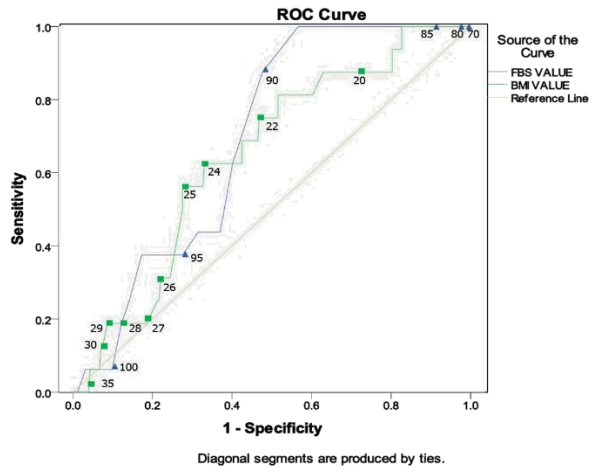
Results and Analysis

Statistical Analysis:

1. First trimester FBS as a screening test for GDM
2. BMI as a screening test for GDM
3. BMI as a comparison for GDM
4. FBS as a comparison for GDM

Table 1: First trimester fasting blood glucose as a screening test for gestational diabetes mellitus (statistical consolidated data)

FBS Level		70	75	80	85	90	95	100
Patients >	Number of case	270	268	257	223	135	67	22
Threshold Value	%	100	99.2	95.1	83	50	24	8.14
Patients with GDM > Threshold Value	Number of case	15	15	15	15	13	5	1
False Positive Rate	%	100	99	91.7	81.6	47.9	24.4	8.3
Sensitivity	%	100	100	100	100	86.6	33.3	6.6
Specificity	%	0	0.78	8.3	18.9	52.1	75.6	91.7
PPV	%	5.5	5.6	5.8	6.7	9.6	7.5	4.5
NNP	%	100	100	100	100	98.5	95	94.4



Patients with FBS>90 had sensitivity of 86.6%, specificity of 52.1%, Positive predictive value of 9.6%, negative predictive value of 98.5%.

Table 2: I Trimester body mass index as a screening test for gestational diabetes mellitus (statistical consolidated data)

BMI		20	22	24	25	26	27	28	29	30	35

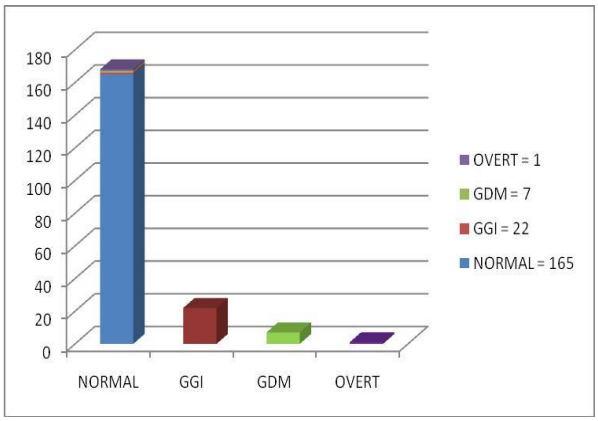
False Positive Rate	%	72.5	46.3	32.5	27.5	21.2	21.2	10.6	8.6	7.1	1.2
Sensitivity	%	93.3	73.3	60	53.3	26.7	20	20	20	13.3	0
Specificity	%	27.5	53.7	67.5	72.5	78.8	78.8	89.9	91.4	92.9	98.9
PPV	%	7	8.5	9.8	10.2	6.9	7.5	10	12	10	0
NNP	%	98.6	97	96.6	96	94.8	94.7	95	95.1	94.8	94.3

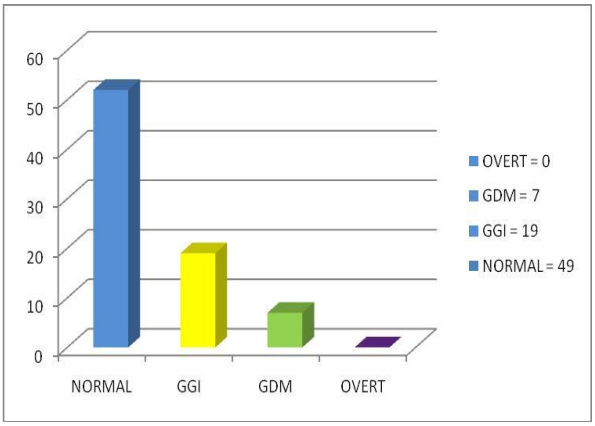
Patients with BMI >24 had sensitivity of 60%, specificity of 67.5%, positive predictive value of 9.8%, negative predictive value of 96.6%.

Receiver operative characteristic curve



Area under curve for FBS=0.694
Area under curve for BMI=0.63

Table 3: Body mass index as a comparison for gestational diabetes mellites (cross tab)

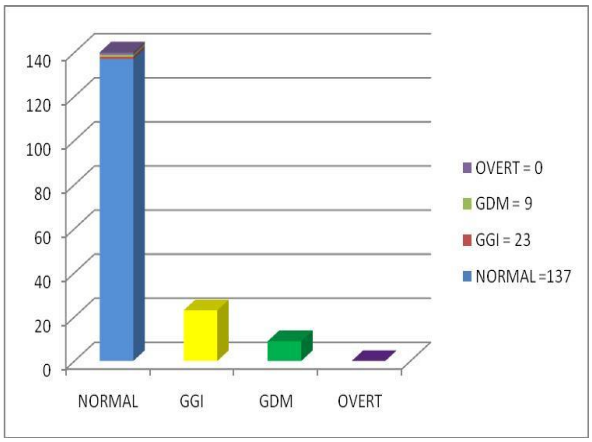


BMI VS GDM	OGTT				
	Normal	GGI	GDM	OVERT	Total
BMI <25	165	22	7	1	195
BMI >=25	49	19	7	0	75
Total	214	41	14	1	270

P value <0.01

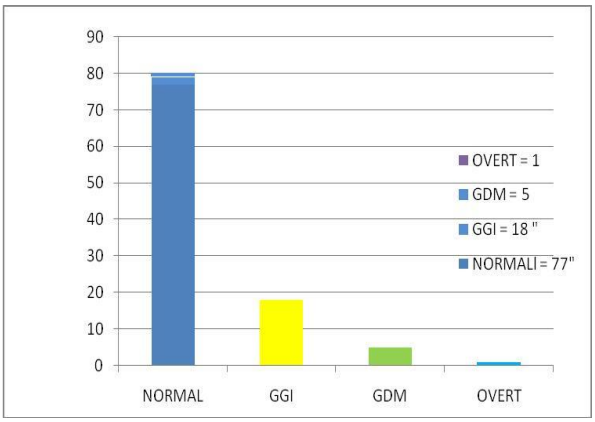
BMI <25

BMI>= 25



Out of 270 patients, patients who had BMI<25 had more normal values. Patients who had BMI >=25 had increased GCT values. This data was found to be statistically significant.

Table 4: Fasting blood sugar as a comparison for gestational diabetes mellites (cross tab)



FBS VS GDM	OGTT				Total
	Normal	GGI	GDM	OVERT	
FBS <92	137	23	9	0	169
FBS >=92	77	18	5	1	101
Total	214	41	14	1	270

P value =0.455

FBS < 92

FBS >=92

In group I patients with FBS <92 were 169 patients, of which 23 developed GGI, 9 developed GDM In group II FBS>=92-105 were 101 patients out of which 18 patients developed GGI, 5 patients developed GDM, 1 patient developed overt diabetes respectively. Group II patients were subjected to diabetic diet earlier in view of initial high sugar values. So analysing the outcomes, we inferred that starting diabetic diet earlier has a significant role in decreasing the risk of developing GDM in advance pregnancy.

Result

Mean calculated continuous variable. Percentage calculated for categorical variable (sensitivity). Pearson chi –square test was used to find association between categorical variable.

In addition sensitivity, specificity, false positive, false negative were calculated. Receiver operating characteristic (ROC) curve was plotted to find cut off value for FBS & BMI for GDM.

Further Area under Curve (AUC) was calculated to observe discriminatory power between FBS & BMI. FBS(AUC=0.69) has little more discriminatory power in identifying GDM than BMI(AUC-0.63). P value <0.05 was considered statistically significant

All statistical analysis was done using SPSS Software (statistical package for social sciences) With a threshold of FBS>90, sensitivity of 86%, specificity of 52%, hence FBS >90mg/dl can be considered as a threshold value for predicting GDM which is lesser than the threshold 92 mg/dl which is already considered as a cut off for prediction of GDM. With a threshold of BMI>24, sensitivity of 60%, specificity of 67.5%, hence BMI >24 is a good predictor of GDM.

Discussion

Our aim was to find out the correlation between FBS and OGTT and to find the threshold value of FBS, BMI for developing GDM.

Out of 270 patients, 14 patients developed GDM which is 5.2% of the total study population. 1 patient developed overt diabetes which is 0.3% of study population.

Our study shows that pregnant women with FBS >90 mg/dl are more likely to develop GDM later in pregnancy and more likely to develop adverse pregnancy outcome if no intervention is done for these patients. Therefore, we suggest that women with Fasting blood glucose >90mg/dl who are more prone to develop GDM hence should be subjected to medical nutritional therapy. FBS (AUC=0.69) is a better than BMI (AUC=0.63) as a screening test for GDM.

Early diagnosis of gestational diabetes mellitus (GDM) is important to improve for both maternal and fetal outcomes. The burden of diabetes in India is very high. It is an urgent need to establish screening and diagnostic procedure which is easy, understandable and simple. FBS measurement is a well-tolerated and inexpensive routine examination.[2] FBS measurement has better test accuracy throughout the pregnancy.[3,4] Riskin-Mashiah et al.[2] study had high predictive value of first trimester FBS, and consider FBS as a screening test and not as diagnostic test with a suggested cut off value. This study concluded that, The FBS value lower than what is be considered as impaired fasting glucose, is associated with development of GDM. There is no clear cut off above which the risk of GDM is substantially increased. So for every 5 mg/dl increase in FBS or 3.5kg/m^2 increase in BMI there was 1.5 fold increased risk. First trimester fasting blood glucose value is an excellent test for determining the need to continue with the oral glucose tolerance test in the second trimester.[4,5]

The hyperglycaemia and adverse pregnancy outcome study estimated that Fasting blood glucose measurement identifies about 50% of all affected women without an additional 1 and 2 hour OGTT values.[6] Though previously FBS was neglected as a screening test for GDM, in high risk population it provides simple, practical algorithm to screen for GDM.[7] Riskin-Mashiah et al,[8] has already reported that mild hyperglycemia in early pregnancy will lead to adverse pregnancy outcomes.

So instead of subjecting all patient to a glucose load to do OGTT in first trimester, which may aggravate nausea, vomiting which is more prevalent in first trimester. If patient vomits during the test, then OGTT has to be repeated again on another day which is time consuming. So, it is better to perform an easy, less time consuming, cost effective test that is fasting blood glucose.

Our study shows that pregnant women with FBS >90 mg/dl are more likely to develop GDM later in pregnancy and more likely to develop adverse pregnancy outcome if no intervention is done for these patients. Therefore, we suggest that these women should be subjected to medical nutritional therapy. FBS as a screening test has little more discriminatory power in identifying GDM than BMI.

Conclusion

Our study shows that FBS at first trimester will be helpful in the early prediction of gestational diabetes mellitus. Early diagnosis and early intervention of diabetes is useful for improving pregnancy outcomes. In conclusion, FBS measurement at first prenatal visit or at the time of first booking will be useful to screen for previously undiagnosed pre-existing diabetes and also help to predict the development of GDM earlier.

Abstract

Background: Autoimmune disorders are chronic multisystem disorders affecting women of their reproductive age. Pregnancy among these women is complicated by the disease itself. Flaring up of disease, uteroplacental insufficiency due to vasculitis and drugs used for treatment are main reason for unfavourable pregnancy outcomes. The objective of this study was to analyze the pregnancy complications and outcome among 113 cases of autoimmune disorders.

Methods: This study is a retrospective analysis of case records of pregnant women with autoimmune disorders. This study was conducted at PSG IMSR and Hospital, Coimbatore, and Tamil Nadu from July 2012 to June 2018. The case sheets were retrieved from medical record department and the details such as type of disease, maternal age, parity, status of disease at conception, treatment taken during pregnancy, maternal complications and fetal complications were collected and analyzed.

Results: During 6-year period there were 113 pregnant women with autoimmune disorders, and they were studied of their previous and present pregnancy outcome. The disease incidence was 7.01% per 1000 deliveries. 40.7% were less than 25 years age group and 71.6% were multigravidae. We had forty-one patients (36%) who were positive for APLA syndrome which were the maximum number of patients with auto immune disorder in pregnancy and 37 patients (32.7) with SLE. We had significant numbers of maternal and fetal complications for common disorders. Most of the rare auto immune disorders were diagnosed before pregnancy and these pregnancies were managed by multi-disciplinary approach, and continued on immunomodulators throughout pregnancy, hence maternal and fetal complications were less for them.

Conclusions: Adequate pre-conceptional counseling, vigilant monitoring during pregnancy and post-partum will avoid pregnancy related complications and have favorable outcomes.

Keywords: Autoimmune disorder, Fetal complications, Immunomodulators, Maternal complications, Pregnancy outcome, Pre-conceptional counseling

Introduction

Autoimmune disorders are chronic multisystem disorders which are characterized by tissue damage and inflammation due to alteration of adaptive immune response in the absence of trigger.[1] Its prevalence is between 7.6%-9.4%.[2] Since most of the autoimmune disorders are diagnosed frequently during reproductive age in females, these women are at high risk not only during pregnancy but also during postpartum.[3] When compared to females without autoimmune disorders, these women carry more incidence of miscarriages in all trimesters, preeclampsia, intrauterine growth restriction, premature rupture of membranes, placental insufficiency, preterm labour, low birth weight and have increased caesarean section rates.[4] Though these pregnancies carry

high incidence of adverse effects, improved care in terms of pre-conceptional counselling and continuation of treatment throughout the pregnancy and post-partum have improved the outcome of pregnancies.[5]

M□□□□ □□

This study is a retrospective analysis of a total 113 case records of pregnant women with autoimmune disorders. This study was conducted at PSG IMSR and Hospital, Coimbatore, Tamil Nadu from July 2012 to June 2018. The case sheets were retrieved from medical record department and the details such as type of autoimmune disorder, maternal age, parity, status of disease at conception, treatment taken during pregnancy, maternal complications like pregnancy induced hypertension, gestational diabetes mellitus, thrombotic events, anemia, renal flares, thrombocytopenia, preterm labour, mode of delivery, indications for caesarian section and fetal complications like abortion, anomalies, intra uterine fetal demise, low birth weight, intra uterine growth restriction, oligohydramnios, need for admission to neonatal intensive care unit, low Apgar score were collected and analyzed.

Inclusion criteria

- All primigravidae and multigravidae who are known case of autoimmune disorder and all primigravidae and multigravidae who are diagnosed with autoimmune disorder during present pregnancy.

Exclusion criteria

- Pregnant mothers without autoimmune disorders.

□□□□ □□□

During this period of 6 years (2012-2018), there were 113 pregnant women with autoimmune disorders and study was carried out based on their previous and present pregnancy outcomes. The incidence of autoimmune disorders in pregnancy was 7.01% per 1000 deliveries.

Table 1 shows the number of pregnancies with autoimmune disorders in our study.

Takayasu	3 (60%)	-	1 (20%)	-	-	-	4 (80%)	-
Sjögren syndrome	-	1 (25%)	-	-	-	-	3 (75%)	□□

In our study, most of the patients were below 30 years of age. Table 2 shows the age group distribution. Multigravida (71.6%) were more in number than primigravida (28.3%) in our study.

Parity distribution is shown in Figure 1.

Table 3 shows the most common autoimmune disorders in our study and their maternal complications.

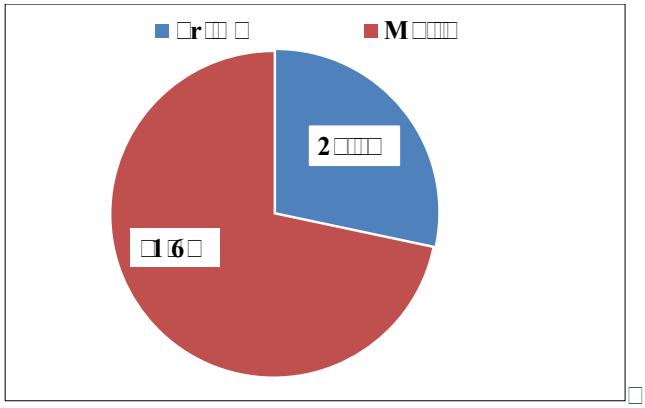

Table 3: Maternal complications in previous pregnancy.

Disorder	Number	Percentage
APLA	26 (63%)	9 (21.9%)
SLE	22 (59%)	5 (13.5%)
ITP	4 (36%)	-
Takayasu	-	1 (20%)
Sjögren syndrome	3 (75%)	-

Two patients diagnosed with SLE had abnormal doppler changes at 32 weeks and 34 weeks respectively and underwent caesarean section. The most common indication for caesarean section was non-progression of labour followed by previous section.

Table 4 shows fetal complications in previous pregnancy for more common disorders in our study.

Table 4: Fetal complications in previous pregnancy.

Disorder	IUGR	Abortion	Stillbirth
APLA	7 (17%)	2 (4.8%)	1 (2.4%)
SLE	13 (35%)	6 (16%)	5 (13.5%)
ITP	2 (18%)	-	1 (9%)
Takayasu	3 (60%)	-	-
Sjögren syndrome	-	2 (50%)	-

Table 5 shows the fetal complications in the current pregnancy for same disorders.

Table 5: Maternal complications in current pregnancy.

Disorder	Current	Previous

Preterm labour	21%	21%

Table 6: Fetal complications in current pregnancy.

Disorder	Current	Previous
Abortion in previous conception	59%	46%
IUD	13.5%	8%
IUGR	35%	32%
LBW	24.3%	22%
NICU admission	13.5%	15%

APLA

Obstetric antiphospholipid antibody syndrome (OB-APS) is defined according to the updated Sydney classification criteria developed by expert consensus agreement in 2006.[6] APLs include the lupus anticoagulant, anticardiolipin IgG and IgM and anti-β2-glycoprotein I antibody. In addition to the detection of aPLs on at least two occasions more than 12 weeks apart, OB-APS is defined by any one of the following adverse pregnancy outcomes: 1) otherwise unexplained recurrent pregnancy loss before the 10th week of gestation, 2) otherwise unexplained fetal death ≥10 weeks of gestation, 3) preterm birth before 34 weeks of gestation due to preeclampsia or placental insufficiency.[7] Other OB-APS complications include catastrophic APS, thrombosis, HELLP syndrome (hemolysis, elevated liver enzymes, and low platelet count), IUGR, fetal distress, premature rupture of membranes, and thrombocytopenia.[8] It has been recognized that among the three aPLs, lupus anticoagulant (LAC) is the primary predictor of poor pregnancy outcome in women both with or without SLE, and with or without other aPLs.[9] Among the 41 patients with APLA, 20 patients were positive for lupus anticoagulant antibody, 11 were positive for anticardiolipin antibody and 10 had anti-β2-glycoprotein I antibody.

In our study, 31.8% of patients with primary APLA and 4.4% of patients with secondary APLA with associated SLE were diagnosed. The incidence of pre-eclampsia among APLA positive patients in our study was 4.8% whereas in Wijeyaratne study, it was 10.9%.[10] Similarly the incidence of GDM in our study was 31% as compared to 19.2% in Wijeyaratne study. In our study 2.4 % had preterm labour and 17% of patients underwent cesarean section. In regard to fetal complications, 63% of patients in our study had previous one or more abortions which was comparable to Wijeyratne study (59.8%). The incidence of IUD in previous pregnancy was 21.9.%. The incidence of low birth weight babies was 12% and babies requiring NICU admission was 2.4% respectively.

SLE

Systemic lupus erythematosus (SLE, or “lupus”), affects females in a 9:1 ratio to males.[11] The adverse pregnancy

outcomes observed with lupus are well known, and include increased rates of intrauterine growth restriction (IUGR), preterm birth and fetal loss, as well as the syndrome of neonatal lupus (NL), associated with trans placental passage of auto antibodies. The risks for thrombosis, infection, thrombocytopenia, and transfusion were each 3- to 7-fold higher for women with systemic lupus erythematosus. Lupus patients also had a higher risk for cesarean sections (odds ratio: 1.7), preterm labor (odds ratio: 2.4), and preeclampsia (odds ratio: 3.0) than other women. Women with systemic lupus erythematosus are more likely to have other medical conditions, including diabetes, hypertension, and thrombophilia, that are associated with adverse pregnancy outcomes.[12]

High disease activity at the time of conception or in the months preceding conception is an independent predictor for increased risk of adverse pregnancy outcomes including prematurity, IUGR and fetal demise. This has led to the current recommendations that lupus patients achieve 6 months of disease quiescence prior to attempting conception.[13] Maternal and fetal complications associated with SLE were compared with Eman et al study.[14] These are shown in table 6 and 7 respectively.

Six patients had first trimester abortions in the current pregnancy.

Takayasu syndrome

In our study, 60% patients had hypertension complicating pregnancy whereas in Mandal et al study had 92.8%.[15] Caesarean section rate in our study was 60%, whereas in Mandal study it was 71.4%. Intrauterine growth restriction was 60% in our study, which was comparable with Mandal et al study (51.7%).

Schönlein-henoch purpura

Schönlein-henoch purpura (SHP) is a systemic vasculitis that affects vessels of a small caliber.[16] The onset of SHP during pregnancy is very rare. Treatment with orally administered corticosteroids may lead to a beneficial outcome for both mother and newborn.[17] In our study, we had 2 patients diagnosed with Schönlein-Henoch purpura, of which one developed GDM, other had uneventful pregnancy.

Medium vessel vasculitis

Most of the women with medium vessel vasculitis fared well during pregnancy without significant disease progression, but instances of aneurysm rupture, renal insufficiency, pulmonary embolism, and myocardial infarction were reported in Gatto et al study.[18] In our study, one patient diagnosed with medium vessel vasculitis developed myocarditis during pregnancy and she was managed with steroids.

ITP

Nine percent of chronic ITP patients in our study had preeclampsia, whereas Diego et al, study had 8.3%.[19] In our study 9% had preterm labour which was comparable to Diego et al (9.5%) study. Diego et al showed 8.5% of gestational diabetes in the study whereas in our study we had 54% of gestational diabetes which could be explained by ethnicity and usage of steroids.

In Yassaee et al, study occurrence of IUGR was 10.5% whereas in our study it was 18%, among which one baby was admitted in NICU.[20] In Yassaee et al study 57% of patients had moderate thrombocytopenia (more than 50,000) whereas 18% of thrombocytopenia and 9% of anemia were diagnosed in our study.

When comparing the caesarean section rate, Yassaee et al had 81% whereas we had 63%.

Rheumatoid arthritis

In women with well-controlled RA, pregnancy outcomes are comparable to the general obstetric population, whereas in women with higher RA disease activity, there is more chances of less favorable pregnancy outcomes.[21,22]

Akasbi et al, study showed improved maternal and fetal outcome in patients with RA in pregnancy. Similarly, in our study two patients diagnosed with RA had uneventful pregnancy.

Guillain-barré syndrome

Guillain-barré syndrome (GBS) represents a heterogeneous group of immune mediated peripheral neuropathies. A feature common to all GBS variants is a rapidly evolving polyradiculoneuropathy preceded by a triggering event, most often an infection. GBS generally manifests as a symmetric motor paralysis with or without sensory and autonomic disturbances. Delayed diagnosis is common in pregnancy or immediate post-partum period because the initial non-specific symptoms may mimic changes in pregnancy. GBS should be considered in any pregnant patient complaining of muscle weakness, general malaise, tingling of the fingers, and respiratory difficulty.[23,24]

We had one patient diagnosed with GBS who had an uneventful course during pregnancy.

Multiple sclerosis

Multiple sclerosis (MS) is an inflammatory disease in which the fatty myelin sheaths around the axons of the brain and spinal cord are damaged, leading to demyelination and scarring as well as a broad spectrum of signs and symptoms.[25] Pregnancy is typically a stabilizing period in the clinical course of MS. During the

third trimester the MS relapse rate can be 70% lower when compared with the time prior to pregnancy, but exaggeration of the disease is commonly seen postpartum. Presently, there is no evidence that MS patients are more susceptible to pregnancy or delivery related complications, such as ectopic pregnancy, pre-eclampsia, gestational diabetes mellitus, prolonged labour or miscarriage than women in general, nor is their infants more likely to be delivered preterm or to be of low birth weight, have malformations or experiences an early death.[26,27] Mothers with MS required operative delivery more often than healthy mothers, which might be attributed to MS-related symptoms such as neuromuscular perineal weakness and spasticity in addition to fatigue and exhaustion.[28] In our study, we had 3 mothers diagnosed with multiple scelerosis, of them one developed PIH, one had GDM.

Sjögren syndrome

Sjögren syndrome is known to occur predominantly in women. Affected women are likely to experience more complicated pregnancies than are women without the disease.[29] Its effect on pregnancy differs according to the maternal disease, disease activity, and severity of organ damage, antibody profile, and drug treatment.6.

Several studies have reported an increased rate of spontaneous abortion and fetal loss associated with Sjögren syndrome.[30] This may be explained by, first, the age of the patients at the time of concep-tion which usually belongs to an elderly age group and, second, a possible immunologic factor involved in the mechanisms of miscarriage.[31]

In our study, out of four mothers diagnosed with Sjögren syndrome, two had spontaneous abortions.

The outcome of pregnancies in women with Sjögren syndrome can be improved with use of a multidisciplinary approach for management involving an obstetrician who has specialized in high-risk pregnancies, a rheumatologist, and a pediatrician.[32]

Hashimotos thyroiditis

Hashimotos thyroiditis is associated with an increase rate of spontaneous.

Abortions, preterm delivery and increased use of cesarean section.[33] All the three patients diagnosed with Hashimotos thyroiditis underwent cesarean section for non-progression of labour.

Ulcerative colitis

Stephansson et al study concluded that pregnant women with ulcerative colitis had a greater number of preterm births, babies with low birth weight and cesarean section deliveries than those without ulcerative colitis.[34] In our study we had one patient who delivered a low birth weight baby of 2.2 kg. One patient diagnosed with multisystem connective tissue disorder had an intra uterine growth restriction and the same baby had low birth weight.

Von Willebrand's disease

Pregnancy and delivery are considered events predisposing to a high risk of bleeding in women with von Willebrand's disease.[35]

Our patient did not have any complication. All the patients diagnosed with GDM were found to be on steroids.

Among the 113 patients, 3 underwent caesarean section in view of abnormal umbilical artery doppler findings.

Patients previously diagnosed were continued on disease modifying agents and this could be the reason for their successful pregnancy outcome.

Rauto immune disorders were diagnosed before pregnancy and these pregnancies were managed by multi-disciplinary approach, and continued on immune modulators throughout the pregnancy, hence minimizing maternal and fetal complications.

□□□□□□□□□□

In our study, most of the patients were either continued on the same treatment they were taking before pregnancy or were started on treatment once they were diagnosed with autoimmune disorders, and hence they were found to have successful pregnancy outcomes. Therefore, appropriate pre-conceptional counselling, continuation of treatment, intense maternal and fetal monitoring and timely delivery plays an important role in improving the pregnancy outcome.

Abstract

Background: Ectopic pregnancy (EP) is a common, life threatening emergency during the first trimester and a significant cause for maternal morbidity and mortality. In any woman of reproductive age presenting with abdominal pain and vaginal bleeding, ectopic pregnancy should be considered. The objectives of the present study is to determine the incidence, risk factors, clinical presentation, type of ectopic pregnancy, treatment, morbidity and mortality.

Methods: Retrospective analysis of case sheets of patients admitted with ectopic pregnancy at PSGIMSR, Coimbatore during the period July 2011 to June 2016 was done. The details noted were age, parity, risk factors {previous abortion, previous EP, previous pelvic surgery, intrauterine contraceptive device, tubectomy, history of pelvic inflammatory disease}, treatment for infertility, clinical presentation, ultrasound findings, investigations including beta HCG value and hemoglobin level, treatment offered, need for blood transfusion, operative findings and morbidity.

Results: During the five year, there were 12,407 deliveries at our hospitals and 88 cases of ectopic pregnancies were managed. The incidence is 6.6/1000 deliveries. Among them 44% belonged to the age group of 25-30 years and multi gravida were 73.8%. Most common risk factors were previous abortion (23.8%) and previous surgeries including caesarean section, tubectomy, appendicectomy, tubal microsurgery (23.8%). Most common presentation was pain abdomen (85.2%). Out of the 88 cases, 73 patients were managed surgically (82.9%) and 11 cases were managed successfully with methotrexate (12.5%). Three of them underwent conservative management and one had Uterine Artery Embolization.

Conclusions: Early diagnosis based on risk factors and timely intervention plays a main role in reducing morbidity and mortality associated with ectopic pregnancy.

Keywords: Beta HCG, Ectopic pregnancy, Methotrexate, Risk factors, Salphingectomy Transvaginal USG

Introduction

An ectopic pregnancy is implantation of fertilized ovum outside the normal endometrial cavity i.e, fallopian tube, ovary, caesarean scar, cervix and peritoneal cavity.[1] In the first trimester, ectopic pregnancy is the most common cause for maternal morbidity and mortality.[2] It has also been shown that EP reduces future fertility and increases the chance of subsequent EP.[3] The incidence of EP is increasing since the last decade, but the incidence of complications like rupture and morbidity are declining due to early diagnosis with serial Beta-HCG(human chorionic gonadotrophin) monitoring, transvaginal USG(ultrasonogram) and minimally invasive surgery.[4] Early diagnosis not only reduces the risk of tubal rupture but also allows for conservative and medical management.[5] Prior damage to the fallopian tube due to PID(pelvic inflammatory disease), tubal surgeries, pelvic adhesions are the major risk factors for ectopic pregnancy.[6] The other identified risk factors are,

advanced maternal age, previous EP, previous pelvic surgeries, IUCD (intra uterine contraceptive device) insertion and infertility treatment.[7-12] Identifying these risk factors among high risk mothers helps in early diagnosis and reduces the morbidity related to this condition.[13] Unfortunately, most of the patients presenting with EP do not have risk factors.

M□□□□□□

This was a retrospective analysis of case records of patients admitted with ectopic pregnancy, done at PSG IMSR Hospital, Coimbatore from July 2011- June 2016.

Inclusion criteria

We included all the patients with suspected ectopic pregnancy who were confirmed by βHCG and transvaginal ultrasound.

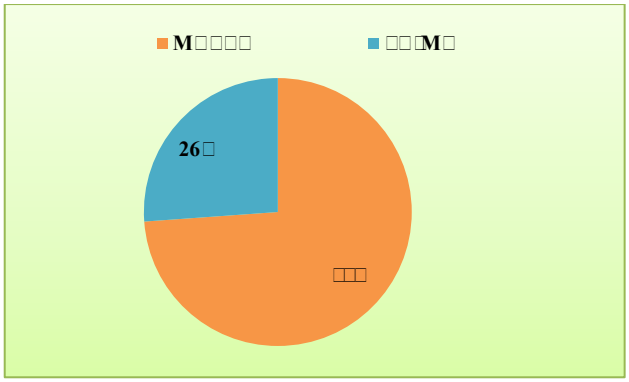
Exclusion criteria

None

Methodology

The case sheets were retrieved from medical record department and the details such as age, parity, risk factors like previous abortion, previous EP, previous pelvic surgery, contraception in the form of IUCD and tubectomy, history of PID, infertility treatment, clinical presentation, investigations including beta HCG value, hemoglobin level, treatment offered, need for blood transfusion, operative findings and morbidity were collected and analyzed.

Statistical analysis



No statistical tool used.

□□□□□□□

During the 5-year period, there were 12,407 deliveries at our institution and 88 cases of ectopic pregnancies were managed. The incidence was 6.6/1000 deliveries. Among the patients most of them belonged to the age group of 25-30 years (Table-1). 26% of patients were primigravida, 73.8% of patients were multigravida (Figure -1).

As shown in (Table 2) 23.8% of patients had one or more spontaneous or induced abortions.23.8% of patients had undergone pelvic surgery (Caesarean section, tubectomy appendicectomy, tubal recanalistion). PID and previous ectopic pregnancy accounted for 4.5% each.

Bleeding PV	52	59

Most of them presented between 5-8 weeks of gestational age (61.3%).27.2% of patients were diagnosed before 4 weeks of amenorrhea and 11.3% were above 9 weeks. All the cases had been confirmed by USG.17 of them had Beta-HCG less than 1000 m I U /ml. A patient with heterotopic pregnancy had Beta -HCG of more than 1 lakh m I U /ml.

Commonest site of ectopic pregnancy was fallopian tube in 93% of patients (Table 4).

Twenty-one patients were fit into medical management, among them 12.5% of patients were managed medically with methotrexate successfully.

10 cases failed to medical management which were subsequently managed with either laparoscopic or laparotomy and salphingectomy.

3 cases were managed conservatively by observing the declining trend of Beta-HCG.

Other types of ectopic

Caesarean scar pregnancy was diagnosed in 3 patients, among them 2 patients underwent surgical excision. One patient was managed with UAE (uterine artery embolisation) followed by methotrexate. Heterotopic pregnancy following ovulation induction which resulted in twin intra uterine gestation and tubal ectopic was noted in one patient and she underwent emergency laparotomy and salpingectomy. Two patients were diagnosed as having ovarian ectopic and surgical excision was offered to both of them. Most common morbidity noted was anemia in 42%, out of which severe anemia (4-7gm) was seen in 5.6% (Table 8). Among them 28.4% of patients received blood and blood products. No surgical site infection or mortality was noted.

[illegible]

The incidence of ectopic pregnancy among women attending emergency department with first trimester abdominal pain, bleeding or both is between 6-16 %(14). A study conducted by Shraddha Shetty et al had incidence of 5.6/1000 deliveries.[15] In our study the incidence is 6.6%/1000 deliveries which is comparable. Majority of patients were between 25-30years which is similar to the above study and Khaleeqe et al.[15,16]

As in Karki et al (17), we had similar higher incidence of ectopic pregnancies (73.8%) in multigravida. In our study, the commonest predisposing factors were previous abortion either spontaneous or induced, previous pelvic surgeries including caesarean section, history of IUCD insertion, tubectomy, history of PID and infertility treatment, which are similar to various other studies.[17,18] As in the studies by Porwal Sanjay et al, Shraddha Shetty et al, the most common symptom in our series was pain abdomen which is comparable.[15,18]

Urinary beta HCG, serum beta HCG, transvaginal USG are the diagnostic tools for diagnosing EP. USG should be the investigation of choice for symptomatic women. In asymptomatic women, serial monitoring of serum beta HCG should be done. As in the study by Shraddha Shetty et al, we also had more number of right sided EP and involvement of the ampullary portion of the tube.[15]

Heterotopic pregnancy is rare in natural conception which is around 1 in 30,000 pregnancies. But the incidence is more in case of ovulation induction or with

assisted reproduction techniques. In our study, we had a case of triplet heterotopic pregnancy following ovulation induction with clomiphene citrate. It is recommended that even patients shown on ultrasound to have intrauterine pregnancy should be given comprehensive pelvic ultrasound so that possibility of synchronous heterotopic pregnancy can be excluded, particularly in pregnancies following fertility treatment.[19]

In our study, ruptured EP was noted in 53% of cases, 43.9% of cases had an unruptured ectopic gestation. In Latchaw G et al study, the same were 59% and 41% respectively.[20]

Laparoscopy and medical therapy have now emerged as the widely used therapeutic modalities with great success in terms of reduced morbidity, shorter hospital stay and conservation of fertility.[21] However choice depends upon early identification of ectopic pregnancy and hemodynamic status of the patients.[22] In our study, 11% of patients responded well to single dose of methotrexate.

Surgery should be the treatment of choice in unstable patient.[19] In our study 13.6% were unstable and all of them were managed surgically. Commonest surgery performed was partial/total salpingectomy. We did bilateral total salpingectomy for patients who had undergone tubectomy previously and were not desirous of future childbearing. It has been extensively studied and reported that conservative management does not increase the risk of future ectopic.[15] In our study, three patients were managed conservatively by observing the declining trend of Beta HCG. Morbidity included anemia, blood transfusion and wound infection. In our study, we had 42% of patients with hemoglobin level of less than 10grams. Among them 28.4% of patients received blood and blood products. No surgical site wound infection was noted.

No maternal mortality was noted in our study which is consistent with the study by A Abbas et al.[23] Early identification of the patients with EP by a multipronged approach including high index of suspicion, risk prediction, serum beta HCG and transvaginal ultrasound helps in improving the prognosis as far as morbidity, mortality and future fertility are concerned.[24]

□□□□□□□□□□

Identification of underlying risk factors, early diagnosis with essential investigating modalities like beta-HCG, transvaginal USG, timely intervention with medical or surgical method will definitely reduce morbidity and mortality and improve the future reproductive outcome.

ABSTRACT

Background: Gynaecological problems of adolescents occupy a special spectrum of gynaecological disorder of all ages. This is because of the transitional phase of the physical nature of the problems which are so unique, special and specific for the age group and also because of the associated physiological factors which are very important in the growth and psychological remodelling of someone in the transition between childhood and womanhood. The study conducted with the objective to assess the extent of awareness regarding adolescent changes and problems among school going adolescents and to compare the same between government and private school adolescent girls.
Methods: We used a preformed questionnaire as our study material to assess the knowledge and attitude regarding nutritional requirement, BMI, obesity, puberty changes, menstrual hygiene and irregularities, anaemia, vaginal discharge, gynaecological tumours and HPV vaccine among the adolescent girls in both government and private schools and thereby, to compare the same between them.
Results: Awareness regarding nutritional requirement (45%, 98%), BMI (66%, 15.5%), obesity related gynaecological problems (9%, 81%) and causes for anaemia (28%, 93%) were less in government school girls when compared private school girls. Awareness on menstrual hygiene was satisfactory in both the groups. Awareness on HPV vaccination was unsatisfactory in both the groups.
Conclusions: Government school girls need better health education regarding adolescent related gynaecological issues. There is need to educate both the groups on HPV vaccination.

Keywords: Adolescence, Government school girls, Menstruation, Private school girls, Puberty

INTRODUCTION

Adolescence is a period of biological, cognitive and social transition of such magnitude and rapidity, that it is no surprise to find that it is associated with the onset or exacerbation of a number of health related problems. India has the largest population of adolescents in the world, accounts for a quarter of the country's population (243 million estimated).[1] WHO identifies adolescence as the period in woman growth and development that occurs after childhood and before adulthood, from age 10 to 19 years. It represents one of the critical transitions in the life span and is characterized by a tremendous pace in growth and change that is second only to that of infancy.[2] It is the level of self-awareness among adolescents, which enables them to see where their thoughts and emotions take them. Adolescents greatly lack correct information related to their bodies' physiological, psychological and sexual changes. There is an urgent need for regular adolescent friendly information, education and communication activities covering different aspects of adolescent knowledge, needs/problems. The study was conducted with the objective to assess the extent of awareness regarding adolescent changes and problems

among school going adolescents and to compare the same between government and private school adolescent girls.

The objective of the study was to know the attitude of the adolescent girls in the awareness regarding the gynaecological problems and to compare the awareness level of government school girls to that of private/management school girls.

METHODS

A observational study on Gynaecological issues in adolescence among private and government school girls was conducted after approval from the Institutional ethics committee PSGIMSR Coimbatore in the year 2015 (3 months).

Study material: Predesigned questionnaire

Sample size: 100 in government school and 100 in private school

Inclusion criteria

All adolescent girls who attained puberty/maturity

Exclusion criteria

Those who does not belong to adolescent age group, unwillingness to participate in the study.

We used a preformed questionnaire as our study material to assess the knowledge and attitude regarding nutrition, BMI, obesity, puberty changes, menstrual hygiene and irregularities, anemia, vaginal discharge, gynaecological tumors and HPV vaccine among the adolescent girls in both government and private schools and thereby, to compare the awareness level of government school girls to that of the private school girls. After getting permission from the school authorities, we explained the aim of the study one by one of our research. Informed written consent was obtained from the students and their parents. Data was collected; statistical analysis was done by percentage and chi-square test. Statistical significance of differences between groups was tested. P value <0.05 was taken as statistically significant.

RESULTS

Table 1: Awareness of nutritional requirements.

School	Nutrition		Chi-square	P value
	Yes	No		
Private	45%	55%	51.42	0.00*
Government	2%	98%		

Table 1 showed that the government school girls had almost no awareness regarding the nutritional requirements and the additional calories needed in this age group. In the private school, about 45 girls were aware about the importance of nutrition and also the additional calorie requirement in adolescence. We observed a statistical significance among the private and the government school girls.

Table 2 showed that in Government school, about 15.5% were aware about BMI and in private school, 66% were aware. Statistical significance was found among the private and government school adolescents.

Table 3 showed that only 9% of the Government school girls and 81% of private school girls were aware of obesity and its consequences. Statistical significance has been found among the private and government school girls.

Table 4 shows that the correct response was about 85% and 89% from government and private schools respectively. No statistically significant value has been found out regarding the awareness about puberty age.

Table 2: Awareness of BMI.

School	Awareness of BMI		Chi-square	P value
	Yes	No		
Private	66%	44%	35.16	0.00*
Government	15.5%	84.5%		

Table 3: Awareness of obesity.

School	Awareness of obesity		Chi-square	P value
	Yes	No		
Private	81%	19%	104.72	0.00*
Government	9%	91%		

Table 4: Awareness regarding puberty age.

School	Awareness of puberty age		Chi-square	P value
	Yes	No		
Private	89%	11%	0.707	0.400
Government	85%	15%		

Table 5: Awareness of physiological body changes in puberty.

School	Puberty changes		Chi-square	P value
	Yes	No		
Private	82%	18%	2.51	0.113
Government	89%	11%		

Table 5 evidences that 89% of the government school girls and 82% of the private school girls showed positive response. The awareness mindset of both the private and the government school girls remained almost same,

which thereby denotes no statistical significance regarding the physiological body changes in puberty.

Menstrual hygiene and irregularities

In our study, we had asked about the awareness of menstrual hygiene and how do they maintain it and the various menstrual irregularities.

Table 6 showed in our study that equal number of girls in both schools was aware of the necessity of hygiene during menstruation. Towards maintenance of hygienic practices during menstruation 88% and 78% of private and government school girls were aware. Regarding normal duration of periods (p=0.106) and factors affecting periods(p=0.00) ,there was a statistical significance found among the government and private school.93% and 86% of private and government school girls were aware of the menstrual irregularities. We found that majority of private school girls were less aware than government school girls regarding the consultation of doctor during menstrual problems.

Table 6: Awareness about menstrual hygiene.

School	Menstrual hygiene		Chi-square	P value
	Yes	No		
Private	100%	0%		
Government	98%	2%	2.02	0.115
	Practices of menstrual hygiene		**Chi-square**	**P value**
	Yes	No		
Private	88%	12%		
Government	78%	22%	1.87	0.171
	Duration of periods		**Chi-square**	**P value**
	Yes	No		
Private	88%	12%		
Government	47%	53%	2.60	0.106
	Factors affecting periods		**Chi-square**	**P value**
	Yes	No		
Private	46%	54%		
Government	58%	42%	38.31	0.00*
School	**Menstrual irregularities**		**Chi-square**	**P value**
	Yes	No		
Private	93%	7%		
Government	86%	14%	1.62	0.203
	Consultation of doctor in case of menstrual irregularities		**Chi-square**	**P value**
	Yes	No		
Private	74%	26%		
Government	96%	4%	18.98	0.00*

Table 7: Awareness of anaemia.

School	Anaemia		Chi-square	p value
	Yes	No		
Private	64%	36%	1.45	0.228
Government	88%	22%		
School	Causes of anaemia		chi-square	P value
	Yes	No		
Private	82%	18%		
Government	93%	7%	8.21	0.004*

Table 7 shows that about 88% and 64% were aware about adolescent prone anaemia and the causes in government school respectively. About 93%, 82% were aware in the private school. No statistical significance was found among them regarding anaemia, but the causes of anaemia had a significant value towards the government school girls.

Vaginal discharge

In our study, two questions were asked about vaginal discharge; one about normal vaginal discharge and the second question about when to consult a doctor in case of vaginal discharge, being excessive, foul smelling or associated with itching. About 57% and 76% were aware about the normal vaginal discharge and 88% and 89% were aware about the abnormal vaginal discharge and the need to consult a doctor.

Table 8: Awareness of vaginal discharge.

School	Normal vaginal discharge		Chi-square	P value
	Yes	No		
Private	76%	24%		
Government	57%	43%	8.10	0.004*
School	**Abnormal vaginal discharge**		**Chi-square**	**P value**
	Yes	No		
Private	89%	11%		
Government	88%	12%	0.49	0.825

Table 8 shows that about 57% and 76% adolescent girls were aware about the normal vaginal discharge and about 88% and 89% adolescent girls were aware about the abnormal vagina discharge from the government and the private school respectively. We found that there was a statistical significance among government and private school girls regarding the normal vaginal discharge.

Table 9: Awareness of gynaecological malignancies.

School	Gynaecological malignancies		Chi-square	P value
	YES	**NO**		
Private	62%	38%		
Government	71%	29%	2.67	0.102

Table 9 shows that about 71% and about 63% adolescents were aware about the gynaecological malignancies from government and private school. There was no statistical difference among them.

HPV vaccination

In our study, there were two questions regarding HPV vaccination; one about whether they were aware of the vaccine and its role and the second about whether they had done the vaccination or not. The results obtained were about 5% and 42% girls from government and private school were aware of the vaccine. Even the percentage of girls, who were aware of the vaccination, did not take the vaccine. None of the girls from government school has done the vaccination and only 8% girls from the private school have done their vaccination.

Table 10: Awareness and attitude regarding HPV vaccination.

School	HPV vaccination		Chi-square	P value
	Yes	No		
Private	42%	58%		
Government	5%	95%	39.58	0.00*
School	**Practice of HPV vaccination**		**Chi-square**	**P value**
	Yes	No		
Private	8%	92%		
Government	0%	100%	8.33	0.004*

DISCUSSION

Nutritionally, adolescent period is the most vulnerable period because of increase demand and requirement for rapid growth and development. Nutrition and physical growth are integrally related. A healthy diet throughout puberty and adolescence is important to provide nutrients that support optimal physical growth and cognitive development. Gurpreet et al showed that adolescent subjects belonging to urban area had better knowledge than subjects belonging to rural area. Regarding height and weight and body mass index, measurement of height and weight and calculation of BMI showed that about 81% were underweight and 1.8% was approaching towards obesity.[8] In our study, government school girls had almost no awareness on nutritional requirement.

Adolescent obesity has been identified as a significant and growing health problem leading to type-2 Diabetes, metabolic syndrome, and other health problems (Thomas and walker, 2012). Rising obesity rates around the world have had a profound impact on female reproductive health. Childhood obesity is associated with early onset of puberty, menstrual irregularities and polycystic ovarian syndrome during adolescence.[9]

The World Health Organization (WHO) describes overweight and obesity as one of the today's most important public health problem, which is being escalated as a global epidemic.[10] It is also increasingly recognized as a significant problem in developing countries and countries undergoing economic transition.[11] The problem of being overweight and obesity is confined not only to adults but also being reported among the children and adolescents in the developed countries during the past two decades as well as similar trends are being observed even in the developing world, though less rapidly.[12-14] In

our study, the awareness on BMI and obesity was about 66% and 81% among the private school girls and 81% and 9% from the government school girls respectively.

Adolescence is a time for growth spurt and puberty changes. It is a stage in which adolescents cross the line between childhood and adulthood.[15] Puberty is a period of several years in which rapid physical growth and psychological changes occur, culminating in sexual maturity. The average onset of puberty is at 10 or 11 for girls and 11 or 12 for boys. Every person's individual timetable for puberty is influenced primarily by heredity, although environmental factors, such as diet and exercise also exert some influences. A cross sectional study was conducted with a sample of 320 adolescent students of ninth to twelfth classes (80 from each class). Data were collected on predesigned, pretested and semi structural schedules by conducting in-depth interviews of selected study adolescents by the investigator. Mean age of female respondents was 15.02 years. 212 study adolescents were aware of at least one adolescent change. 248/272 adolescents perceived those changes as 'normal' and on the contrary, 24/272 adolescents either did not consider these changes as normal or they did not know whether the changes were normal or abnormal.[16] Our results showed that both government and Private School girls had almost same knowledge on pubertal body changes.

Menstruation is a milestone event in a girls' life and the beginning of reproductive life so all aspects of menstruation need to be understood by adolescent girls.[17] Lack of knowledge and poor personal hygiene practices can lead to various gynaecological problems including reproductive tract infections.

Rupali Patle

They found that awareness regarding menstruation was more in urban adolescent girls (63.38%) as compared to rural (47.57%).Many studies revealed that most of the adolescent girls had incomplete and inaccurate information about the menstrual physiology and hygiene.[18] Our study showed that, total awareness regarding need of menstrual hygiene is 100% and 98% among the private and government school girls, which was satisfactory.

The awareness about gynaecological malignancies is important in this age group as the lifestyle and attitude can prevent the occurrence of the tumours. Though gynaecological malignancies are rare among adolescents, awareness about gynaecological malignancies is important in this age group as treatment of cancers may affect the future reproductive health. In our study, 62% and 71% awareness was present among the private and the government school girls, respectively.

Recently two HPV vaccines quadrivalent Gardasil and bivalent Cervarix have been shown to be highly effective in preventing infection with high-risk type HPV16 and HPV18, the two most oncogenic types. As these vaccines are highly effective before exposure to HPV, current guidelines priorities adolescent girls as primary group for HPV vaccination.[19] HPV vaccine implementation is still facing challenges even though it seems to be a definitive intervention to control mortality from cervical cancer and has the potential to address challenges of screening in India. Implementation faces barriers of cost, acceptance and lack of awareness.[20]

Our study showed almost none of the girls from the government school had done the vaccination. Only 8% of the private school girls are vaccinated.

CONCLUSION

In our study, we found that private school girls were more aware in the aspects of nutritional requirement, BMI, obesity related gynaecological problems and vaginal discharge. HPV vaccine awareness was unsatisfactory in both the respondents. Thus, there is a need to educate and aware the adolescent girls regarding HPV vaccination. Awareness regarding the prevalence of HPV infection and the cancer prevention benefits of the vaccine has to be made at the earliest to prevent the tomorrow's mothers being affected by cervical cancer.

Abstract

Background: Autoimmune disorders are chronic multisystem disorders affecting women of their reproductive age. Pregnancy among these women is complicated by the disease itself. Flaring up of disease, uteroplacental insufficiency due to vasculitis and drugs used for treatment are main reason for unfavourable pregnancy outcomes. The objective of this study was to analyze the pregnancy complications and outcome among 113 cases of autoimmune disorders.

Methods: This study is a retrospective analysis of case records of pregnant women with autoimmune disorders. This study was conducted at PSG IMSR and Hospital, Coimbatore, and Tamil Nadu from July 2012 to June 2018. The case sheets were retrieved from medical record department and the details such as type of disease, maternal age, parity, status of disease at conception, treatment taken during pregnancy, maternal complications and fetal complications were collected and analyzed.

Results: During 6-year period there were 113 pregnant women with autoimmune disorders, and they were studied of their previous and present pregnancy outcome. The disease incidence was 7.01% per 1000 deliveries. 40.7% were less than 25 years age group and 71.6% were multigravidae. We had forty-one patients (36%) who were positive for APLA syndrome which were the maximum number of patients with auto immune disorder in pregnancy and 37 patients (32.7) with SLE. We had significant numbers of maternal and fetal complications for common disorders. Most of the rare auto immune disorders were diagnosed before pregnancy and these pregnancies were managed by multi-disciplinary approach, and continued on immunomodulators throughout pregnancy, hence maternal and fetal complications were less for them.

Conclusions: Adequate pre-conceptional counseling, vigilant monitoring during pregnancy and post-partum will avoid pregnancy related complications and have favorable outcomes.

Keywords: Autoimmune disorder, Fetal complications, Immunomodulators, Maternal complications, Pregnancy outcome, Pre-conceptional counseling

Introduction

Autoimmune disorders are chronic multisystem disorders which are characterized by tissue damage and inflammation due to alteration of adaptive immune response in the absence of trigger.[1] Its prevalence is between 7.6%-9.4%.[2] Since most of the autoimmune disorders are diagnosed frequently during reproductive age in females, these women are at high risk not only during pregnancy but also during postpartum.[3] When compared to females without autoimmune disorders, these women carry more incidence of miscarriages in all trimesters, preeclampsia, intrauterine growth restriction, premature rupture of membranes, placental insufficiency, preterm labour, low birth weight and have increased caesarean section rates.[4] Though these pregnancies carry

high incidence of adverse effects, improved care in terms of pre-conceptional counselling and continuation of treatment throughout the pregnancy and post-partum have improved the outcome of pregnancies.[5]

M□□□□ □□

This study is a retrospective analysis of a total 113 case records of pregnant women with autoimmune disorders. This study was conducted at PSG IMSR and Hospital, Coimbatore, Tamil Nadu from July 2012 to June 2018. The case sheets were retrieved from medical record department and the details such as type of autoimmune disorder, maternal age, parity, status of disease at conception, treatment taken during pregnancy, maternal complications like pregnancy induced hypertension, gestational diabetes mellitus, thrombotic events, anemia, renal flares, thrombocytopenia, preterm labour, mode of delivery, indications for caesarian section and fetal complications like abortion, anomalies, intra uterine fetal demise, low birth weight, intra uterine growth restriction, oligohydramnios, need for admission to neonatal intensive care unit, low Apgar score were collected and analyzed.

Inclusion criteria

- All primigravidae and multigravidae who are known case of autoimmune disorder and all primigravidae and multigravidae who are diagnosed with autoimmune disorder during present pregnancy.

Exclusion criteria

- Pregnant mothers without autoimmune disorders.

□□□□ □□□

During this period of 6 years (2012-2018), there were 113 pregnant women with autoimmune disorders and study was carried out based on their previous and present pregnancy outcomes. The incidence of autoimmune disorders in pregnancy was 7.01% per 1000 deliveries.

Table 1 shows the number of pregnancies with autoimmune disorders in our study.

Takayasu	3 (60%)	-	1 (20%)	-	-	-	4 (80%)	-
Sjögren syndrome	-	1 (25%)	-	-	-	-	3 (75%)	□□

In our study, most of the patients were below 30 years of age. Table 2 shows the age group distribution. Multigravida (71.6%) were more in number than primigravida (28.3%) in our study.

Parity distribution is shown in Figure 1.

Table 3 shows the most common autoimmune disorders in our study and their maternal complications.

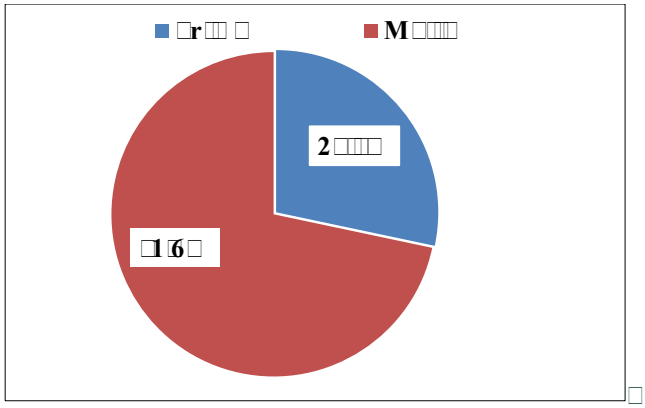

Table 3: Maternal complications in previous pregnancy.

Disorder	Number	Percentage
APLA	26 (63%)	9 (21.9%)
SLE	22 (59%)	5 (13.5%)
ITP	4 (36%)	-
Takayasu	-	1 (20%)
Sjögren syndrome	3 (75%)	-

Two patients diagnosed with SLE had abnormal doppler changes at 32 weeks and 34 weeks respectively and underwent caesarean section. The most common indication for caesarean section was non-progression of labour followed by previous section.

Table 4 shows fetal complications in previous pregnancy for more common disorders in our study.

Table 4: Fetal complications in previous pregnancy.

Disorder	IUGR	Abortion	Stillbirth
APLA	7 (17%)	2 (4.8%)	1 (2.4%)
SLE	13 (35%)	6 (16%)	5 (13.5%)
ITP	2 (18%)	-	1 (9%)

LBW	24.3%	22%
NICU admission	13.5%	15%

APLA

Obstetric antiphospholipid antibody syndrome (OB-APS) is defined according to the updated Sydney classification criteria developed by expert consensus agreement in 2006.[6] APLs include the lupus anticoagulant, anticardiolipin IgG and IgM and anti-β2-glycoprotein I antibody. In addition to the detection of aPLs on at least two occasions more than 12 weeks apart, OB-APS is defined by any one of the following adverse pregnancy outcomes: 1) otherwise unexplained recurrent pregnancy loss before the 10th week of gestation, 2) otherwise unexplained fetal death ≥10 weeks of gestation, 3) preterm birth before 34 weeks of gestation due to preeclampsia or placental insufficiency.[7] Other OB-APS complications include catastrophic APS, thrombosis, HELLP syndrome (hemolysis, elevated liver enzymes, and low platelet count), IUGR, fetal distress, premature rupture of membranes, and thrombocytopenia.[8] It has been recognized that among the three aPLs, lupus anticoagulant (LAC) is the primary predictor of poor pregnancy outcome in women both with or without SLE, and with or without other aPLs.[9] Among the 41 patients with APLA, 20 patients were positive for lupus anticoagulant antibody, 11 were positive for anticardiolipin antibody and 10 had anti-β2-glycoprotein I antibody.

In our study, 31.8% of patients with primary APLA and 4.4% of patients with secondary APLA with associated SLE were diagnosed. The incidence of pre-eclampsia among APLA positive patients in our study was 4.8% whereas in Wijeyaratne study, it was 10.9%.[10] Similarly the incidence of GDM in our study was 31% as compared to 19.2% in Wijeyaratne study. In our study 2.4 % had preterm labour and 17% of patients underwent cesarean section. In regard to fetal complications, 63% of patients in our study had previous one or more abortions which was comparable to Wijeyratne study (59.8%). The incidence of IUD in previous pregnancy was 21.9.%. The incidence of low birth weight babies was 12% and babies requiring NICU admission was 2.4% respectively.

SLE

Systemic lupus erythematosus (SLE, or “lupus”), affects females in a 9:1 ratio to males.[11] The adverse pregnancy

outcomes observed with lupus are well known, and include increased rates of intrauterine growth restriction (IUGR), preterm birth and fetal loss, as well as the syndrome of neonatal lupus (NL), associated with trans placental passage of auto antibodies. The risks for thrombosis, infection, thrombocytopenia, and transfusion were each 3- to 7-fold higher for women with systemic lupus erythematosus. Lupus patients also had a higher risk for cesarean sections (odds ratio: 1.7), preterm labor (odds ratio: 2.4), and preeclampsia (odds ratio: 3.0) than other women. Women with systemic lupus erythematosus are more likely to have other medical conditions, including diabetes, hypertension, and thrombophilia, that are associated with adverse pregnancy outcomes.[12]

High disease activity at the time of conception or in the months preceding conception is an independent predictor for increased risk of adverse pregnancy outcomes including prematurity, IUGR and fetal demise. This has led to the current recommendations that lupus patients achieve 6 months of disease quiescence prior to attempting conception.[13] Maternal and fetal complications associated with SLE were compared with Eman et al study.[14] These are shown in table 6 and 7 respectively.

Six patients had first trimester abortions in the current pregnancy.

Takayasu syndrome

In our study, 60% patients had hypertension complicating pregnancy whereas in Mandal et al study had 92.8%.[15] Caesarean section rate in our study was 60%, whereas in Mandal study it was 71.4%. Intrauterine growth restriction was 60% in our study, which was comparable with Mandal et al study (51.7%).

Schönlein-henoch purpura

Schönlein-henoch purpura (SHP) is a systemic vasculitis that affects vessels of a small caliber.[16] The onset of SHP during pregnancy is very rare. Treatment with orally administered corticosteroids may lead to a beneficial outcome for both mother and newborn.[17] In our study, we had 2 patients diagnosed with Schönlein-Henoch purpura, of which one developed GDM, other had uneventful pregnancy.

Medium vessel vasculitis

Most of the women with medium vessel vasculitis fared well during pregnancy without significant disease progression, but instances of aneurysm rupture, renal insufficiency, pulmonary embolism, and myocardial infarction were reported in Gatto et al study.[18] In our study, one patient diagnosed with medium vessel vasculitis developed myocarditis during pregnancy and she was managed with steroids.

ITP

Nine percent of chronic ITP patients in our study had preeclampsia, whereas Diego et al, study had 8.3%.[19] In our study 9% had preterm labour which was comparable to Diego et al (9.5%) study. Diego et al showed 8.5% of gestational diabetes in the study whereas in our study we had 54% of gestational diabetes which could be explained by ethnicity and usage of steroids.

In Yassaee et al, study occurrence of IUGR was 10.5% whereas in our study it was 18%, among which one baby was admitted in NICU.[20] In Yassaee et al study 57% of patients had moderate thrombocytopenia (more than 50,000) whereas 18% of thrombocytopenia and 9% of anemia were diagnosed in our study.

When comparing the caesarean section rate, Yassaee et al had 81% whereas we had 63%.

Rheumatoid arthritis

In women with well-controlled RA, pregnancy outcomes are comparable to the general obstetric population, whereas in women with higher RA disease activity, there is more chances of less favorable pregnancy outcomes.[21,22]

Akasbi et al, study showed improved maternal and fetal outcome in patients with RA in pregnancy. Similarly, in our study two patients diagnosed with RA had uneventful pregnancy.

Guillain-barré syndrome

Guillain-barré syndrome (GBS) represents a heterogeneous group of immune mediated peripheral neuropathies. A feature common to all GBS variants is a rapidly evolving polyradiculoneuropathy preceded by a triggering event, most often an infection. GBS generally manifests as a symmetric motor paralysis with or without sensory and autonomic disturbances. Delayed diagnosis is common in pregnancy or immediate post-partum period because the initial non-specific symptoms may mimic changes in pregnancy. GBS should be considered in any pregnant patient complaining of muscle weakness, general malaise, tingling of the fingers, and respiratory difficulty.[23,24]

We had one patient diagnosed with GBS who had an uneventful course during pregnancy.

Multiple sclerosis

Multiple sclerosis (MS) is an inflammatory disease in which the fatty myelin sheaths around the axons of the brain and spinal cord are damaged, leading to demyelination and scarring as well as a broad spectrum of signs and symptoms.[25] Pregnancy is typically a stabilizing period in the clinical course of MS. During the

third trimester the MS relapse rate can be 70% lower when compared with the time prior to pregnancy, but exaggeration of the disease is commonly seen postpartum. Presently, there is no evidence that MS patients are more susceptible to pregnancy or delivery related complications, such as ectopic pregnancy, pre-eclampsia, gestational diabetes mellitus, prolonged labour or miscarriage than women in general, nor is their infants more likely to be delivered preterm or to be of low birth weight, have malformations or experiences an early death.[26,27] Mothers with MS required operative delivery more often than healthy mothers, which might be attributed to MS-related symptoms such as neuromuscular perineal weakness and spasticity in addition to fatigue and exhaustion.[28] In our study, we had 3 mothers diagnosed with multiple scelerosis, of them one developed PIH, one had GDM.

Sjögren syndrome

Sjögren syndrome is known to occur predominantly in women. Affected women are likely to experience more complicated pregnancies than are women without the disease.[29] Its effect on pregnancy differs according to the maternal disease, disease activity, and severity of organ damage, antibody profile, and drug treatment.6.

Several studies have reported an increased rate of spontaneous abortion and fetal loss associated with Sjögren syndrome.[30] This may be explained by, first, the age of the patients at the time of concep-tion which usually belongs to an elderly age group and, second, a possible immunologic factor involved in the mechanisms of miscarriage.[31]

In our study, out of four mothers diagnosed with Sjögren syndrome, two had spontaneous abortions.

The outcome of pregnancies in women with Sjögren syndrome can be improved with use of a multidisciplinary approach for management involving an obstetrician who has specialized in high-risk pregnancies, a rheumatologist, and a pediatrician.[32]

Hashimotos thyroiditis

Hashimotos thyroiditis is associated with an increase rate of spontaneous.

Abortions, preterm delivery and increased use of cesarean section.[33] All the three patients diagnosed with Hashimotos thyroiditis underwent cesarean section for non-progression of labour.

Ulcerative colitis

Stephansson et al study concluded that pregnant women with ulcerative colitis had a greater number of preterm births, babies with low birth weight and cesarean section deliveries than those without ulcerative colitis.[34] In our study we had one patient who delivered a low birth weight baby of 2.2 kg. One patient diagnosed with multisystem connective tissue disorder had an intra uterine growth restriction and the same baby had low birth weight.

Von Willebrand's disease

Pregnancy and delivery are considered events predisposing to a high risk of bleeding in women with von Willebrand's disease.[35]

Our patient did not have any complication. All the patients diagnosed with GDM were found to be on steroids.

Among the 113 patients, 3 underwent caesarean section in view of abnormal umbilical artery doppler findings.

Patients previously diagnosed were continued on disease modifying agents and this could be the reason for their successful pregnancy outcome.

Rauto immune disorders were diagnosed before pregnancy and these pregnancies were managed by multi-disciplinary approach, and continued on immune modulators throughout the pregnancy, hence minimizing maternal and fetal complications.

□□□□□□□□□□

In our study, most of the patients were either continued on the same treatment they were taking before pregnancy or were started on treatment once they were diagnosed with autoimmune disorders, and hence they were found to have successful pregnancy outcomes. Therefore, appropriate pre-conceptional counselling, continuation of treatment, intense maternal and fetal monitoring and timely delivery plays an important role in improving the pregnancy outcome.

Abstract

Background: Ectopic pregnancy (EP) is a common, life threatening emergency during the first trimester and a significant cause for maternal morbidity and mortality. In any woman of reproductive age presenting with abdominal pain and vaginal bleeding, ectopic pregnancy should be considered. The objectives of the present study is to determine the incidence, risk factors, clinical presentation, type of ectopic pregnancy, treatment, morbidity and mortality.

Methods: Retrospective analysis of case sheets of patients admitted with ectopic pregnancy at PSGIMSR, Coimbatore during the period July 2011 to June 2016 was done. The details noted were age, parity, risk factors {previous abortion, previous EP, previous pelvic surgery, intrauterine contraceptive device, tubectomy, history of pelvic inflammatory disease}, treatment for infertility, clinical presentation, ultrasound findings, investigations including beta HCG value and hemoglobin level, treatment offered, need for blood transfusion, operative findings and morbidity.

Results: During the five year, there were 12,407 deliveries at our hospitals and 88 cases of ectopic pregnancies were managed. The incidence is 6.6/1000 deliveries. Among them 44% belonged to the age group of 25-30 years and multi gravida were 73.8%. Most common risk factors were previous abortion (23.8%) and previous surgeries including caesarean section, tubectomy, appendicectomy, tubal microsurgery (23.8%). Most common presentation was pain abdomen (85.2%). Out of the 88 cases, 73 patients were managed surgically (82.9%) and 11 cases were managed successfully with methotrexate (12.5%). Three of them underwent conservative management and one had Uterine Artery Embolization.

Conclusions: Early diagnosis based on risk factors and timely intervention plays a main role in reducing morbidity and mortality associated with ectopic pregnancy.

Keywords: Beta HCG, Ectopic pregnancy, Methotrexate, Risk factors, Salphingectomy Transvaginal USG

Introduction

An ectopic pregnancy is implantation of fertilized ovum outside the normal endometrial cavity i.e, fallopian tube, ovary, caesarean scar, cervix and peritoneal cavity.[1] In the first trimester, ectopic pregnancy is the most common cause for maternal morbidity and mortality.[2] It has also been shown that EP reduces future fertility and increases the chance of subsequent EP.[3] The incidence of EP is increasing since the last decade, but the incidence of complications like rupture and morbidity are declining due to early diagnosis with serial Beta-HCG(human chorionic gonadotrophin) monitoring, transvaginal USG(ultrasonogram) and minimally invasive surgery.[4] Early diagnosis not only reduces the risk of tubal rupture but also allows for conservative and medical management.[5] Prior damage to the fallopian tube due to PID(pelvic inflammatory disease), tubal surgeries, pelvic adhesions are the major risk factors for ectopic pregnancy.[6] The other identified risk factors are,

advanced maternal age, previous EP, previous pelvic surgeries, IUCD (intra uterine contraceptive device) insertion and infertility treatment.[7-12] Identifying these risk factors among high risk mothers helps in early diagnosis and reduces the morbidity related to this condition.[13] Unfortunately, most of the patients presenting with EP do not have risk factors.

M□□□□□□

This was a retrospective analysis of case records of patients admitted with ectopic pregnancy, done at PSG IMSR Hospital, Coimbatore from July 2011- June 2016.

Inclusion criteria

We included all the patients with suspected ectopic pregnancy who were confirmed by βHCG and transvaginal ultrasound.

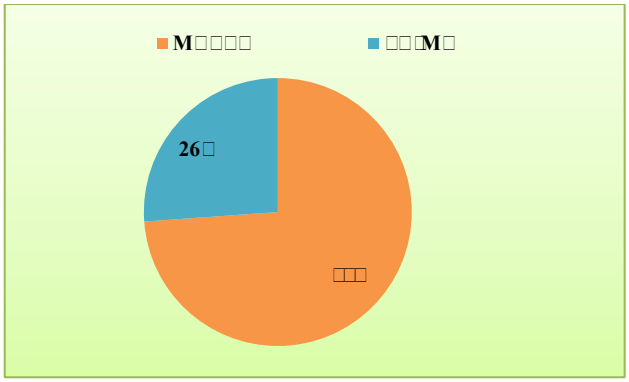
Exclusion criteria

None

Methodology

The case sheets were retrieved from medical record department and the details such as age, parity, risk factors like previous abortion, previous EP, previous pelvic surgery, contraception in the form of IUCD and tubectomy, history of PID, infertility treatment, clinical presentation, investigations including beta HCG value, hemoglobin level, treatment offered, need for blood transfusion, operative findings and morbidity were collected and analyzed.

Statistical analysis



No statistical tool used.

□□□□□□□

During the 5-year period, there were 12,407 deliveries at our institution and 88 cases of ectopic pregnancies were managed. The incidence was 6.6/1000 deliveries. Among the patients most of them belonged to the age group of 25-30 years (Table-1). 26% of patients were primigravida, 73.8% of patients were multigravida (Figure -1).

As shown in (Table 2) 23.8% of patients had one or more spontaneous or induced abortions.23.8% of patients had undergone pelvic surgery (Caesarean section, tubectomy appendicectomy, tubal recanalistion). PID and previous ectopic pregnancy accounted for 4.5% each.

Most of them presented between 5-8 weeks of gestational age (61.3%).27.2% of patients were diagnosed before 4 weeks of amenorrhea and 11.3% were above 9 weeks. All the cases had been confirmed by USG.17 of them had Beta-HCG less than 1000 m I U /ml. A patient with heterotopic pregnancy had Beta -HCG of more than 1 lakh m I U /ml.

Commonest site of ectopic pregnancy was fallopian tube in 93% of patients (Table 4).

Laparoscopy	2	2.4
Conservative	3	3.6

Twenty-one patients were fit into medical management, among them 12.5% of patients were managed medically with methotrexate successfully.

10 cases failed to medical management which were subsequently managed with either laparoscopic or laparotomy and salphingectomy.

3 cases were managed conservatively by observing the declining trend of Beta-HCG.

Other types of ectopic

Caesarean scar pregnancy was diagnosed in 3 patients, among them 2 patients underwent surgical excision. One patient was managed with UAE (uterine artery embolisation) followed by methotrexate. Heterotopic pregnancy following ovulation induction which resulted in twin intra uterine gestation and tubal ectopic was noted in one patient and she underwent emergency laparotomy and salpingectomy. Two patients were diagnosed as having ovarian ectopic and surgical excision was offered to both of them. Most common morbidity noted was anemia in 42%, out of which severe anemia (4-7gm) was seen in 5.6% (Table 8). Among them 28.4% of patients received blood and blood products. No surgical site infection or mortality was noted.

[illegible]

The incidence of ectopic pregnancy among women attending emergency department with first trimester abdominal pain, bleeding or both is between 6-16 %(14). A study conducted by Shraddha Shetty et al had incidence of 5.6/1000 deliveries.[15] In our study the incidence is 6.6%/1000 deliveries which is comparable. Majority of patients were between 25-30years which is similar to the above study and Khaleeqe et al.[15,16]

As in Karki et al (17), we had similar higher incidence of ectopic pregnancies (73.8%) in multigravida. In our study, the commonest predisposing factors were previous abortion either spontaneous or induced, previous pelvic surgeries including caesarean section, history of IUCD insertion, tubectomy, history of PID and infertility treatment, which are similar to various other studies.[17,18] As in the studies by Porwal Sanjay et al, Shraddha Shetty et al, the most common symptom in our series was pain abdomen which is comparable.[15,18]

Urinary beta HCG, serum beta HCG, transvaginal USG are the diagnostic tools for diagnosing EP. USG should be the investigation of choice for symptomatic women. In asymptomatic women, serial monitoring of serum beta HCG should be done. As in the study by Shraddha Shetty et al, we also had more number of right sided EP and involvement of the ampullary portion of the tube.[15]

Heterotopic pregnancy is rare in natural conception which is around 1 in 30,000 pregnancies. But the incidence is more in case of ovulation induction or with

assisted reproduction techniques. In our study, we had a case of triplet heterotopic pregnancy following ovulation induction with clomiphene citrate. It is recommended that even patients shown on ultrasound to have intrauterine pregnancy should be given comprehensive pelvic ultrasound so that possibility of synchronous heterotopic pregnancy can be excluded, particularly in pregnancies following fertility treatment.[19]

In our study, ruptured EP was noted in 53% of cases, 43.9% of cases had an unruptured ectopic gestation. In Latchaw G et al study, the same were 59% and 41% respectively.[20]

Laparoscopy and medical therapy have now emerged as the widely used therapeutic modalities with great success in terms of reduced morbidity, shorter hospital stay and conservation of fertility.[21] However choice depends upon early identification of ectopic pregnancy and hemodynamic status of the patients.[22] In our study, 11% of patients responded well to single dose of methotrexate.

Surgery should be the treatment of choice in unstable patient.[19] In our study 13.6% were unstable and all of them were managed surgically. Commonest surgery performed was partial/total salpingectomy. We did bilateral total salpingectomy for patients who had undergone tubectomy previously and were not desirous of future childbearing. It has been extensively studied and reported that conservative management does not increase the risk of future ectopic.[15] In our study, three patients were managed conservatively by observing the declining trend of Beta HCG. Morbidity included anemia, blood transfusion and wound infection. In our study, we had 42% of patients with hemoglobin level of less than 10grams. Among them 28.4% of patients received blood and blood products. No surgical site wound infection was noted.

No maternal mortality was noted in our study which is consistent with the study by A Abbas et al.[23] Early identification of the patients with EP by a multipronged approach including high index of suspicion, risk prediction, serum beta HCG and transvaginal ultrasound helps in improving the prognosis as far as morbidity, mortality and future fertility are concerned.[24]

□□□□□□□□□□

Identification of underlying risk factors, early diagnosis with essential investigating modalities like beta-HCG, transvaginal USG, timely intervention with medical or surgical method will definitely reduce morbidity and mortality and improve the future reproductive outcome.

Abstract

Background Recent literature supports the removal of myomas during cesarean section, which traditionally was considered a relative contraindication, given a higher complication rate. This study is to share our experience of cesarean myomectomy in the last decade.

Methods This study is a retrospective review of our prospectively maintained database, from January 2008 to December 2017, at a tertiary care level teaching institution. All patients who underwent myomectomy during cesarean section were included. There were no exclusions.

Results A total of twenty patients underwent myoma removal along with the cesarean operation during this period with a mean age of 30 years. Majority of patients were nulliparous (70%). Common comorbidities were diabetes mellitus (40%) and hypothyroidism (20%). Mean size of myomas were 5.33 cm (± 2.08), and the number varied from one to three. The most common location was the posterior surface of the uterus with the commonest variety being subserous. Most patients were discharged on the fifth postoperative day.

Conclusion This study demonstrates that cesarean myomectomy to be a safe and feasible procedure in experienced hands. It offers the advantage of avoiding a second surgery in selected patients.

Keywords Cesarean myomectomy · Myoma uterus · Cesarean delivery · Myomectomy

Introduction

The myomas are the most common benign tumors of the uterus. The highest reported incidence of myomas during pregnancy is 10.7% [1]. The myomas are common during the reproductive period due to an influence of higher estrogen levels. Their increased incidence during pregnancy can be partly explained by the late age of conception [2]. Myomas in pregnancy are associated with a significantly higher risk for cesarean section (CS).

Conventionally, concomitant myomectomy during CS was considered a relative contraindication, given perceived higher complication rate. Last decade has witnessed emerging literature evidence supporting myoma excision along with CS, with acceptable results [3]. This study aims to share our experience of cesarean myomectomy during the last decade.

Materials and Methods

This study is a retrospective review of our prospectively maintained database of the last decade, from January 2008 to December 2017, at a tertiary care teaching hospital. All consecutive patients who underwent myomectomy during cesarean section, in this mentioned duration, were included.

This formed a small subset, among the patients, having uterine myomas and pregnancy, a majority of those underwent vaginal delivery or had LSCS, without myomas removal. Those not matching the inclusion were not considered. There were no exclusions. The institutional ethical committee approved the study, and waiver of consent was obtained, in view of retrospective nature.

Data were collected from outpatient and inpatient records, operative and discharge notes. Data included maternal demographics such as age, parity, medical diseases, prior surgery, gestational age at the time of CS, type of anesthesia, indication for CS, elective/emergency and number of previous operations including CS. Myoma characteristics such as size, number, location and variety were noted. Other parameters like an indication for myomectomy, the number of incisions made and the presence of adhesions were observed. The total duration of surgery was taken as the time from the initial skin incision to skin closure. Approximate intraoperative blood loss was measured, and record of transfusion if any was noted. Postoperative drop in hemoglobin was checked at 48 h after surgery, and blood transfusion was given if the fall was more than 3 gm/dl. Postoperative complications like pyrexia (> 38-degree C) and wound infection were analyzed. Duration of hospital stay was noted, and patients were followed up after 2 weeks in the outpatient department.

Patients were counseled during the early third trimester regarding the need for myomectomy depending on the mode of delivery and consent obtained for the same.

Experienced gynecologists performed surgery with minimum of 10 years of experience. Preoperatively, half an hour before skin incision Inj. Tranexamic acid 1 gm in 100 ml isotonic saline was infused over 20 min. Except in four cases, myomas were situated at the incision site, and in other instances, CS preceded myomectomy. When myomas were located at the lower uterine segment, myomectomy was performed before delivery of the fetus. During CS, myomas were inspected for their size, number, type and location after the closure of the uterine incision (Fig. 1).

Though myomectomy was tried with a single incision, in few cases where multiple fibroids were present, more than one incision over uterus was needed. An incision was made over myoma by using monopolar cautery, and the tumor was enucleated. To achieve hemostasis, bipolar cautery was used. The defect in the myometrium was closed with 1-0 vicryl suture (Fig. 2). High-dose oxytocin infusion was continued postoperatively for 24 h to prevent bleeding.

Results

A total of twenty patients underwent myoma removal along with the cesarean operation during this period with a mean age of 30 years. Majority of patients were nulliparous (70%).

Fig. 1 Multiple fibroids over the anterior surface of uterus postdelivery of the baby

Fig. 2 Postmyomectomy, closure by baseball sutures

Common comorbidities were diabetes mellitus (40%) and hypothyroidism (20%). One except all patients received regional anesthesia (spinal/epidural); the only case needed general anesthesia due to the presence of idiopathic intracranial hypertension. Sixty-five percent of surgeries were elective operations. The details of various preoperative characteristics are shown in Table 1.

Intraoperatively, two patients had small bowel and omental adhesions at the operative site. Two patients (10%) received a blood transfusion during the procedure. The mean hemoglobin drop reported 24 h postoperative was 1.23 (± 1.16) grams. No patient warranted blood transfusion in the postoperative period (Table 2).

Majority of patients got the discharge on the fifth day of surgery. There were no incidences of postpartum pyrexia or

surgical site infections. The patients were regularly followed in the outpatient department.

Discussion

Fibroid excision along with caesarian section was considered difficult until recently. Fibroids with pregnancy might cause miscarriage, preterm delivery, premature rupture of membranes, early separation of the placenta, labor dystocia, postpartum hemorrhage and increased rate of operative deliveries. Fibroids might also undergo red degeneration and associated complications. Myomectomy during CS has not been done routinely due to the risk of uncontrolled bleeding and the possibility of hysterectomy [4]. If myomectomy is not performed along with CS patient might need another surgery to remove it, which amounts to two operations, two anesthetic exposures and increasing cost, and there is also an enhanced risk of complications caused by fibroids in a subsequent pregnancy.

The average age of mothers in our study was 30 years. Most studies have shown myomas to be more common in nulliparous women [5]. We too observed a higher incidence of myomas among nulliparous women (70%) [6]. This could be explained due to hormonal changes and reduced sensitivity of leiomyoma to estrogen receptor [7].

Similar to many other studies, the average gestational age at the time of CS was 37 to 38 weeks in our study [4, 6, 8]. We had four patients delivering at 35 to 36 weeks of gestation. Among these four patients who had delivered prematurely, three deliveries can be attributed to the presence of fibroids. Two out of these patients have already undergone fibroid removal before becoming pregnant. The possible explanation for preterm labor could be decreased distensibility of uterine myometrium due to the presence of fibroids as the pregnancy advances [9].

Though CM is to be avoided in cases of the previous myomectomy due to more chances of complications [10], we had the opportunity to do repeat CS for one of our patient who underwent CS myomectomy 3 years ago. The indication for primary CS was a transverse lie. The malpresentation was suspected to be due to a single large (8 cm), intramural fibroid located in the lower uterine segment. Incidentally, this was the largest myoma we had come across in our study. As the fibroid was situated in the incision site, myomectomy was followed by CS. During repeat CS, which was done 3 years later, there was no fibroid detected intraoperatively. There were three more cases of lower uterine segment (LUS) fibroids; if they were less than 5 cm, then myomectomy were done following the delivery of the baby. All fibroids present in the LUS were removed through the same CS incision, without any additional incision on the uterus. The same technique was suggested in several other studies [11, 12].

Three of our patients had undergone myomectomy previously in the non-pregnant state. One of the women had undergone myomectomy twice before becoming pregnant. This confirms the well-established fact that fibroids are recurrent [13]. Among the study group, the patients who had undergone previous myomectomies had a high incidence of intraoperative adhesions as expected. However, in all three patients, the surgery was uneventful with minimal blood loss and no added morbidity.

Eight of our study subjects had multiple fibroids. Six patients had fibroids of size 8 cm (largest dimension). 55% of the myomas had size > 5 cm. The smallest dimension encountered was 2.5 cm. We had more anterior wall fibroids than posterior [4]. Traditionally myomectomy is avoided in cases of fundal and cornual sites because of excessive

bleeding and possible obstruction of fallopian tubes [14, 15], but in our study, myomectomy was done regardless of the location of the myomas.

Except for a single instance of the submucosal fibroid, there was an even distribution of intramural and subserosal fibroids. Removal of submucosal fibroids during cesarean section is usually avoided as it involves resection of the full thickness of myometrium and reduced contractility might lead on to increased hemorrhage [16]. Secondary changes due to red degeneration were found in a case with single sizeable fundal fibroid. Histopathological reports of all myomectomy specimens were closely followed up, and none showed malignant change.

The same incision removed fibroids in the anterior wall and close to CS incision. Whenever possible, a minimal number of incisions were made, and adjacent ones removed through the same incision. This was done to reduce blood loss and future adhesions and improve reproductive outcome. While the operating time was more or less uniform in most of our cases, two of the cases exceeded the average operating time significantly. In these two instances, the increased operating time could be explained by multiple fibroids needing more than a single incision for removal. Other studies have also observed more than average operating time in cases of multiple fibroids [17].

Intraoperative blood transfusion was done in two cases only as they met the criteria for blood loss of more than one liter. One case had a fibroid at the incision site. The second patient who had a loss of more than two liters which was the largest in our series had three fibroids at different locations and they were removed by as many incisions. Despite intraoperative transfusion and other pharmacological measures to attain hemostasis, she had a significant drop in hemoglobin at 48 h postoperatively and needed another transfusion. She had no other postoperative morbidity like pyrexia or ileus and was discharged on the fourth day after surgery.

CM is not done routinely, because of the associated hemorrhage and the need for the hysterectomy [15]. Specific hemostatic techniques have been advocated by various authors [18, 19], but we have followed tranexamic acid infusion, vasopressin instillation, uterine artery ligation, electrocautery and high-dose oxytocin. There was not a single case which needed a hysterectomy in our study of twenty cases, though patients were counseled regarding the possibility in the prenatal period due to intractable hemorrhage. We also found no increased postoperative morbidity or expanded hospital stay in any of our patients who underwent CM as was observed by Dam Hye Kwon et al. [8].

There are a few limitations to our study. Its retrospective design coupled with proportionally small sample size limits generalization of results. This study also lacks long-term follow-up of these patients and thus to highlight effect on future pregnancies. Additionally, as this study was conducted in a tertiary level medical college setup with available expertise, the results cannot be generalized, especially in comparison with smaller installations or in the absence of an expert.

We author would like to stress this to the readers that routine use of myomectomy during CS is neither advisable nor been followed in the current study. The CM should be carefully planned for selected patients in an appropriate setup and expertise. A similar conclusion is drawn by a recent review on this topic [20], recommending standardization of best practices for CM, with the availability of more robust data and in the presence of necessary facilities.

Conclusion

Overall, our series has shown CM to be a safe and feasible procedure in well-selected patients in a tertiary care center with experienced hands. It can offer an advantage of avoiding a second intervention in selected patients. Appropriate hemostatic techniques can curtail hemorrhage which is the most severe complication. Long-term morbidity concerning future reproductive outcome should be addressed in a study with large participants and reliable design.

Authors' Contributions All authors have a significant contribution for preparation of this manuscript, following ICMJE Guidelines. First and second authors share the first position.

Compliance with Ethical Standards

Conflict of interest No author has any potential conflict of interest.

Ethical approval The current study is approved by the responsible institutional ethics committee for human research and fully comply with the declaration of Helsinki for guideline on human research.

Background: Authors sought to determine the possible factors in the causation of nonimmune hydrops foetalis by perinatal autopsy with placental examination and to reduce the number of cases in which the cause remains elusive.

Methods: Twenty five cases of nonimmune hydrops foetalis were identified in about 200 consecutive perinatal autopsies (including placental examination) performed during a 11 year period. The results were correlated with clinical, laboratory and imaging characteristics in an attempt to establish the aetiology.

Results: Perinatal autopsy and placental examination confirmed the following aetiologies: cardiovascular causes (8) [isolated (4), syndromic (3) and associated chromosomal (1)], placental causes (5), chromosomal (4) [isolated(3) and associated cardiovascular disease (1)], intrathoracic (3), genitourinary causes (3), infections(1),gastrointestinal lesions (1) and idiopathic causes (1). Placental mesenchymal dysplasia was a unique pathology identified among the placental lesions, which constituted the second most common cause of nonimmune hydrops foetalis. Despite careful examination no cause was identified in one case. In more than 50% of studied cases, autopsy examination either refuted or altered the ultrasound diagnosis completely.

Conclusions: The perinatal autopsy in combination with placental study and prenatal imaging represents the most promising tool in the evaluation of aetiology of nonimmune hydrops foetalis. The identification of a cause for nonimmune hydrops foetalis will provide a better correlation with recurrence risk and parental counselling.

Keywords: Aetiology, Nonimmune hydrops foetalis, Perinatal/foetal autopsy, Placental mesenchymal dysplasia, Prenatal imaging

Introduction

Foetal hydrops is a syndrome characterized by generalized skin oedema and abnormal accumulation of fluid in one or more serous cavities of foetuses. It has been broadly classified into immune mediated (materno - foetal blood group incompatibility) and non immune types. There is a steady fall in the incidence of immunologic hydrops foetalis due to the prevention of maternal isoimmunisation and treatment of affected foetuses in utero.[1] This has shifted the focus towards the non immunologic causes of hydrops which now constitutes up to 90% of cases of foetal hydrops.[2]

There are many impressive and ever growing causes of non immune hydrops foetalis (NIHF) and its development is known to be associated with maternal, foetal and placental diseases.[3] The foetal hydrops can be identified anytime throughout the pregnancy. The perinatal mortality rate is generally high. The spectrum of possible causative factors of NIHF include cardiovascular diseases, chromosomal aberrations, haematologic

abnormalities, infections, intrathoracic lesions, lymphatic dysplasias and placental causes including twin-twin transfusion syndrome. The other causes are syndromes, urinary tract malformations, inborn errors of metabolism, extra thoracic tumours, gastrointestinal disorders, miscellaneous and idiopathic.[4]

Improvements in obstetric ultrasound (USG) and foetal echocardiography enable the early and frequent detection of hydrops, resulting in foetal interventions / termination of pregnancy and have altered the incidence of hydrops.[5]

Given the multiple aetiologies of NIHF, we sought to determine the presence of possible factors in its causation by analysing the autopsy with placental material and to reduce the number of cases in which the cause remains elusive.

M□□□□□□□

Twenty five cases of NIHF were identified in about 200 consecutive perinatal autopsies (including placental examination) performed during a 11 year period from January 2007 to December 2017 at the department of pathology, PSG Institute of Medical Sciences and Research. The institutional ethical review board approval was obtained for the study.

Exclusion criteria

Hydrops foetalis of immunologic origin were excluded from the study on the basis of blood typing, direct and indirect coomb's tests.

The detailed maternal history, antenatal ultrasounds and genetic tests if any were collected. The autopsy was performed after getting informed consent. Photograph of the foetus was routinely taken with special attention to sites where abnormalities were suspected. A thorough systematic examination of foetuses and placenta was done, which included foetogram, foetal weight, anthropometric measurements (head circumference, chest circumference, abdominal circumference, crown rump length, crown heel length, foot length), external and internal examination.

After opening the body cavities, serous fluid collections were measured, and the thoracic and abdominal organs were removed en bloc. All the visceral organs were examined, and the bits were given for microscopic analysis. The brain was removed, inspected, weighed and suspended in a formalin fixative. After fixation, the brain was sliced; examined and relevant bits were taken. Examination of bone, including marrow and spinal cord were performed in selected cases. The placenta and cord were also examined thoroughly, photographed (maternal / foetal surfaces, parenchyma, umbilical cord), cut at 1cm intervals and the parenchyma was assessed for specific lesions. Relevant lesional sections were taken along with 2 sections of membrane roll, 2 sections from the umbilical cord and 3 full thickness sections of the normal parenchyma.

All the histologic sections were stained with haematoxylin and eosin. Special stains such as Grocott-Gomori's methenamine silver (GMS), Giemsa stains for toxoplasma gondii, warthin starry stain for spirochetes and reticulin stain for vascular network were done, when required. Immunohistochemical marker for cytomegalovirus was available, hence done for suspected infectious cases. After the microscopic study, the results were correlated with clinical, laboratory and imaging characteristics and the final results were drawn.

□□□□□□□□

Out of 200 perinatal autopsies performed during the 10-year period, 25 cases met the criteria for NIHF, representing 12.5%. The gestational age ranged from 13 weeks to 35 weeks. All were dead-born foetuses except two. The two liveborn foetuses were delivered at 35 weeks and survived only a few hours postnatally. There were no cases of multiple gestation.

Clinical findings

Maternal age ranged from 19 to 35 years, of whom 9 were primigravidas. Five cases each of polyhydramnios and oligohydramnios were present. Maternal medical diseases included 2 cases each of preeclampsia and autoimmune diseases and 1 case each of hypothyroidism and rheumatic heart disease. None of the mothers had diabetes. Recurrence of hydrops was found on 5 occasions. Previous history of hydrops was documented in 2 cases of cardiac (complete heart block and transposition of great arteries with ventricular septal defect), one case each of intra thoracic lesion (Congenital pulmonary airway malformation), chromosomal (Down syndrome) and placental mesenchymal dysplasia.

Ultrasound findings

Hydrops foetalis is diagnosed with typical findings during prenatal imaging. The sonographic features include subcutaneous / scalp oedema, fluid accumulation in different serous cavities (Figure 1), polyhydramnios and placentomegaly. Correlation between prenatal USG and autopsy findings in elucidating the causes of hydrops were studied (Table 1). Complete agreement between prenatal USG and autopsy findings were seen in 11 cases (44%), while in 6 cases autopsy examination revealed additional findings (24%). In 8 cases, autopsy findings changed the diagnosis (32%).

Autopsy findings

Foetus

There were 12 males and 13 females with an almost equal gender distribution. Hydrops was noted in <20 weeks (10

cases), 21-28 weeks (10 cases) and >28 weeks (5 cases) of gestation. Aetiological distribution of NIHF is listed in Table 2.

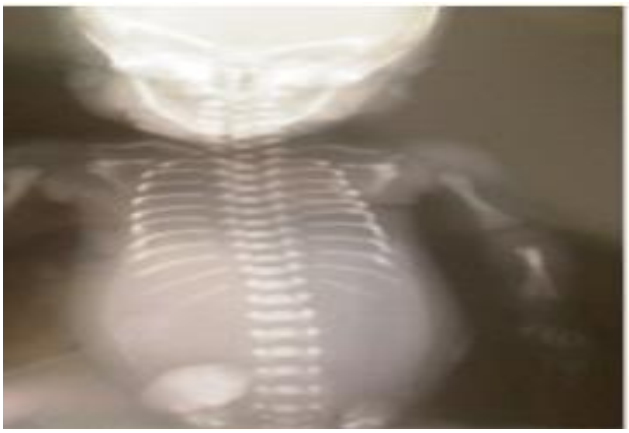
Cardiovascular diseases (n=8)

Congenital cardiac defects represented the largest aetiological group and were seen in 8 foetuses (32.0%). Among these 8 cases, 7 foetuses had structural malformations and 1 had functional defect. 2 cases of isolated cardiac defects, 3 cases of syndromic association and one case of chromosomal abnormalities were identified (Table 3). Cystic hygroma was noted in 2 instances.



[illegible]

[illegible]	[illegible]
Premature closure of ductus	
Complete heart block secondary to fibrosis of cardiac conduction system, immune mediated	
TGA with hypoplastic pulmonary arterial trunk	
Subaortic VSD	
TOF with right aortic arch and left sided PDA	VACTERL association
Secundum ASD	Multiple congenital anomaly syndrome -? Zellweger syndrome-? Smith Lemli Opitz syndrome
Common atrium with complete common AVSD	Ellis- Van Creveld syndrome
Common AVSD with persistent left superior vena cava and mild tubular hypoplasia of aortic arch	Down syndrome
TGA and VSD	Partial urorectal septum malformation sequence (Cloacal dysgenesis sequence)

TGA-transposition of great arteries; VSD-ventricular septal defect; TOF-tetralogy of fallot; PDA-patent ductus arteriosus; VACTERL-vertebral defects, anal atresia, cardiac defects, tracheo-esophageal fistula, renal anomalies, and limb abnormalities; ASD-atrial septal defect; AVSD- atrioventricular septal defect.

The most common causes of NIHF in our series were cardiovascular diseases, of which structural anomalies predominate. The most frequently found structural heart lesion with hydrops is atrio ventricular septal defects, and transposition of great vessels. Less common structural cardiac abnormalities observed were premature closure of ductus, tetrology of Fallot and secundum atrial septal defect. There were 2 cases of isolated heart defects. One foetus had premature closure of ductus and the other was a neonate with complete heart block. In the second instance, an association with maternal connective tissue disease was identified. This newborn female with complete heart block also had a sibling delivered at same gestational age with similar hydropic features and died within a few hours of birth. Autopsy was not performed

for the sibling. Our newborn was delivered preterm at 34 weeks of gestational age due to severe bradyarrhythmia. The neonate was hydropic, hypertonic and had intractable bradycardia at birth. Pace maker insertion was not acceptable to the parents. Child expired within 3 hours of birth. Autopsy examination revealed biventricular hypertrophy, dysplasia of atrioventricular valves, fibrosis of sinoatrial and atrioventricular nodes and patchy endocardial fibroelastosis.

In present series, cardiac defects were also seen in association with Ellis-Van Creveld Syndrome (Figure 2), Multiple congenital anomaly syndrome and VACTERL association.

There were 3 cases of Down syndrome, all with typical phenotypic manifestations and one with atrioventricular septal defect (Figure 5). The other significant associated anomaly noted was partial urorectal septum malformation sequence (Cloacal dysgenesis sequence).

Other disorders associated with NIHF

Placental, intrathoracic and genitourinary lesions are summarized in (Table 4).

Placental lesions (n=5)

The placenta was examined in all the cases and showed villous edema, prominent Hofbauer cells and villous capillary erythropoiesis.

Placental causes of hydrops were found in 5 cases. Two cases each of maternal vascular malperfusion and placental mesenchymal dysplasia. The underlying pathology in the fifth case was foetal vascular malperfusion (organising and recanalizing thrombi with avascular villi), villitis of unknown aetiology and acute chorioamnionitis.

Histologically, the cases with maternal vascular malperfusion had multiple parenchymal infarcts, increased syncytial knotting and distal villous hypoplasia. Preeclampsia was noted in both the mothers.

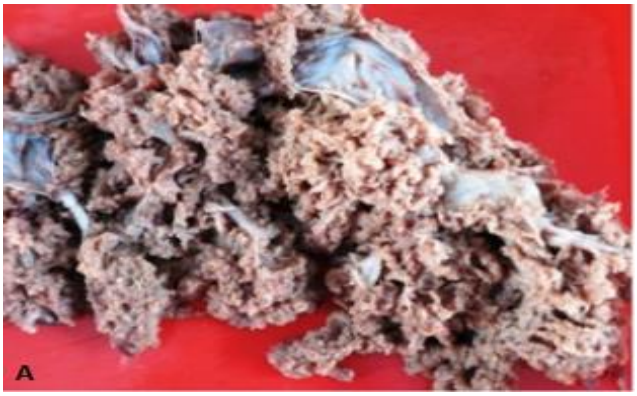


Figure 6: Gross photograph of placenta showing hypercoiled cord, parenchymal disruption with thick, oedematous villi and small vesicles

The placentas with mesenchymal dysplasia grossly showed hypercoiled cord, parenchymal disruption with thick, oedematous villi and small vesicles (Figure 6). Histologically, all villi showed collapsed vesicle with central cystic degeneration with absent trophoblastic proliferation and markedly dilated vascular channels (Figure 7).

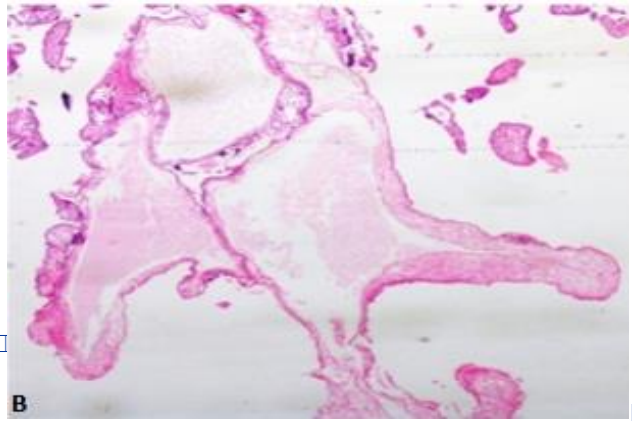

Figure 7: Histology showing collapsed vesicle with central cystic degeneration with absent trophoblastic proliferation and markedly dilated vascular channels

Table 2: Distribution of cases with non-immune hydrops fetalis and associated malformations

Placental causes (N=5)	Case 1: Preeclampsia, Multiple parenchymal infarcts, increased syncytial knotting: MVM
	Case 2: Preeclampsia, infarcts, Distal villous hypoplasia: MVM
	Case 3: The Placental parenchyma is disrupted, fleshy, pulled apart and the villi appear thick. The stem villi oedematous, hypercoiled cord : Placental mesenchymal dysplasia
	Case 4: Small vesicles in the parenchyma, thick stem villi: Placental mesenchymal dysplasia
	Case 5: placenta with FVM.VUE and A/C CAM
Intra thoracic lesions (n=3)	Case 1: Both lungs: dilated airways and lymphatics : CPAM
	Case 2: The right lung appears large and occupies almost the entire thoracic cavity: CPAM
	Case 3: Laryngeal (Glottic) atresia : CHAOS
Genitourinary abnormalities (n=3)	Case 1: BOO due to posterior urethral valve causing dilated posterior urethra, bladder, ureters and bilateral hydronephrosis. Ventriculomegaly, absent corpus callosum
	Case 2: Distal urethral stenosis with dilatation and hypertrophy of the urinary bladder: BOO. Pulmonary hypoplasia
	Case 3: BOO due to posterior urethral valves. Mild dilatation of both ureters and pelvis

CPAM- congenital pulmonary airway malformation; CHAOS- congenital high airway obstruction syndrome; BOO- bladder outlet obstruction; MVM-maternal vascular malperfusion; FVM- foetal vascular malperfusion; VUE- villitis of unknown aetiology; A/C CAM- acute chorioamnionitis

Authors did not find any chorangioma as a cause of NIHF.

Intrathoracic lesions (n=3)

There were 3 instances of intrathoracic lesions causing NIHF. Two cases of congenital pulmonary airway malformation (CPAM) (Figure 8) and one case of congenital high airway obstruction Syndrome (CHAOS) were identified in our series. Mediastinal deviation was noted in all foetuses.

Genitourinary abnormalities (n=3)

Three foetuses with NIHF were complicated by genitourinary causes. Two of them had bladder outlet obstruction (BOO) due to posterior urethral valves, and the third one had distal urethral stenosis with dilatation and hypertrophy of the urinary bladder. However, one

subject with posterior urethral valve also had ventriculomegaly, absent corpus callosum, deep posterior fossa, hypoplastic ductus and pulmonary arteries.

[illegible]

Chromosomal abnormalities (n=4)

Among cases with chromosomal abnormalities, we found one foetus with Turner syndrome, in which cytogenetic study revealed partial deletion of short arm of X chromosome. There were 3 cases of Down syndrome, all with typical phenotypic features and one foetus additionally had cardiac defect.

Miscellaneous causes

Congenital parvovirus B 19 infection was suspected in one instance. The foetus had marked subcutaneous oedema, serous effusions, enlarged liver and spleen. Lymphocytic infiltration of all viscera, predominantly myocardium with no identifiable inclusions were seen. The placenta had no lesion.

One of the foetus had hypertrophic pyloric stenosis which is a relatively uncommon cause of NIHF. The mother had polyhydramnios and autopsy revealed thickened and narrowed pylorus.

The cause of the hydrops foetalis could not be determined in only one case (4%) and it was classified as idiopathic. Subcutaneous oedema, serous effusions, micrognathia, high arched palate and dysmorphic villi were identified, and chromosomal abnormality was suspected. However, the karyotype was normal.

[illegible]

Nonimmune hydrops foetalis is a clinical sequel of wide range of pathology and is not a diagnosis in itself. It is known to be associated with maternal, foetal and placental diseases. In the past, the causes of hydrops were not identified in significant number of cases, even after extensive investigations. Postmortem examination including clinical assessments and targeted investigations can identify the underlying cause in majority of cases.

Cardiovascular diseases

Cardiovascular causes of NIHF accounts for about 20% of cases and includes both structural and functional defects.[6] In the present study cardiac defects represented the largest group and were found in 32% of foetuses.

Association of cardiac lesions with well-defined syndromes, chromosomal aberrations such as Down syndrome, cystic hygroma and additional major congenital anomalies were also noted in some of our cases.

The lone functional cardiac cause for hydrops identified in our study was complete heart block, which had serological evidence of maternal connective tissue disease. Even though sectioning is difficult, and time consuming, microscopic examination is critical in identifying fibrosis of the conduction system.

The cardiogenic hydrops would result from increase in right atrial pressure, reduced preload reserve and congestive cardiac failure.[7]

The immaturity of foetal myocardium (both structural and functional) with reduced relaxation is more vulnerable to any in utero insult leading to decrease in cardiac output.[1]

Hydrops associated with cardiac malformations generally have poor prognosis with high mortality. Recent developments in diagnostic capabilities of prenatal ultrasound along with in utero interventions will probably improve the outcome of foetuses with congenital cardiac lesions.[8]

Placental lesions

Interestingly, in present study group, placental lesions constituted the second most common cause of NIHF. Five of our patients demonstrated exclusive placental lesions significant enough to explain the aetiology of hydrops. Rodriguez et al, demonstrated placental pathology as the cause of hydrops in 10 patients (19.6%). In agreement with their study we too observed a similar incidence.[9]

Notwithstanding its rarity, we found placental mesenchymal dysplasia (PMD) as a unique pathology in two of our cases. PMD is an underreported and under recognized placental vascular anomaly causing hydrops.

It is characterized by placentomegaly (>90th percentile) with hydropic villi and absent trophoblastic proliferation.

The vascular changes observed in PMD might have led to heart failure with hydrops and ultimately resulting in intrauterine foetal demise.[10]

The other causes identified were maternal vascular malperfusion, foetal vascular malperfusion, villitis of unknown aetiology and acute chorioamnionitis.

Intrathoracic lesions

Among the intrathoracic causes (CPAM and CHAOS), an increase in intrathoracic pressure by enlarged lungs leading to impaired venous return could have contributed to foetal hydrops.[11]

Genitourinary abnormalities

Bladder outlet obstruction causing hydrops foetalis have been well documented in the literature. Mechanical obstruction of great vessels due to enlarged urinary bladder with resultant reduced venous return to heart is the underlying pathology.[12] Early onset oligohydramnios secondary to BOO leads to pulmonary hypoplasia, further reducing the survival chances.

Chromosomal abnormalities

In previously reported series of NIHF, chromosomal abnormalities were found in 10% of cases.[4,6,13] In the present study, there was 1 case of Turner syndrome and 3 instances of Down syndrome accounting for 16% of cases. Except for the Turner syndrome, none were confirmed by karyotyping. Among the 4 foetuses, 3 were identified in early gestation and one was associated with cardiac defect and cystic hygroma. Chromosomal analysis should be performed in all cases of NIHF, more so when identified in earlier gestation and when associated with structural anomalies.[14]

Miscellaneous causes

Intrauterine infections can cause foetal hydrops. There was one case of Parvovirus B19 infection in our study which showed hepatosplenomegaly with dense lymphocytic infiltration of myocardium. The underlying mechanisms include foetal anaemia, viral myocarditis and impaired hepatic function.[14,15] High index of suspicion and prenatal screening for intrauterine infections will make the interpretation easier. Incidence of "idiopathic" category varies among studies.[9,16,17] After detailed and systematic examination of foetuses including placenta, we found only one case (4%) of NIHF in which the cause was not identified. This highlights the value of autopsy with accompanying placental examination as the most complete procedure to establish the cause of NIHF.

Ultrasound correlation

Studies comparing the utilisation of foetal autopsy with prenatal USG findings have shown correlation in 98% of cases.[18,19] But these studies did not involve cases with hydrops foetalis. In more than 50% of studied cases, autopsy examination either refuted or altered the USG diagnosis completely. Though it is known that USG might miss some findings due to many reasons like equipment quality, sonographer expertise, maternal body habitus and liquor volume, this gross discrepancy is speculative. This might emphasis the need for autopsy, especially in cases of hydrops to arrive at a final aetiological diagnosis.

Also worthy of mention are the absence / rare diagnosis of inborn errors of metabolism and infective diseases in our series of cases. A better and complete laboratory work up with utilization of immunohistochemistry for lymphatic dysplasia/viral inclusions may be helpful to overcome this low diagnostic yield.

The causes of NIHF is heterogenous and the survival of the foetus depends on the underlying aetiology. The most promising tool in understanding the aetiology of NIHF is systematic evaluation of the foetuses including placenta. Multidisciplinary approach including foetal imaging, laboratory work up, postmortem bacterial / viral culture, genetic study, complete autopsy with utilization of immunohistochemistry (when necessary) will identify the potential causes in foetuses with suspected NIHF. This will determine new strategies for in utero therapy, and thus make a positive impact on perinatal outcome. Knowledge about the aetiology and pathogenesis will provide a better correlation with risk of recurrence. It may also improve parental counselling and prevent similar mishaps in subsequent pregnancies.

□□□□□□□□□□

In conclusion, the autopsy provides the final diagnosis and enables us to understand the disease process and its natural history. The decline in clinical autopsies is a matter of great concern to the clinicians and pathologists alike. State of the art imaging devices and molecular biology techniques can complement, but not replace a comprehensive autopsy.

Abstract

Background: Nonimmune hydrops foetalis (NIHF) is a terminal catastrophic event of pregnancy caused by numerous diverse etiology. The aim of this study was to assess the significance of foetal autopsy and to compare the prenatal ultrasound (USG) and foetal autopsy findings in cases of NIHF.

Methods: All perinatal autopsies performed at the department of pathology between March 2011-February 2018 were retrospectively reviewed. Of the received 130 autopsies, twenty cases of NIHF were identified, records of which were collected and correlated with maternal medical history, prenatal imaging and autopsy findings.

Results: The malformations with hydrops foetalis were classified according to the involved organ system. They were cardiothoracic (7/20 cases), genitourinary (3/20 cases), gastrointestinal lesions (1/20 cases), chromosomal (4/20 cases) and multisystem anomaly/syndromic association (5/20 cases). Complete agreement between USG and autopsy was seen in 8 (40%) cases. In 5 (25%) cases autopsy findings were in total disagreement with USG diagnosis. The rest of the 7 (35%) cases, autopsy revealed additional information and changed the recurrence risk in two cases.

Conclusions: Present study demonstrates the high rate of discordancy between USG and autopsy examination in cases complicated by NIHF. Foetal autopsy confirms the USG findings (quality control/audit), adds additional findings or changes the final diagnosis, which helps in redefining the recurrence risk and plausible genetic counselling for future pregnancies. Hence present study underscores the need for autopsy in all cases of NIHF.

Keywords: Nonimmune hydrops foetalis, Perinatal/ foetal autopsy, Prenatal imaging, Ultrasound

Introduction

Hydrops foetalis remains a distressing pregnancy complication with high perinatal mortality. It is characterized by generalized oedema and presence of fluid in pleural, peritoneal and pericardial cavities. Polyhydramnios and abnormally thickened placenta are often associated with hydrops.[1]

Traditionally, hydrops is classified into immune and nonimmune types. There is marked reduction in the incidence of immune hydrops due to effective immunologic prophylaxis for maternal isoimmunisation. Currently, the focus is on nonimmune hydrops foetalis (NIHF), which accounts for >90% of cases of hydrops.[2]

NIHF is associated with multiple aetiology. The various causes include cardiovascular, genitourinary, thoracic lesions, chromosomal aberrations, infections, haematological, genetic/metabolic, placental and idiopathic.[3]

Initial diagnosis of hydrops foetalis is usually made by ultrasound. In most of the cases, an accurate and complete antenatal imaging also points to the cause behind the development of hydrops. Despite having a

high diagnostic accuracy, foetal ultrasonography (USG) has some limitations, especially in cases with hydrops. Foetal autopsy in such instances can help to overcome the challenges.

The goals of this retrospective study were to compare the accuracy and completeness of prenatal ultrasonography with perinatal autopsy in cases of NIHF.

M□□□□□□

All perinatal autopsies performed at the department of pathology between March 2011-February 2018, were retrospectively reviewed. It included foetuses of all gestational ages. Causes of deaths were termination of pregnancy for foetal malformations, spontaneous abortions, stillbirths and early neonatal deaths. Of the 130 autopsies, twenty cases of NIHF were identified, records of which were collected and correlated with maternal medical history and prenatal imaging studies.

Immune hydrops foetalis were excluded from the study. Institutional ethical committee approval was obtained. Maternal data collection included maternal age, obstetric history, maternal medical diseases, gestational age of the foetus, and prenatal ultrasound findings.

Sonograms were predominantly performed by radiologists and some by obstetricians trained in obstetric ultrasound examination. The diagnostic criteria for hydrops foetalis were foetal skin oedema >5.0mm with one serous cavity effusion or fluid collection in at least two serous cavities (peritoneal, pleural or pericardial cavities).

The autopsies were performed by pathologists with perinatal experience. Informed written consent was obtained for all cases. A standard autopsy protocol was followed which included foetogram, photography, biometric measurements, external and internal examination. Microscopic examination of relevant organs such as thyroid, thymus, lungs, heart, liver, spleen, pancreas, adrenals, kidneys and ovary (in case of female), testis (in case of male) were done.

The brain was removed and fixed in formalin solution with the help of a gauze in a hanging position, then relevant sections were studied. Spinal cord, bone, muscle were also studied when necessary.

Special stains such as Periodic acid–Schiff (PAS) and Perls' Prussian blue were done if needed. Placental examination was done in all cases, but findings were not considered for the present study.

Placental causes of hydrops were also excluded from the study. Results of karyotype, if known was collected. The final autopsy diagnosis was correlated with prenatal ultrasound findings and results were drawn.

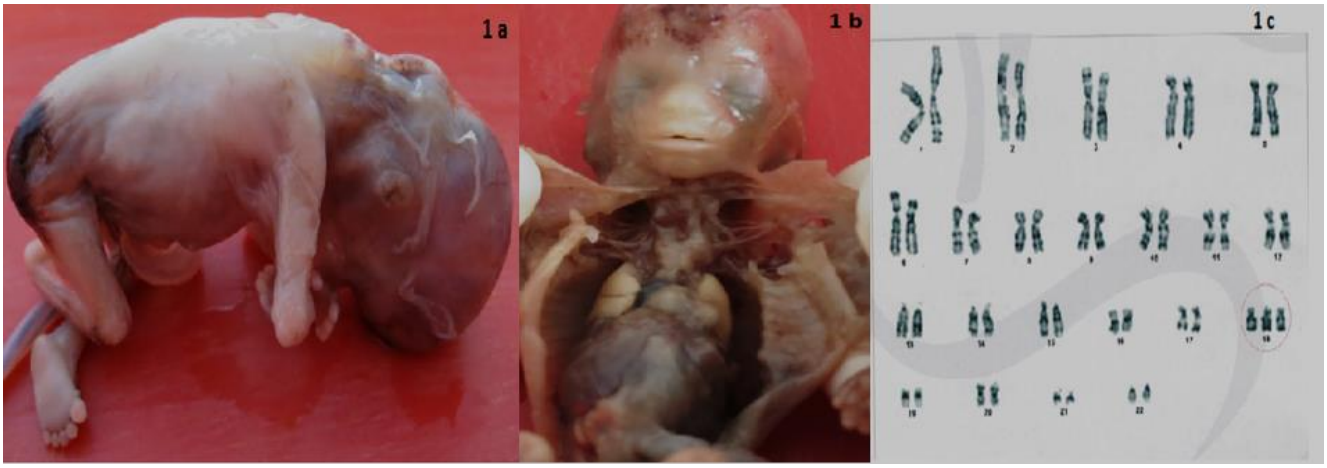
□□□□□□□

The maternal age ranged from 19 to 35 years with the mean age of 25.55years. Gestational age ranged from 13 to 35 weeks, with the mean gestational age of 21.45 weeks. There were 18 stillborn foetuses and 2 neonates with the Male: Female ratio of 3:2. Authors did not come across any multiple gestation. Four cases had recurrent hydrops.

Prenatal diagnosis of hydrops was noted in 14 cases and in the remaining 6, diagnosis was made at post-mortem. present data showed prenatal diagnosis of the presence of hydrops in only two-third of the cases.

Subcutaneous oedema and serous cavity effusions were identified in the rest one-third only during autopsy. All of these were second trimester foetuses. Cystic hygroma was identified in five cases.

The malformations with hydrops foetalis were classified according to the involved organ system. They were cardiothoracic (7/20 cases), genitourinary (3/20 cases), gastrointestinal lesions (1/20 cases), chromosomal (4/20 cases) and multisystem anomaly/syndromic association (5/20 cases).



Cardiac lesions (n=4): The cardiovascular malformations included premature closure of ductus (1case), complete heart block(1case), atrioventricular septal defect (AVSD) with persistent left superior vena cava (SVC) with other findings suggestive of Down syndrome(1case) and 1 case of transposition of great arteries (TGA), which also had an associated partial urorectal septum malformations.

Thoracic lesions (n=3): The thoracic lesions were congenital pulmonary adenomatoid malformations (CPAM, 2 cases) and congenital high airway obstruction syndrome (CHAOS, 1 case).

Genitourinary lesions (n=3): Three cases of bladder outlet obstruction (BOO) were included in the group of urogenital malformations, of which one had an associated ventriculomegaly, absent corpus callosum (ACC) with hypoplasia of ductus, right and left pulmonary arteries, distal aortic arch and left subclavian artery

Gastrointestinal lesions (n=1): The gastrointestinal lesions included, a 28weeks foetus with hypertrophic pyloric stenosis.

Chromosomal abnormalities (n=4): Of the 4 cases, two showed phenotypic features of Down syndrome, but karyotype confirmation was not available. Karyotyping was possible in the remaining 2 cases of which one showed partial deletion of short arm of X chromosome (Turner syndrome) and the other showed trisomy 18 (Edwards syndrome) (Figure 1).

[illegible] (Edward's [illegible]

Multisystem anomalies/ syndromic association (n=5): The autopsy findings suggested syndromic associations in five instances. They were one case each of Ellis- Van Creveld syndrome, Multiple congenital anomaly syndrome, VACTERL (vertebral defects, anal atresia, cardiac defects, tracheo-esophageal fistula, renal anomalies and limb abnormalities) association, FRYNS Syndrome and Cerebro-oculo-facio-skeletal syndrome. Karyotype analysis was done for the last two cases and were found to be normal.

Correlation between prenatal ultrasound and autopsy findings: Complete agreement between USG and autopsy was seen in 8 (40%) cases. In 5 (25%) cases, autopsy findings were in total disagreement with USG diagnosis. The rest of the 7 (35%) cases, autopsy revealed additional information.

[illegible]

[illegible]	[illegible]	[illegible]	[illegible]
1.	Cardiac	HF	Premature ductus closure.
2.	Thoracic	Large cystic hygroma	CPAM
3.	Chromosomal	HF, oesophageal atresia, absence of stomach	Phenotypic features of foetal trisomy No oesophageal atresia Karyotype-not done
4.	Urogenital	No anomaly	BOO-distal urethral stenosis
5.		HF	BOO-distal urethral stenosis Ventriculomegaly, ACC

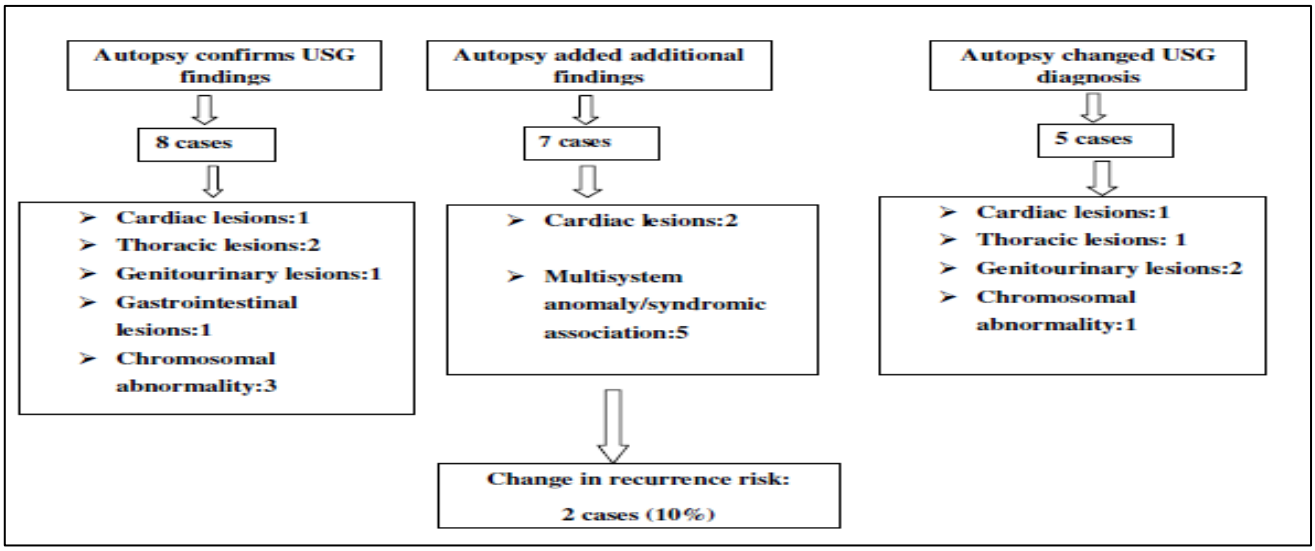
HF- hydrops foetalis; BOO- bladder outlet obstruction; CPAM- congenital pulmonary airway malformation; ACC –absent corpus callosum.

Cases with complete disagreement has been shown in Table 1.

Two had bladder outlet obstruction, one each had CPAM and premature closure of ductus.

In all the four cases, there was a complete change in the diagnosis after the autopsy.

The fifth case showed no oesophageal atresia, in contrast to prenatal imaging.

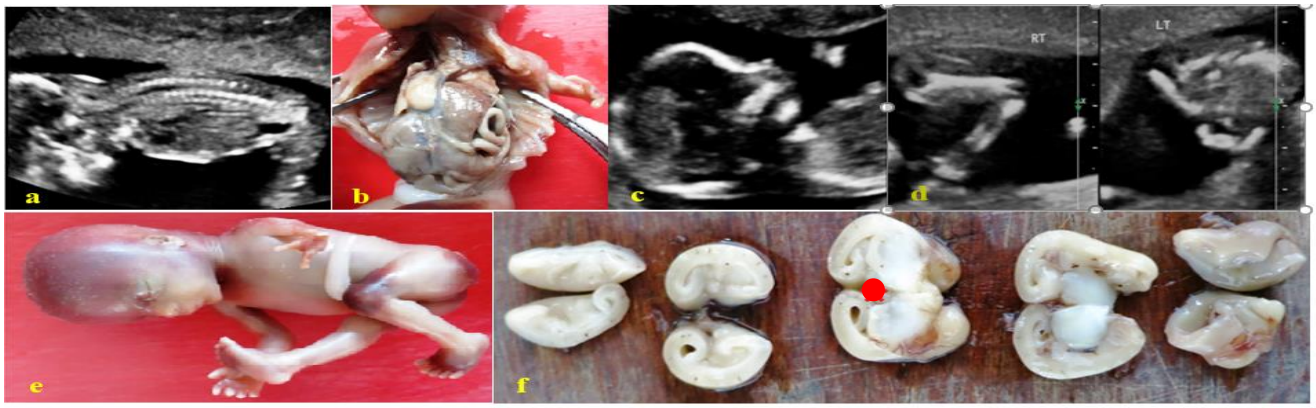


Though this was a significant disagreement, there was no major shift in the final diagnosis as both modalities suggested chromosomal aetiology.

[illegible]

[illegible]	[illegible]	[illegible]
1.	Short long bones, polydactyly, tricuspid atresia with VSD-probably Ellis Van Creveld syndrome	Common atrium with complete AVSD- Ellis-Van Creveld syndrome
2.	Polyhydramnios, HF, micrognathia, hypospadias, cleft soft palate, ACC, cardiomegaly, tricuspid regurgitation	Hypotelorism, depressed nasal bridge, low set ears, Heart – secundum ASD, Liver – haemosiderosis Pancreas – giant islets and nesidioblastosis Multiple congenital anomaly syndrome, Zellweger syndrome, Smith Lemli Opitz syndrome.
3.	SUA, TOF, ectopic hydronephrotic Left kidney, Left club foot with absent 2nd to 5th digits	Hemivertebra, fusion of ribs on the left side, Atresia of distal sigmoid, rectum with absent anal opening VACTERL association
4.	Left diaphragmatic hernia, hypoplastic left heart, short humerus on left side, absent forearm with claw hand on left side; dilated jugulolymphatic sacs: multiple anomalies and with SUA, could be VACTERL association.	Partial ACC, and hydrocephalus Karyotype was normal -Suggestive of FRYNS Syndrome
5.	HF, Foetal akinesia deformation sequence, sloppy forehead, micrognathia, gross bilateral lateral ventriculomegaly	Cerebro-oculo-facio-skeletal syndrome with persistent urogenital sinus
6.	Increased nuchal translucency, cystic hygroma, absent nasal bone	AVSD with persistent left SVC -Suggestive of Down syndrome
7.	Cystic hygroma with TGA and VSD	Partial urorectal septum malformation

VSD-ventricular septal defect; AVSD- atrioventricular septal defect; HF- hydrops foetalis; ACC-agenesis of corpus callosum; ASD-atrial septal defect; SUA-single umbilical artery; TOF-tetralogy of Fallot; VACTERL-vertebral defects, anal atresia, cardiac defects, tracheo-esophageal fistula, renal anomalies, and limb abnormalities; SVC-superior vena cava; TGA-transposition of great arteries



There were seven cases with additional autopsy findings which has been summarized in Table 2. Authors had two cases with cardiac lesions and the rest of the cases showed multisystem involvement. After autopsy, two out of seven cases had a change in recurrence risk (Figure 2).

[illegible]

In cases of multi system involvement, the autopsy finding of hemi vertebra, atresia of distal sigmoid, rectum, anal canal with absent anal opening, completed the diagnosis of VACTERL association (case 3, table 2).

In the same group (case 4, table 2), prenatal diagnosis of VACTERL association was changed to FRYNS syndrome after the identification of central nervous system anomaly (Figure 3).

[illegible]

Table 3 highlights the cases that showed full agreement between USG and autopsy findings. This included three cases of chromosomal abnormality, two cases of thoracic lesions (CPAM and CHAOS) and one case each from cardiovascular system (complete heart block), genitourinary (BOO) and gastrointestinal group (hypertrophic pyloric stenosis). There were none from the multiple anomaly group.

After extensive search of literature authors came across many studies comparing prenatal USG findings with post-mortem examination. Most of these studies dealt with cases of foetal malformations, stillbirth and neonatal death.[4-8] But, there were only few studies comparing the same in cases of NIHF.[9,10] Hence authors chose to address the accuracy of prenatal USG findings and compare it with perinatal autopsy in cases of NIHF.

Prenatal diagnosis of hydrops was missed in one third of present cases. Fluid collection is initially diagnosed by USG during the first or mid trimester. Significant fluid accumulation is recognized easily, but sometimes the effusions are limited and can escape diagnosis during imaging.

Present data showed complete agreement between USG and autopsy findings in 40% of cases. This was similar to a study by Antonella et al done in 2012.[11] In their study they have compared the USG and autopsy findings of 144 second trimester foetuses. In 49% of cases there were total agreement between the two. Additional information was provided by post-mortem in 34% of cases, while in present study it was 35%. Astonishingly in 13% of their cases, functional anomalies detected by ultrasound could not be confirmed by autopsy. This is due to the fact that ultrasound examination is a dynamic examination, optimum to reveal functional changes like valve insufficiencies, flow reversals and sometimes even cavity effusions. This should not be considered as false positive USG findings, but as an advantage of the imaging modality.

In 7 cases (35%), there were additional findings in autopsy not detected by USG. In two of these cases, the additional findings provided by autopsy redefined the recurrence risk. It seems that the higher proportion of additional findings in the present study might be due to critical identification of minor anomalies at autopsy such as anal atresia, partial agenesis of corpus callosum and urorectal septum malformation.[10]

The identification of these minor anomalies is significant as they might change the diagnosis from an isolated lesion to complex malformation.[4]

All cases in the multiple anomaly had additional findings in autopsy. The identification of partial agenesis of corpus callosum with hydrocephalus in a case with prenatal imaging diagnosis of VACTERL association changed the final diagnosis to be Fryns syndrome. The other anomalies were concordant. The foetus was 16 weeks at the time of diagnosis, and identification of the cranial anomaly at this gestational age is challenging.[12] Fryns syndrome (FS) is the commonest autosomal recessive syndrome in which congenital diaphragmatic hernia (CDH) is a cardinal feature.[13]The autosomal recessive inheritance in FS contrasts with the sporadic inheritance seen in cases of VACTERL anomaly.[14] This underscores the importance of the correct diagnosis for accurate genetic counselling.

Among the cases with cardiovascular lesions, prenatal ultrasound showed increased nuchal translucency, cystic hygroma and absent nasal bone which was all suggestive of trisomy 21. The presence of AVSD, the characteristic heart lesion in these foetuses was made out by post-mortem examination. This more or less confirmed the diagnosis of Down syndrome.

In addition to multiple anomaly, the histological presence of haemosiderosis of the liver with giant islets and nesidioblastosis of the pancreas led to the suggestive diagnosis of multiple congenital anomaly syndrome, Zellweger syndrome, Smith Lemli Opitz syndrome.

One of the study case showed USG findings of Foetal akinesia deformation sequence, with gross bilateral lateral ventriculomegaly. But post-mortem examination also revealed hydranencephaly, lens opacity along with facial and skeletal lesions which led to the diagnosis of cerebro-oculo-facio-skeletal syndrome. Persistent urogenital sinus was noted additionally.

There was total discordance between USG and autopsy in 5 cases of 20(25%). In all 5 cases, though hydrops was diagnosed prenatally, the causative lesion could not be detected by imaging. But autopsy revealed structural anomaly in 4/5 cases. Though all these four lesions (premature closure of ductus, CPAM, BOO) could be identified by antenatal imaging, they were missed. As hydrops foetalis carries a bad prognosis and once it is evident by ultrasound, further careful and complete imaging is overlooked. This could have led to the non-identification of structural abnormality by USG and the discordance with post-mortem examination.

USG as well as autopsy have unavoidable limitations in analysing cases of NIHF. So, they are considered complementary to one another. Both of these modalities depend on the expertise of the personnel, the technological advancement of the ultrasound equipment and the autopsy technique.

The causes for differences in prenatal USG include early gestational age (structures are too tiny to evaluate, respective organs not completed development structurally or functionally), abnormal amount of liquor (oligo/polyhydramnios) which makes visualization of organs difficult, altered maternal habitus (obese, thick abdominal wall) and foetal position. Authors found that additional findings were high in cases of multi system involvement, which was similar to the observation by Rossi et al.[5] This is attributed to the increased focus of the sonographer on severe and more interesting abnormalities, overlooking minor or less lethal abnormalities or not completing the examination once a major/lethal anomaly is detected .[4]

The main limitations of post-mortem examination are longer duration of reporting and the need for appropriate training and expertise in the field of perinatal pathology. There are a few other factors which may hinder the accurate post-mortem examination:

- intrauterine foetal death with long period of foetal retention and superimposed maceration may distort the foetal anatomy
- in foetuses with suspected CNS abnormality, the autopsy findings may be inconclusive due to extreme autolysis
- satisfactory dissection may not be possible in foetuses of very early gestation with small organs (can be overcome by dissecting microscope) and presence of post-mortem artefacts
- functional anomalies can be missed.[10,15-18]

Although present study is a retrospective analysis involving less number of cases, it is the only study to specifically correlate the prenatal USG findings and post-mortem examination of foetuses with nonimmune hydrops. This knowledge and further studies involving large number of cases of NIHF will contribute to improve parental counselling.

NIHF is a terminal catastrophic event of pregnancy caused by numerous diverse aetiology and is known for its low diagnostic yield. Initial recognition of hydrops is usually made by ultrasonographic examination. But the aetiology in many cases remains elusive even after a carefully performed imaging.

In such instances post-mortem study of the foetus including placental examination and other ancillary work up like genetic study, testing for infections and metabolic derangements help in identifying the cause. present study demonstrates a high rate of discordancy between USG and autopsy examination in cases complicated by NIHF.

Foetal autopsy confirms the USG findings (quality control/audit), adds additional findings or changes the final diagnosis. Although, foetuses with nonimmune hydrops carry worse prognosis, it is indispensable to identify the genesis of the hydrops to counsel the couple regarding prognosis, recurrence risk and future pregnancy outcomes. Hence present study underscores the need for autopsy in all cases of NIHF.

[illegible]

[illegible] The purpose of this study was to evaluate gross umbilical cord abnormalities and to examine its relationship with placental pathological features and perinatal outcome.

M [illegible] We retrospectively collected 101 singleton placentas with gross umbilical cord abnormalities over 3-year period (delivered on or after 20 weeks of gestational age). Association between gross umbilical cord abnormalities such as hypercoiled cords, hypocoiled cords, thin cords, true knot, strictures, excessively long cord, and abnormal cord insertions were reviewed and evaluated for placental histology, clinical parameters and perinatal outcome.

[illegible] The most common umbilical cord abnormality (UCA) observed was coiling abnormality (hypercoiling, hypocoiling and strictures). Gross UCAs were associated with maternal factors (preeclampsia, oligohydramnios and gestational diabetes), foetal factors (intrauterine foetal death, SGA and intrapartum complications such as NRFHR tracing and low Apgar scores) and histologic placental features (maternal vascular malperfusion, foetal vascular malperfusion, villous capillary lesions and inflammation). Cords with multiple abnormalities were significantly correlated with histologic evidence of foetal vascular obstruction and intrauterine foetal death.

[illegible] Gross UCAs, especially when multiple were associated with clinically significant placental findings and adverse perinatal outcome. Therefore, our study reinforces that all placentas with gross UCAs should be submitted for examination with complete (full length of the) umbilical cord.

[illegible] Coiling abnormality perinatal outcome, Foetal vascular malperfusion, Maternal vascular malperfusion, Placental histology, Umbilical cord abnormalities

[illegible]

Umbilical cord (UC) is a vital structure which acts as a conduit between the developing foetus and placenta. It carries nutrients, oxygen and fluids necessary for the intrauterine life. This unique lifeline needs optimal protection which is provided by Wharton's jelly, amniotic fluid and coiling of the umbilical vessels.[1] The fully developed umbilical cord is pearly white, 50-60cms long with an average diameter of 1-2cm. It contains 2 arteries and a vein which course through the Wharton's jelly in a helical fashion with one coil/twist every 5 cms of cord. The cord normally inserts on the placental surface, more often near or at the center.[2]

Conditions such as abnormal cord length, abnormal coiling, knots, entanglements, constrictions, velamentous vessels, single umbilical artery (SUA) and thrombosis

may lead to cord compression and consequent reduction of blood flow in the umbilical vessels and have been associated with adverse foetal outcome and intrauterine foetal demise (IUFD).[3]

The purpose of this study was to evaluate gross patterns of umbilical cord abnormalities and determine correlations with placental histology and perinatal outcome.

M□□□□□□□

This retrospective study was carried out from January 2014 to December 2016 in the Departments of Obstetrics and Gynaecology and Department of Pathology.

101 Placentas with gross umbilical cord abnormalities delivered on or after 20 weeks of gestational age were taken for study consideration. Clinical indications for histological examination of the placenta were stillbirth, foetal growth restriction, preterm premature rupture of membranes, severe pre- eclampsia, diabetes, gross abnormalities of the placenta, clinical suspicion of infection or abruption and compromised neonatal outcome.

Umbilical cord abnormalities (UCA) included in the study were hypercoiled cord (>3 coils/10cm segment of umbilical cord), hypocoiled cord (< 1 coil per 10 cm), thin /narrow cord due to diminished Wharton's jelly (maximum cord diameter <0.8 cm), strictures (focal narrowing/thinning in relation to the remaining UC), true knot(TK), SUA, abnormal cord insertion-marginal (< 1cm from the true disc margin-MUC) / velamentous (membranous insertion-VEL) / furcate (umbilical vessels splitting and leaving Wharton's jelly prior to reaching the chorionic plate surface).[4] Excessively long umbilical cord (ELUC) was defined as those UCs measuring approximately 2 standard deviations (SD) above the mean or ≥ 70cms in length.[4,5]

Clinical details obtained along with the placental specimens were maternal age, gravidity and parity, gestational age, medical conditions complicating pregnancies, presence of IUFD, foetal growth restriction (FGR), non-reassuring foetal heart rate (NRFHR), meconium stained liquor, Apgar scores at 1 and 5 minutes and birth weight as recorded by the obstetricians. Infants with birth weight <10th percentile and >90th percentile of the gestational age were termed as small for gestational age (SGA) and large for gestational age (LGA) respectively. The rest were considered as appropriate for gestational age (AGA).[6]

Umbilical cord and placental assessment were based on gross and microscopic examinations. An entire placenta was available from all 101 patients and were fixed in 10% formalin. Placentas were weighed after the membranes and umbilical cord were trimmed off and compared with the reference weights for trimmed singleton placentas.[7]

Umbilical cord was examined for length, diameter, colour, insertion site, number of twists and vessels. Photography of the placentas were routinely taken after examining foetal, maternal surfaces and parenchyma. Relevant lesional sections were taken along with 2 sections of membrane roll, 2 or 3 sections from the UC at the stricture and non-strictured area and 3 full thickness sections of the normal parenchyma. All the histologic sections were stained with haematoxylin and eosin.

Umbilical cord abnormalities were correlated with gross, histologic placental characteristics and foetal outcome.

□□□□□□□□

Hundred and one cases were identified with gross UCAs. There were 48 cases of hypercoiling (Figure 1), 31 cases of hypocoiling (Figure 2) and 11 cases each of thin cords and strictures (Figure 3). Abnormal cord insertions were seen in 7 cases each of MUC, VEL (Figure 4) and 2 cases of furcate. Other less commonly seen abnormalities were 2 cases each of TK (Figure 5), ELUC and SUA. Of the 101 cases of analysed placentas 20 had more than one umbilical cord abnormality.

Isolated UCAs were each analyzed for association with clinical and histologic findings (Tables 1 and Table 2).

Clinical characteristics

The most common UCA identified was hypercoiling, followed by hypocoiling. Stillbirth was observed in 42 cases across all cord abnormalities but was by far most frequently associated with abnormal coiling.

Preeclampsia, oligohydramnios and gestational diabetes were the commonest maternal characteristics observed in UCAs. Infections, PPROM, polyhydramnios and autoimmune diseases were other maternal features identified in altered structure of UCs.

NRFHR, low Apgar and Meconium stained liquor were common in coiling abnormalities, more so in the group with hypercoiling. Fifty percent of hypercoiled and one third of hypocoiled cords had birth weights of < 10th percentile.

Placental findings

More than 50% of the placentas with UCAs were small for gestational age. Significant histologic features identified were maternal vascular malperfusion (MVM-35/101), foetal vascular malperfusion (FVM-26/101) and villous capillary lesions (19/101). The other microscopic features noted were distal villous immaturity (DVI), massive perivillous fibrin deposition (MPVFD), and inflammatory lesions.

Table 3: Clinical and histologic findings in cases with multiple UCAs

Parameter	Cases with multiple UCAs (n= 31)	IUFD (n=11)	Live born (n=20)	SGA (n=11)	AGA (n=20)	Hyper coiling (n=20)	Hypo coiling (n=20)	Strictures (n=20)	Thin cord (n=20)
Placental weight									
SGA	31	19	10	0	4	1	2	4	5	1
MVM	21	8	4	0	1	0	1	3	2	1
Infarcts	13	10	4	0	1	0	0	1	2	0
Retroplacental haematoma	3	5	1	0	0	0	0	0	1	0
Intervillous thrombus	9	8	2	0	0	0	0	1	1	1
MPVFD	1	1	0	0	2	1	0	0	0	0
FVM	8	10	5	0	6	0	2	3	1	0
Chorionic plate/stem villous vessel thrombus	5	7	2	-	6	0	2	3	1	0
Avascular villi	8	8	5	-	6	0	2	3	0	0
Villous Stromal Karyorrhexis	4	5	4	-	2	0	1	0	0	0
Nucleated RBCs	2	3	-	-	1	0	1	1	0	0
Inflammation	8	9	3	1	2	0	1	1	4	1
Acute chorioamnionitis	2	5	0	1	1	0	0	0	2	0
VUE	6	4	3	0	1	0	1	1	2	1
Villous capillary/vascular lesions	14	3	3	2	2	1	0	0	0	0
Chorangiosis	9	1	1	1	1	0	0	0	0	0
Chorangiomatosis	3	2	2	0	1	1	0	0	0	0
Villous congestion	2	0	0	1	0	0	0	0	0	0
DVI	5	4	1	0	0	0	0	2	1	0

Infarcts, intervillous thrombus, retroplacental haematoma and MPVFD (histologic markers of MVM) were observed in cases with gross UCAs. The other features noted were decidual vasculopathy, distal villous hypoplasia, increased syncytial knotting, cell islands, villous agglutination, and multinucleate trophoblastic giant cells.

The histologic features of chronic FVM such as chorionic plate /stem villous vessel thrombus, avascular villi, villous stromal karyorrhexis and nucleated red blood cells were significantly more common in cords with hyper, hypo coiling and strictures. Ectatic vessels were also noted in many of the chorionic plate /stem villous vessels of FVM.

Villous vascular lesions such as chorangiosis (increased number of capillaries - more than 10 capillaries/terminal villi, in 10 villi) in many areas of the placental parenchyma, patchy and occasional multifocal chorangiomatosis (excessive capillaries with surrounding pericytes in immature intermediate / stem villi) and villous congestion were found to be associated with hypercoiled cords.

Multiple UCAs

Placentas with multiple UCAs and their associations with clinical and histologic findings were also analysed. IUFD was significantly associated with the presence of multiple UCAs (13/20). In the remaining live born cases the clinical outcome was SGA (6/20) and AGA (1/20). The most common maternal obstetric complication was hypertension and the commonest placental histology was foetal vascular malperfusion (FVM) (Figure 6). These findings are summarized in (Table 3).

Discussion

The coiling pattern of the UC largely affects umbilical blood flow that is vital for sustaining foetal growth and development and its pathophysiological significance has been studied by many authors. UCAs often result in mechanical compression leading to venous stasis, endothelial damage and loss of perfusion to a large area of placental gas exchanging villi and ultimately resulting in foetal distress and hypoxia.[8-10] This study analyzed the UCAs such as hypercoiling, hypocoiling, strictures, thin cord, true knot, SUA, ELUC and abnormal insertions in

relation to gross, histologic placental changes as well as clinical parameters and foetal outcome.

Table 2: Correlation between umbilical cord coiling abnormalities and clinical parameters and foetal outcome

Parameters	Total number of cases	Total number of hypercoiled cords	Total number of hypocoiled cords	Total number of normal coiled cords	Total number of IUFD	Total number of FGR (<10th percentile)	Total number of NRFHR tracing	Total number of low Apgar score (<7 at 1 min)	Meconium stained liquor	Total number of preterm births (<37 weeks)
Gestational age										
<28 weeks	8	6	5	0	4	0	0	1	3	1
>28 weeks	40	25	6	2	7	2	2	6	4	1
Maternal factors										
HT	15	6	2	0	1	0	0	2	3	0
GDM	8	0	0	1	1	0	0	1	0	1
Rh Negative	1	0	0	0	0	0	0	1	0	0
Oligo	10	6	2	0	0	0	0	1	3	0
PPROM	3	6	2	0	0	0	0	0	1	0
Polyhydramnios	1	1	0	0	0	0	1	0	0	0
Auto immune	1	1	2	0	1	0	0	1	1	0
Infections	4	1	1	0	1	0	0	0	0	0
Foetal factors										
SGA	21	9	5	0	1	0	0	5	2	1
AGA	10	8	1	0	1	0	0	0	0	0
LGA	3	0	0	1	0	0	0	0	0	0
IUFD	14	14	5	1	9	2	2	2	5	1
NRFHR	15	2	1	0	1	0	0	2	1	1
Liquor										
<4 @1 mt	6	1	0	0	0	0	0	1	0	0
<7 @ 1 mt	7	2	1	0	1	0	0	1	0	0
Thick meconium stained liquor	4	1	0	0	0	0	0	0	0	0

Consistent with prior studies, our investigation showed that UCA has significant association with IUFD, SGA and intrapartum complications such as NRFHR tracing and low Apgar scores.[8-10] Meconium stained liquor was not a consistent finding in our study.

Umbilical cord coiling abnormality

Little is known about factors determining cord coiling. It is generally believed that coiling is established very early in gestation and is thought to be the result of foetal activity. Lack of coiling may then reflect foetal inactivity, which is supported by the fact that coiling is reduced in cases of restricted foetal movements due to various causes.1 The prenatal ultrasonographic evaluation of umbilical cord is usually limited to vessel number and umbilical artery Doppler. Predanic et al demonstrated a strong correlation between mid-trimester umbilical coiling index (UCI) and post-natal coiling index.[11]

Among 101 studied placentas, abnormal coiling was the commonest UCA, which accounted for 80%. The frequency and clinical correlations of hypercoiled cords were FGR (43%), IUFD (29%), NRFHR (31%). For hypocoiled cords, the frequencies of adverse outcomes were IUFD (45%) and FGR (29%). Our results were in contrast to the study by Machin et al who observed more IUFDs among hypercoiled cords. Our data support the finding that abnormal coiling may cause chronic umbilical cord obstruction and unfavourable foetal outcome.[12]

Among hypercoiled umbilical cords, specific gross patterns of coiling were recognized with histologic evidence of foetal vascular malperfusion and stillbirth.[8]

The placental weight was small for gestational age in more than two thirds of the studied cases. Placental histologic findings associated with UC coiling abnormalities include villous capillary congestion, chorangiosis, chorionic plate / stem villous vessel thrombi, avascular villi, MVM, inflammatory lesions and DVI. Placental infarcts and intervillous thrombus are the conspicuous lesions observed among coiling abnormality cases in our series.

They represent deficient maternal circulation (maternal vascular malperfusion) leading to parts of placental atrophy or infarction in areas of poor nutrition. However,

the association between MVM and cord coiling abnormalities appear speculative.

We wondered whether the less placental reserve due to deficient intervillous circulation can affect foetal outcome if cord coiling abnormalities arise additionally.

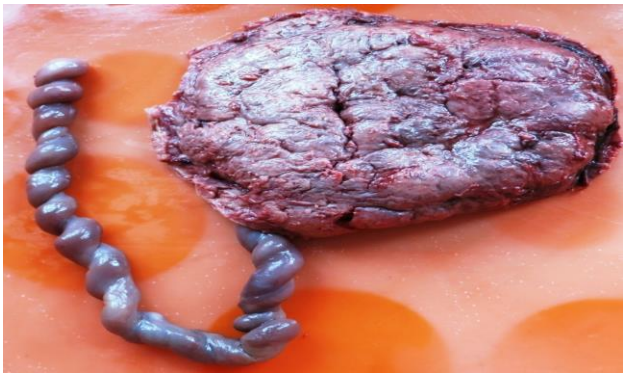

Figure 1: Hypercoiled cord

Presence of avascular villi, thrombosis of foetal vasculature, VSK and NRBCs reflect foetal blood flow obstruction and hypoxia. In our study 25% of the abnormal coiling cases tended to have FVM suggesting that these lesions would have caused chronic vascular obstruction.[10]

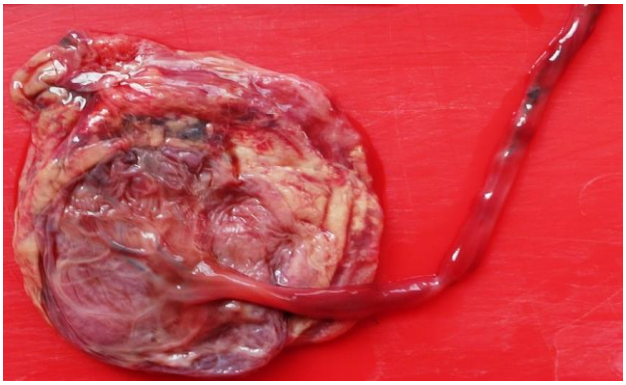

Figure 2: Hypocoiled cord

Figure 3: Hypocoiled cord

Chorangiosis, multifocal chorangiomatosis are overlapping villous capillary lesions believed to be related to hypoxia. Benirschke observed an association between chorangiosis and cord problems.[13] It is an adaptive mechanism to overcome hypoxia occurring in coiling abnormalities. Our observations were also similar.[14] Some of the cases also showed distal villous immaturity, one other lesion known to be associated with coiling abnormalities.

Figure 4: Hypercoiled cord with avascular villi and thrombosis

There was some correlation between inflammatory lesions such as VUE and, acute chorioamnionitis with individual UCA.

Figure 5: Hypercoiled cord with avascular villi and thrombosis

Cord strictures

Most investigators considered strictures and hypercoiling to be similar or related entities. In our study we observed a total of 11 cases with cord strictures. Four among the cases were associated with hypercoiling; one each with hypocoiling, velamentous cord insertion and ELUC. 4 cases had isolated stricture. This data suggested that cord stricture is a distinctive entity as agreed upon by Hong Qi Peng et al in their study.[15] We have also noted a high incidence (more than 80%) of foetal demise associated with cord stricture, coiling abnormalities or a

combination of both. Foetal vascular malperfusion was common when strictures and hypercoiling were coexistent. This implies that UC strictures and hypercoiling could decrease the blood flow with possible predisposition to development of thrombosis.

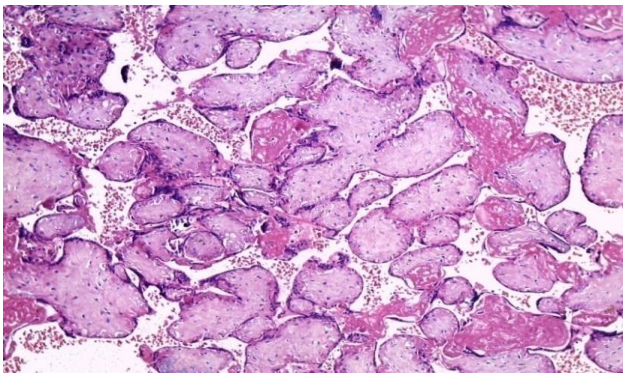

Figure 6: Photomicrograph of placental villi showing avascular hyalinised villi, villous stromal karyorrhexis and nucleated RBCs suggesting that these lesions would have caused prolonged obstruction (H&E, 10×)

Thin cord, SUA

It has been suggested that diameter of the umbilical cord is determined by the water content of Wharton's jelly. Previous studies have found an association of thin cord with FGR and other poor foetal outcome.[16,17]

A Wharton's jelly reductions have also been recognized as a possible cause of foetal death in the presence of single umbilical artery, which is the most common abnormality of the umbilical cord. These associations were confirmed in our study. According to Heifetz SA, non-malformed SUA infants can have an increased mortality rate, although SUA with associated malformations are the common cause of the high perinatal mortality.[18]

True knot, ELUC

Interestingly, both cases of true knot were associated with LGA. The case with a tight TK ended up in IUFD. Common associations like multi gravida and ELUC were also observed in our study. Like earlier studies we also found an association between ELUC and other multiple UCAs.[5] Both cases of ELUC were associated with multiple UCAs such as nuchal cord, TK and stricture and expectantly both resulted in IUFD.

Abnormal cord insertions

Marginal and velamentous insertions are suggested to result from disturbances of implantation and considered a marker of placental insufficiency.[19] We found that non-reassuring foetal status, SGA and IUFD were significantly associated with abnormal insertion which may reflect intrauterine hypoxia.

Multiple UCAs

Any UCA can sufficiently reduce placental function, when multiple predispose the foetus to placental circulatory stasis lesions and thrombosis, thus leading to vascular obstruction and unfavourable clinical sequelae.[3]

In our study the majority of multiple UCA cases tended to have extensive rather than focal FVM with admixture of avascular hyalinised villi, villous stromal karyorrhexis and nucleated RBCs suggesting that these lesions would have caused prolonged obstruction. Infants with multiple UCAs where FVM is extensive were found to have brain imaging abnormalities and/or abnormal neurological follow-up.

There were some limitations in our data. First, as a retrospective study, the clinical information was available only for the immediate neonatal period and further follow up could not be ascertained. Second, not all placentas and complete length of the UC (that remained attached to the neonate) were available for examination. Finally, different patterns of hypercoiling were not studied.

Conclusions

Gross UCAs, especially when multiple was associated with clinically significant placental findings and adverse perinatal outcome. Therefore, our study reinforces that all placentas with gross UCAs should be submitted for examination with complete (full length of the) umbilical cord. Coiling index with patterns of coiling should be a part of routine examination. A prospective study that also includes the follow up of these neonates could address the clinical effects of UCAs.

Abstract

Background: Pregnancy in women with autoimmune diseases is frequently associated with placental insufficiency leading to adverse perinatal outcome. Aim of the study was to investigate the presence and possible clinical significance of placental lesions in mothers with different autoimmune disorders.

Methods: In this retrospective study, 11 placentas from 10 mothers with diverse autoimmune diseases including systemic lupus Erythematosus (SLE), antiphospholipid antibodies (APLA), idiopathic thrombocytopenic purpura (ITP) and antinuclear antibodies (ANA) were studied.

Results: Placental correlates were reduced placental weight, maternal vascular under perfusion, abruption, villitis of unknown etiology, multifocal chorangiomatosis, distal villous immaturity, massive perivillous fibrin deposition/maternal floor infarction and foetal thrombotic vasculopathy. Of the 11 pregnancies 3 were untreated (1 SLE, 2 APLA) and resulted in intrauterine foetal demise. The lesions were more severe in these cases. All the treated pregnancies resulted in live born babies (8), of which 3 were growth restricted, 2 were complicated with oligohydramnios and 3 were delivered preterm.

Conclusions: In this group of diverse autoimmune disorders, placental lesions were not specific for each of them. Apart from maternal vascular under perfusion, lesions like villitis of unknown etiology, distal villous immaturity and massive perivillous fibrin deposition were identified and may recur in subsequent pregnancies and treatment should be directed towards modifying it. The placental examination should be mandatory in all cases of maternal autoimmunity and pregnancies with poor foetal outcome.

Keywords: Maternal autoimmune diseases, Maternal vascular under perfusion, Placental lesions

Introduction

Placenta plays a major role for a pregnancy to proceed normally, ensuring an adequate blood supply to support and promote the growth of the developing foetus. Autoimmune disease, both organ specific and non-organ specific is associated with intrauterine growth retardation (IUGR), preterm delivery and intrauterine foetal demise (IUFD) and appears to be a consequence of failure of the normal uterine physiologic changes to occur with resultant placental insufficiency and the features that accompany a failing placenta.[1] Despite being an important etiology of poor perinatal outcome, placental lesions and its clinical correlation of autoimmune diseases lack a unified diagnostic criterion.

These clinical associations as well as foetal outcome suggest that there may be multiple pathologies that

complicate and disrupt pregnancy in patients with autoimmune disorders.[2]

Given these uncertainties surrounding the placental pathology of autoimmune diseases, we sought to determine the presence and possible clinical significance of maternal vascular lesions, chronic villitis of unknown etiology (VUE), distal villous immaturity (DVI), massive perivillous fibrin deposition/maternal floor infarction (MPVFD/MFI) in placentas of mothers with different autoimmune disorders.

M□□□□□□

This retrospective study was carried out from January 2014 to April 2017 in the Departments of Obstetrics and Gynecology and Department of Pathology at PSG IMS and R.

A total of 11 placentas were studied from ten mothers with maternal immunological disorders which included systemic lupus erythematosus (SLE) with secondary anti phospholipid antibodies (APLA), primary anti phospholipid antibodies (APLA), idiopathic thrombocytopenic purpura (ITP) and one with antinuclear antibody (ANA).

All patients had singleton pregnancies without any foetal malformations. Infants below tenth percentile were considered as having intrauterine growth restriction.

According to the revised sydney classification criteria, apla is defined by

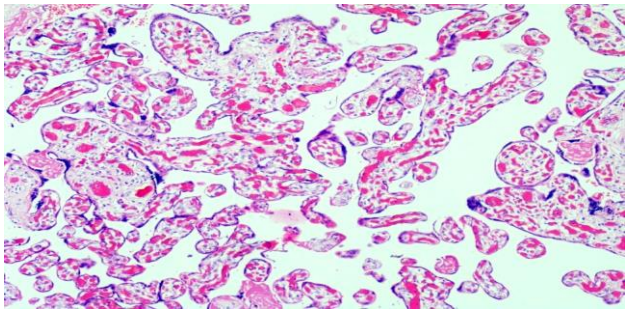
- Presence of lupus anticoagulant (LA) in plasma on two or more occasions at least 12 weeks apart
- Presence of moderate to high levels of anticardiolipin (aCL) (IgG or IgM) in serum or plasma (i.e., >40 IgG phospholipid units (GPL)/mL or IgM phospholipid units (MPL)/mL or >99th percentile) on two or more occasions at least 12 weeks apart
- Presence of moderate to high levels of anti–beta-2 glycoprotein I antibodies (IgG or IgM) in serum or plasma (> 99th percentile) on two or more occasions at least 12 weeks apart.[2]

Patients with SLE were diagnosed according to the American Rheumatism Association Diagnostic Criteria.[2] Both patients with ITP were diagnosed during the pre-pregnancy period.[4]

An entire placenta was available from all 10 patients and were fixed in 10% formalin. Placentas were weighed after the membranes and umbilical cord were trimmed off and compared with the reference weights for trimmed singleton placentas. Two rolls of membranes were taken and umbilical cord was examined for length, diameter, colour, insertion site and number of twists.[5] Photography of the placentas were routinely taken after examining foetal and maternal surfaces.

The placentas were cut at 1cm intervals and the parenchyma was assessed for colour, sponginess and specific lesions. Relevant lesional sections were taken along with membrane roll, cord and normal parenchyma. All the histologic sections were stained with hematoxylin and eosin.

□□□□□□□□



Over a period of 3-years 11 placentas from 10 mothers with the clinical and laboratory evidence of maternal autoimmune diseases were included in the study.

Two out of ten studied patients had SLE with secondary APLA, five had primary APLA, two had ITP and one with ANA positivity. One patient with ITP had two consecutive pregnancies and both placentas were studied

Patients with SLE

Clinical data and placental findings from the two studied patients with SLE are shown in Table 1. Both of our patients had SLE with secondary APLA.

Patient 1 was diagnosed 9 years before the index pregnancy. Her first pregnancy was an induced abortion owing to SLE flare, while the second was a spontaneous abortion. She had active renal involvement and superimposed preeclampsia in the present pregnancy. She was treated with low molecular weight heparin (LMWH), immunomodulators, anti-hypertensives and aspirin. She delivered a preterm small for gestational age (SGA) baby at 34 weeks of gestation due to preterm premature rupture of membranes (PPROM). Her placenta was small with thin hypercoiled cord (8 twists for 11.0cms of cord length-). Microscopically it showed maternal vascular underperfusion which included distal villous hypoplasia, increased syncytial knots, abundant perivillous fibrin deposition and calcification. Multifocal chorangiomatosis (Figure 1) was also noted.

Patient 2 was a second gravida with previous spontaneous abortion at 8 weeks. Now she was referred with an intrauterine foetal demise at 24 weeks of gestation. On evaluation she was found to have malar rash,

thrombocytopenia and presence of anti Sm antibodies. On investigating further, she also had an abnormal lupus anticoagulant (LA), with elevated titres of anticardiolipin (aCL) antibody IgG and beta 2 glycoprotein 1 IgM.

The placenta was very small (less than 10th percentile) and had thin, flat umbilical cord. The parenchyma grossly showed marginal atrophy and a basal firm yellow nodule. Microscopically, some of the chorionic plate and stem villous vessels showed recanalizing thrombi and haemorrhagic endovasculitis (foetal thrombotic vasculopathy). There was laminar necrosis of the decidua, patchy lymphohistiocytic villitis, intervillositis (Figure 2), microinfarcts and foci of avascular, hyalinized villi. Basal haematoma with indentation of parenchyma was also noted.

Microscopy	Maternal vascular underperfusion (Distal villous hypoplasia, Increased syncytial knots, Abundant perivillous fibrin deposition and calcification)	Thrombi, infarcts Recanalizing thrombi and haemorrhagic endovasculitis of stem villous vessels, avascular hyalinized villi (Foetal thrombotic vasculopathy)
	Multifocal chorangiomatosis	Retroplacental haematoma Villitis and perivillositis Laminar necrosis of the decidua

Patients with APLA

Clinical data and placental findings from the five studied patients with primary antiphospholipid antibodies are shown in Table 2. In patients 4 and 6, presence of APLA were diagnosed postpartum and the pregnancies resulted in intrauterine foetal demise. In the remaining three patients two were diagnosed even before attempting the studied pregnancies and were treated optimally which resulted in live births. Patient 3 was diagnosed to have APLA at the end of first trimester. She was tested during the ongoing pregnancy as she had previously delivered a premature, growth restricted baby with absent diastolic flow in umbilical artery doppler. Two out of the 3 live births were appropriate for gestational age (AGA). Of the three treated patients two were delivered near term, while the third (patient 3) was preterm.

In four out of 5 patients, the placental weight was small for gestational age. The placenta of the three live born

fetuses showed maternal vascular under perfusion (infarcts, intervillous thrombi and decidual vasculopathy) and vascular ectasia with hypercapillarization.

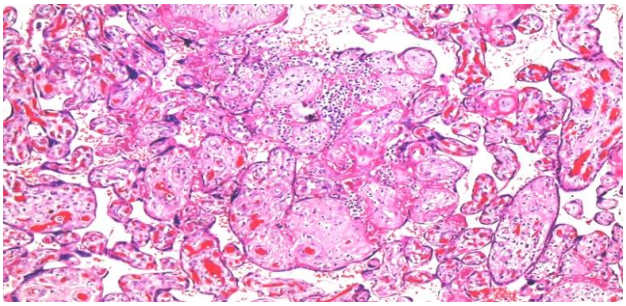

Figure 2. Placenta of patient 6 (IUFD) showed retroplacental haematoma with parenchymal indentation, subchorionic haematoma and intervillous thrombus. Interestingly the other IUFD (patient 4) had a AGA stillbirth and her placenta showed distal villous immaturity (Figure 3).

There were patchy, multifocal chorangiomatosis and villous stromal karyorrhexis. Lowgrade, focal villitis of unknown etiology was also noted.

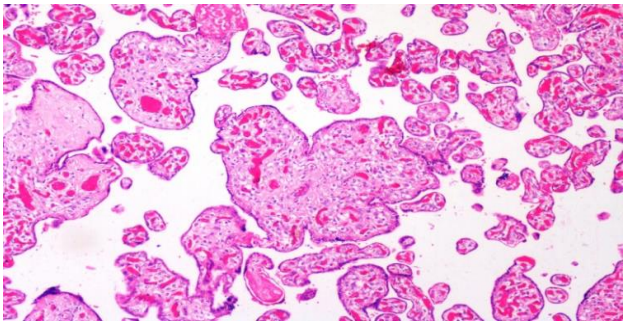

Figure 3. Placenta of patient 4 (IUFD) showed distal villous immaturity. Placenta of patient 8 showed chorangiomatosis and villous stromal karyorrhexis. Lowgrade, focal villitis of unknown etiology was also noted.

Patients with ITP

Clinical data and placental findings from the 3 studied pregnancies with idiopathic thrombocytopenic purpura are shown in Table 3.

Patient 9 had two successive pregnancies that were studied. Both the pregnancies were complicated by oligohydramnios. She had active disease during her first pregnancy and was treated with immunoglobulins, steroids and multiple transfusions. None of the babies were SGA or stillborn.

Almost all the placentas were ≤ 10th percentile. Maternal vascular underperfusion was found in 2 placentas of the three studied pregnancies (patient 8 and 9B) with ITP. Hypercoiling of the cord and haemorrhage around the umbilical vessels were present in patient 9B.

Transmural massive perivillous fibrin deposition (maternal floor infarction) was noted in patient 9A (Figure 4). Intervillous thrombi and lymphocytic deciduitis were also identified.

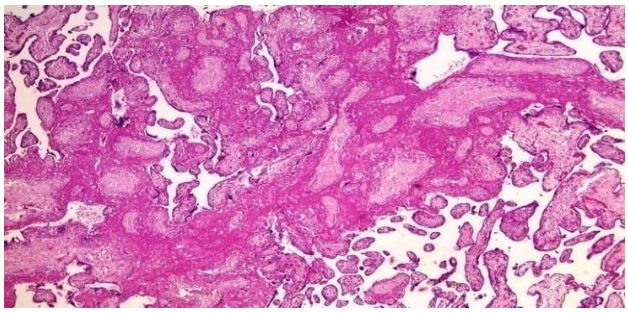

Figure 4. Placenta of Patient 9A showed massive perivillous fibrin deposition (maternal floor infarction) and intervillous thrombi. Placenta of patient 10 showed hypercapillarization of villi.

Patient with ANA

Clinical data and placental findings of the patient with antinuclear antibody is shown in Table 3.

Patient 10 was a low risk primigravida and on routine screening was found to have high resistance flow in uterine artery at mid trimester. On screening for auto-immunity she tested positive for antinuclear antibodies. She was treated with LMWH from 20 weeks and delivered a SGA baby at near term.

Placenta showed both maternal vascular under perfusion and foetal thrombotic vasculopathy which was evident by infarcts, distal villous hypoplasia, hypercapillarization, increased syncytial knots and fibrin thrombi of chorionic plate and stem villous vessels with large foci of avascular hyalinized villi (more than two foci/average of 15 or more affected villi/slide/ foetal vessel lesions) (Figure 5).[6,7]

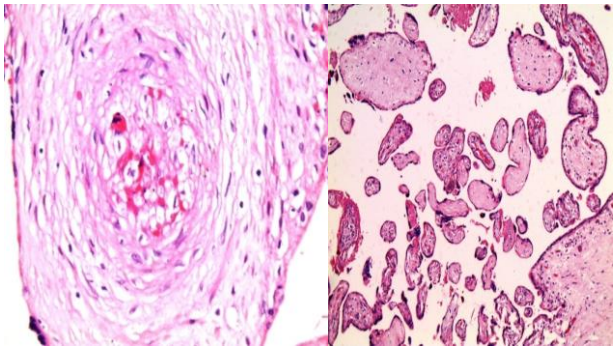

Figure 5. Placenta of patient 10 showed hypercapillarization of villi. Placenta of patient 1 showed

Maternal age	24 Years	23 years	19years	22years	28 years

Many physiologiocal changes must occur to allow the foetus to persist and grow. Part of the implantation process involves syncytiotrophoblast invasion and erosion of maternal endometrial blood vessels resulting in the development of a utero-placental circulation. Ultimately, the trophoblast becomes incorporated into the wall of the vessel which has now become a thin walled, dilated vascular channel with lack of muscle, thereby ensuring an adequate blood supply to the developing foetus. These vascular changes have been termed physiological change and lack of physiological change or decidual vasculopathy has been found to be a significant placental feature in certain diseases, for example preeclampsia alone, chronic hypertension with

superimposed preeclampsia, autoimmune diseases and idiopathic SGA infants.[8-10]

In this report, we describe clinical and pathologic findings of 11 placentas from 10 patients with autoimmune diseases. We prefer to specify the lesions that are present rather than to embrace them all in the imprecise terminology of placental insufficiency. The primary pathology observed in the present study was maternal vascular underperfusion (fibrin thrombi in the decidual vessels, intervillous thrombi, infarcts, distal villous hypoplasia and increased syncytial knotting).[8-10] Interestingly, the other pathological features observed were chorangiomatosis, villitis, massive perivillous fibrin deposition, distal villous immaturity, abruption and foetal thrombotic vasculopathy.

Distal villous immaturity (DVI) is a maturation defect of the terminal villi.[13] Microscopically the terminal villi are enlarged with excessive stroma, increased vascularity, with a continuous layer of syncytiotrophoblast, paucity of vasculosyncytial membranes and lack peripheral polarization of capillaries. This in turn decreases the efficiency of maternal-foetal exchange leading to late gestational hypoxia and IUFD. This finding is most often associated with maternal diabetes. DVI was apparent in the only term IUFD of our study. Contrary to the observations made so far in the literature, there was no evidence of glucose intolerance in the mother, but she had primary APLA. Presence of DVI in autoimmune diseases remains speculative and needs further characterization.

Chorangiomatosis involves immature intermediate villi or stem villi and the vessels are surrounded by pericytes with increased stromal cellularity and collagen. Diffuse multifocal chorangiomatosis is associated with extreme prematurity, IUGR, preeclampsia and it has been suggested that it may be a developmental abnormality of the villi.[14] This was the major lesion along with maternal vascular underperfusion in one of the studied SLE patients with secondary APLA. The pregnancy was complicated by preeclampsia, prematurity and intrauterine growth restriction.

The other patient who had SLE with secondary APLA was diagnosed postpartum and was not treated antenatally. She had a severe growth retarded foetus which resulted in stillbirth. The predominant lesion in the placenta was villitis of unknown etiology (VUE), perivillositis and retroplacental haematoma.[15] The villi were invaded and expanded by lymphohistiocytic infiltrate and showed secondary changes of ischemia,infarction,recanalizing thrombi in the stem villous vessels with resultant groups of avascular villi (foetal thrombotic vasculopathy).

VUE is a well-recognized entity, but remains a significant challenge because of its frequency, high recurrence rate and associated poor outcome. The most accepted theory is that VUE is an immune reaction akin to placental "rejection".[16]

Thrombi in the foetal circulation of the placenta cause a pattern of clustered avascular fibrotic villi called foetal thrombotic vasculopathy (FTV). Causal factors of FTV include stasis, maternal autoimmune diseases and vascular injury. The most serious outcomes include growth restriction, neurologic injury and perinatal death.[6,7]

Our patient with ANA positivity also had foetal thrombotic vasculopathy with superimposed maternal vascular under perfusion and resultant SGA baby.[11,12]

Apart from maternal vascular underperfusion, one of the placenta of ITP patient also showed massive perivillous fibrin deposition/maternal floor infarction (MPVFD/MFI). This particular patient had active disease during pregnancy and was treated with immunoglobulins, steroids and had improved pregnancy outcome. MPVFD/MFI has a recurrence rate of 30% or more.[17] We had an opportunity to study the subsequent pregnancy of the same patient where the lesion did not recur. There were no associations found between placental lesions and foetal outcome in all three studied ITP cases.

□□□□□□□□□□

Placenta remains an undervalued and underutilized surgical specimen in the evaluation of maternal autoimmune disorders. Studies have clearly demonstrated that there are a multitude of mechanisms where by autoimmunity can prevent normal placental development and can cause significant pathology. In this group of diverse autoimmune diseases placental lesions were not specific for any of them.

But it appears that diseases that are clinically more severe have more severe placental vascular changes, related to foetal outcome.

Therefore, although the histopathologic lesions are similar, there appears to be a "grading" in severity. Placental thrombosis and infarction are just one part of the placental lesions. Analyzing previous placentas has been helpful as patients appear to repeat the recurrent lesions such as VUE, MPVFD/MFI and DVI. Pathologists should be aware of these changes and alert the clinicians to the possibility of recurrences in subsequent pregnancies.

Given the heterogeneity of histologic findings, it would be unlikely that a single treatment would be effective in all cases. Perhaps placental pathology should be used to guide therapy; however, it needs to be validated by a study on a larger sample. Placental examination should be indicated in defined subset of patients which includes maternal autoimmune disorders.

Authors would like to thank Dr. Ammu Sivaraman, Emeritus Professor, Department of Pathology, PSGIMSR.

Abstract

Background: This study was designed to evaluate the institutional Maternal Mortality Ratio (iMMR) in our institution, a tertiary private medical college hospital and to suggest recommendations and possible interventions to reduce it.

Methods: This retrospective descriptive study was conducted by reviewing the hospital records over a period of ten years from January 2009-December 2018. The case records were reviewed for maternal demographic characteristics and complications.

Results: The total number of deaths during the study period was 21, giving an iMMR of 85.268 per 100000 live births. Most of the maternal deaths (>80%) occurred postpartum. Obstetric causes contributed to 57% of the deaths with hypertension and hemorrhage topping the list. Other causes were sepsis and non obstetric causes including one case of maternal suicide. 52.38% of the women died more than 48 hours after admission to the hospital, while 28.57% succumbed in less than six hours. Secondary complications noted were ICU admission, extended intubation, massive transfusion, operative intervention and multi organ dysfunction.

Conclusions: The classical triad of Hypertension, Hemorrhage and Sepsis continues to be the major determinant of maternal mortality and are potentially preventable by promoting universal access to quality health care, strengthening of health services and ensuring accountability.

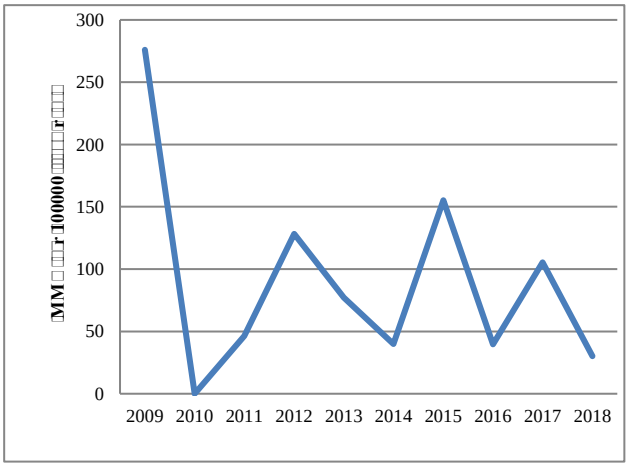
Keywords: Hemorrhage, Hypertension, Maternal mortality, MMR, Multi organ dysfunction, Suicide

INTRODUCTION

In the year 2000, the United Nations adopted the Millennium Development Goals (MDG) out of which MDG 5 was targeted on reducing the Maternal Mortality Ratio (MMR) by three fourths between 1999-2015.[1] By the year 2015, Sustainable Development Goals (SDG) were introduced and SDG 3 aimed at Good Health and Well-Being.[2] Under this, the aim is to bring down the global maternal mortality to below 70 per 100000 by the year 2030.

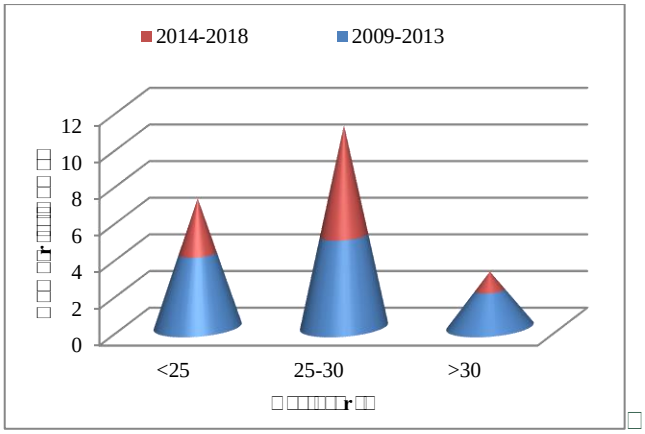
At an MMR of 130 per 100,000 live births in 2016,India is ranked 128 in the world.[3,4] WHO commended India for its groundbreaking progress in reducing maternal mortality by 77% to the present rate.[3] Strategies responsible for this achievement include (i) Increased coverage of maternal health services and promoting institutional deliveries (ii) Incentives and financial support for women delivering in the public health system (iii) Improving literacy among women and increasing the average age at marriage (iv) promotion of public-private partnerships in the care of pregnant women.[3]

To put the country on track to achieve the SDG targets, Government of India established the NITI (National Institution for Transforming India) in the year 2015 to monitor, coordinate and ensure implementation of the SDGs.[2]



This study was designed to evaluate the MMR in our institution, a tertiary private medical college hospital and to suggest recommendations and possible interventions to reduce the institutional Maternal mortality ratio (iMMR). Continued and focussed efforts to end preventable deaths due to pregnancy and childbirth will help our country reach the SDG.

M□□□□□□



This retrospective descriptive study was undertaken in the Department of Obstetrics and Gynecology at the PSG Institute of Medical Sciences and Research, Coimbatore, India during the period from January 2009- December 2018. The approval of the Institutional Human Ethics Committee was obtained. Informed consent was not required since it was a retrospective study and there was no direct patient contact. The case records of all the women who died during pregnancy or within 42 days of delivery due to complications of pregnancy or other causes were reviewed for the following factors: age, obstetric history, antenatal complications and co morbidities, gestational age at onset of symptoms (if any), ICU admission, the need for ventilator support, blood transfusion, multidisciplinary management, cause of death and admission death interval. The number of live births during the study period was obtained from the parturition register. MMR was calculated as number of maternal deaths per 100000 live births.

□□□□□□□

There were a total of 24628 live births in our institution during the study period. Data regarding the socioeconomic status, urban/rural divide were difficult to ascertain from the case records.

The total number of deaths during the study period was 21, giving an iMMR of 85.268 per 100000 live births. The annual trend in iMMR has been pictorially represented in Figure 1. The age of the women ranged from 20-32 years (mean-25.9±3.6 years). The age distribution of the women is graphically represented in Figure 2.

Blood transfusion>5 units	6	3	42.87
Operative intervention	1	2	14.28

Majority of the women died postpartum, except for three. Two of the women who died antenatally were referred to our facility in a moribund state and died within two to three hours of admission despite intensive resuscitative measures. Ten of the women were multiparous and eleven of them were primiparous. Referrals from outside facilities were predominant in the first five years. Obstetric causes dominated the scenario in the first five years (6/11), whereas deaths during the next five years were mainly due to medical disorders (Table 1).

52.38% of the women died more than 48 hours after admission to the hospital, while 28.57% succumbed in less than six hours of admission (Figure 3).

Secondary complications noted were ICU admission, extended intubation, massive transfusion, operative intervention and multi organ dysfunction. Commonest among the above was ICU admission (71%) and the least common was operative intervention (14.28 %) (Table 2).

Maternal mortality is considered an index of the quality of healthcare services in a society. MMR of Tamil Nadu (a state in South India) at 66 per 100,000 live births is low as compared to most of the states in India.[4]

The lower rates are due to a higher proportion of institutional deliveries, effective healthcare delivery system and high quality emergency obstetric care provided by CEmONC (Comprehensive Emergency Obstetric and Newborn Care) centres.

In the present study, the highest mortality rates were in the age group 25-30 years, which is comparable to those of similar studies from South India.[5,6] This may be explained by the fact that the highest proportion of the pregnant population belongs to this age group.71.43% of the women were primiparous as against other studies where multiparous women formed the majority.[7] Both vaginal deliveries and cesarean sections were encountered equally in our series.

A fluctuating trend in iMMR was observed during the study period with peaks during the years 2009, 2012 and 2015. This was a chance observation since the women were referred from maternity units from the surrounding areas and there was a modest but steady increase in the number of deliveries over the years.

Major proportion of the deaths occurred in the postpartum period (80.95%).[6,8] One perimortem caesarean section was done on a patient with peripartum cardiomyopathy (PPCM) who had a cardiac arrest on table.

Two thirds of the women who died were referred from other hospitals.[5] Increased mortality was seen in patients who were referred from other hospitals, due to the bad general condition in which they were received and the time delay. The type of delay could not be assessed in the referral cases as the primary care was given elsewhere.

Obstetric causes of maternal mortality include those resulting from obstetric complications of the pregnant state (pregnancy, labour and puerperium). Non obstetric causes result from pre existing diseases or those that develop during pregnancy and which is not due to direct obstetric cause, but was aggravated by the physiological effects of pregnancy.[9]

Interestingly, 57% of the deaths were due to direct obstetric causes in contrast to those by Sowjanya kumari et al (85%), B. Paul et al (76.7) %, Murthy et al (72.5%) and similar to Khandale SN et al (61%).[6,10-12]

The leading causes of death were hypertensive disorders (23.8%) and haemorrhage (23.8%) comparable to the study by Paily et al. The major cause of death in women with hypertension in our series was hepatic dysfunction (60%).[13]

Severe preeclampsia is associated with high rates of maternal mortality and morbidity. The major contributors to maternal mortality in preeclampsia are eclampsia, HELLP, cerebral haemorrhage, renal dysfunction and coagulopathy. The two pronged approach to management of preeclampsia, i.e., control of hypertension with Labetalol and seizure prophylaxis with Magnesium sulphate has to be adopted to minimise complications.[14] Standard protocols have to be in place for early detection, referral, appropriate treatment and timely delivery.[15]

80% of the women who succumbed to obstetric haemorrhage were referred from other hospitals in a critical condition and died within few hours of admission despite intensive resuscitative measures including obstetric hysterectomy. Atonic postpartum haemorrhage (PPH) was the cause of death in four cases while one patient died due to rupture uterus. Rupture uterus followed a second trimester termination in a woman with two previous cesarean sections with an inappropriate dose of misoprostol.

Active management of third stage of labour (AMTSL) and oxytocin as the first line uterotonic has been advocated as the gold standard in preventing complications due to PPH.[16] In health care settings without facilities like access to blood and blood products and specialist care, early referral will play a pivotal role in preventing mortality. Women at high risk for PPH could be appropriately managed antenatally and delivered in a tertiary centre so that complications arising henceforth could be anticipated and prevented. Staff in the tertiary centres have to be trained in protocols for management of PPH with frequent mock drills.

Since our institution is an urban centre, the prevalence of cases of severe anaemia was less.[13] This could be attributed to early identification of women with anaemia and institution of appropriate treatment. Still anaemia was a contributory factor in five women in our series. Blood transfusion for moderate anaemia close to delivery was the trigger for deterioration of the maternal condition in three instances. Two of the three women were diagnosed with transfusion reaction which led to acute renal failure requiring dialysis.[6,8] The importance of early detection of anaemia, its correction and the need for raising the threshold for transfusion is reiterated by these cases.

Two women in our study had a diagnosis of PPCM (9.52%) as compared to Creanga et al (10-15%).[17] One of them was diagnosed antenatally at 29 weeks and the other followed a normal vaginal delivery.

Four women had hepatic dysfunction and jaundice, out of which three were due to preeclampsia and one was due to viral hepatitis. All patients with hepatic dysfunction were referred from other hospitals due to availability of good intensive care facilities and were directly referred to the gastroenterology unit. The incidence of pulmonary embolism, hepatitis and sepsis in our series were similar to that of Singh et al.[8]

One death in our study was due to suicide. According to the ICD-MM guidelines published by the WHO all antepartum and post partum suicide deaths should be included as direct obstetric deaths even if it is not possible to establish the diagnosis of depression or puerperal psychosis.[18] This is a major deviation in maternal mortality reporting and has the potential to increase the MMR since hitherto unreported deaths will be accounted for henceforth.[13,19]

The commonest complications encountered by these women were prolonged ICU stay and ventilator support. Multidisciplinary care was required in more than 50% of our cases, commonest being the involvement of nephrologist, gastroenterologist and cardiologist. 29% of the women died within six hours of admission, whereas 52% succumbed to complications after 48 hours, the longest being 33 days.[5,7,8,12]

The only operative intervention performed was obstetric hysterectomy which was required in three women-two following failed medical management of atonic PPH and one following rupture uterus. 50% of our patients required multiple transfusions since obstetric haemorrhage was a leading cause of mortality, and coagulopathy due to hepatic dysfunction was also seen in a few cases.

More than 50% of deaths in our study were due to obstetric causes, which are largely preventable. This could be achieved by intensive monitoring with incorporation of early obstetric warning tools.[20] Early warning tools include monitoring of maternal vital parameters such as blood pressure, heart rate, temperature, oxygen saturation, respiratory rate and altered sensorium; and notification to the physician in case of any abnormality.

As with all retrospective studies, our study also has limitations. Our institution being a private medical college in a city with many other well equipped hospitals, we reported a lesser number of maternal deaths. Fewer numbers preclude adequate statistical analysis and hence reduce the power of the study. Higher proportions of cases were referred from far-off areas and hence details regarding the initial management could not be accessed. In addition, autopsy was not performed routinely and therefore, the exact cause of death could not be verified in many of the cases.

□□□□□□□□□□

Though the iMMR has shown a fluctuating trend, it has remained at acceptable levels in comparison to the state and national averages. The classical triad of Hypertension, Haemorrhage and Sepsis remains the major determinant of maternal mortality in our institution and most of them are preventable. By promoting universal health coverage, access to quality health care, strengthening of health services and ensuring accountability, we can strive to reduce deaths due to pregnancy and childbirth.

Effect of Antenatal Yoga on Labour Outcome- A Non-Randomized Control Study from a Tertiary Hospital in South India

[1]Dr. Saira Rajan, [2]Dr. Reena Abraham, *[3]Dr. Chippy Tess Mathew
[1]Senior Resident, Department of Obg, Kmch Institute of Health Sciences and Research, Coimbatore, Tamil Nadu, India
[2]Professor, [3]Associate Professor, Department of OBG, PSG Institute of Medical Sciences and Research Coimbatore (Affiliated to the Tamil Nadu Dr. MGR Medical University), Tamil Nadu, India

INTRODUCTION: Giving birth to a healthy baby is one of the happiest moments in a woman's life. Yoga is a 'body-mind' practice. The prospective of yoga to create balance along emotional, mental, physical, and spiritual dimensions is immense. It uses physical positions (asana), meditation (dharana and dhyana), concentration, breathing exercises (pranayama) and contemplative practice. OBJECTIVE: To study the effect of yoga on antenatal outcome. MATERIALS AND METHODS: It is a Prospective study done during the time period July 2013 to July 2014.In a series of 50 women who fit in the inclusion criteria, attending the antenatal clinic of a private medical college in Tamilnadu, training to practice yoga as relaxation therapy during pregnancy and labour was given and it was compared with 50 antenatal women who obtained regular care. The various outcomes like Mode of delivery, Bishop's score, Duration of active labour; Administration of analgesics and Weight of infant were studied. RESULTS: The major advantage noted in this study was reduced duration of active phase of labour. 70% of the antenatal women doing yoga went into spontaneous labour. 34% of induced labour in the control group were noted. All the patients in the yoga arm delivered at term. Whereas 4% of the patients in control arm had preterm delivery. CONCLUSION: Practicing yoga in the antenatal period decreases induced labour and shortens the duration of active phase of labour. The mode of delivery has a multifactorial contribution and cannot be compared in this study.

Keywords: Yoga, Pregnancy, Labour, Active Phase

INTRODUCTION

Motherhood transforms a woman forever. It extracts out a life lying dormant for months deep within her. Remaining physically active during pregnancy is the best a woman can do. At least thirty minutes of moderate exercise each day is recommended for improving the health and wellbeing of non pregnant women according to Len Kravitz (1998). In accordance with the American College Of Obstetrics and Gynaecology (2002), exercise during the period of pregnancy is very good and appropriate in pregnant women without any obstetric and medical complications. Yoga may be able to provide a gentle alternative to physical activity.Yoga is a 'body - mind' practice .It is a combination of various physical positions, breathing and relaxation exercises according to Smith C.A (2011). The word 'Yoga' comes from the Sanskrit word which means "to join" and can be understood as unity or oneness It uses physical positions (asana), meditation (dharanaanddhyana), concentration, breathing exercises (pranayama) and contemplative practice. Yoga mends psychological wellbeing. Labour is the active process of delivering a foetus and is characterised by regular, painful uterine contractions which increase in frequency and intensity. It is difficult to predict the length of labour. Duration of labour was positively corelated with the weight of the infant, duration of pregnancy, weight gain and prepregnant weight. It was negatively corelated with mother's height. Mother's age did not influence duration of labor according to Britt-Ingjerd Nesheim (1988). According to Kelly Riley (2017) Malpositions of the head prolonged labor in nulliparas, but not in multiparas, while breech presentation had no influence. 35 trials lecturing the outcomes of yoga on anxiety and stress were reviewed by LiAW et al in (2012) and the results were indicative of the role of yoga in alleviating stress and concern· Randomized controlled study on 74 women by Pamela Jones (2008) who

reported that in yoga group there was improved comfort during labour and after labour. The interval of first stage of labour was also shorter as well as the total labour duration according to a study done in Prince of Songkla university in Thailand by Chuntharapat S(2008) .So ours is an attempt to evaluate the effect of yoga on antenatal outcome in our study population.

METHODOLOGY

Study Design: Prospective non randomized control study
Time period: July 2013 to July 2014
Ethical approval: OBTAINED FROM ETHICS COMMITTEE OF PSGIMSR AND INFORMED CONSENT TAKEN.

A series of 50 women attending the antenatal clinic of a private medical college in Tamilnadu were given training to practice yoga as relaxation therapy during pregnancy and the labour outcome was compared with 50 antenatal women who obtained regular care.

Pregnant women of gestational age> 12 weeks are given training in 6 separate sessions by specially trained people in yoga through training sessions. They are encouraged to practice this on a regular basis. The regularity is assessed through personal interview. They are advised to do yoga minimum of 5 times a week.

Inclusion criteria
- Singleton pregnancy
- Primi less than 35 years
- Spontaneous conception
- No antenatal complications
- Co-operative and compliant patients

Exclusion criteria
- Multiple pregnancy
- Threatened abortion or previous preterm delivery
- Elderly Primi
- Multigravida
- Patients not willing to participate in the study

Types of outcome measured
- Mode of delivery
- Bishop's score
- Duration of active labour
- Administration of analgesics
- Weight of infant
- Type of delivery was assessed as normal vaginal delivery, assisted vaginal delivery (instrumental) or caesarean section.

➢ BISHOP'S SCORE (TABLE-1)

Table 1: BISHOP'S SCORE

Sign	Points				Score
	0	1	2	3	
Position	Posterior	Intermed.	Anterior		
Consistency	Firm	Intermed.	Soft		
Effacement	0-30%	31-50%	51-80%	>80%	
Dilation	0 cm	1-2 cm	3-4 cm	>5 cm	
Fetal station	-3	-2	-1, 0	+1, +2	
Results	The Bishop Score is: Calculate Bishop Score Reset				

The Bishop Score scores patients who would be most likely to accomplish a successful induction. It is a pre induction record. A score that go beyond 8 defines the patient most likely to accomplish a fruitful vaginal birth. A low Bishop's score frequently designates that induction is unlikely to be fruitful. Kelly C (2019) specify that only a score of 8 or more is reliably prognostic of a positive induction

➢ Active phase duration

Cervical dilatation of 4cm or more with uterine contractions can be taken to dependably signify the onset of active labour .According to Friedman the mean duration of active phase of labour in nullipara was 4 .9 hours .As the standard deviation of 3 .4 hours is large ,the active phase was testified to have a numerical maximum of 11 .7 hours .In all patients in labour we plot a partogram and the active phase duration was calculated.

➢ Analgesia

The various analgesia options in labour are epidural, sedation and inhalational analgesia with entonox. The use of epidural analgesia was examined in our study.

THE VARIOUS POSTURES OF YOGA PRACTICED IN PREGNANCY ARE AS FOLLOWS: TABLE 2

Figure 12: MukhaDhauti

Inhale. exhale and press the thighs and knees downward towards the floor. Make a gentle effort to keep pressing them forward. Start flapping both the legs up and down.

SURYA NADI PRANAYAMA - FIGURE 4

This refers to the Breathing Exercise. Inhale through the right nostril, Exhale through the left, press the index and middle finger of the right hand against the palm of that hand. Use thumb to occlude the right nostril. Ring and little fingers to occlude the left nostril.

KADICHAKRASANA - FIGURE 5:

Exhale and twist from the waist to the right and look back over the right shoulder. Keep the distance between your palms constant. Inhale comeback to the center, Exhale and turn to left and repeat the yoga posture on your left side.

CHOPPING WOOD POSE – FIGURE 6

Sit in a squatting position with your back straight .Clasp the hands in front and with inhalation raise the hands gently up in the air and come down with an exhale .

PAWANAMUKTHASANA PART 1

Sit outstretched, keep both the knees together and the heel on floor spine and the neck in the same level. put the palms of the hands on the floor. Keep the fingers outstretched. Apply pressure on the palm. Close eyes and breath. Begin the exercise with open eyes

VAJRASANA - FIGURE 7

The name comes from the Sanskrit words *vajra* - "thunderbolt". Sit on heels with the calves beneath thighs. There should be four finger gap between the knee-caps., sit straight.

WARRIOR POSE - FIGURE 8

VEERABHADRASANA – FIGURE 9

Breathe in as you come up and exhale as you go down with your hands from side. Redo the same from left side

CAT STRETCH FIGURE:10

STEP 1: Position your palm directly below your shoulders. Place knees directly below your hips . Spread your fingers with the middle fingers pointed straight.

STEP 2: Press towards the floor using your hands and then lift yourself up out of your shoulders. Go back and forth several times. Exhale and sag shoulders.

SEATED SIDE STRETCH - FIGURE 11

Rotate your head to look beyond your left elbow. Retain this position for 5 seconds. Now inhale and lift trunk and move left upper limb upward. Breathe out by bringing down left upper limb.

MUKHA DHAUTI- FIGURE 12

Lean forward and rest the arms on the respective thighs keeping the arms straight. Inhale through the nose and exhale forcefully through the mouth. Stand in Tadasana and relax.

RESULTS

In the study of antenatal yoga on labour outcome 100 antenatal women who were not age matched were included. 50 women were doing yoga and 50 received regular antenatal care.

TABLE 3: The age distribution is as follows

Age Distribution			
Age	Group		Total
	Yoga	Control	
<20	0	4	4
21-25	25	24	49
26-30	21	20	41
31-35	4	2	6
Total	50	50	100

The result shows that there is no significant age difference among the antenatal in group who were doing yoga and in routine care category

NO OF YOGA CLASSES ATTENDED BY THE ANTENATAL WOMEN IN YOGA GROUP.

46% of the antenatal women in yoga group had attended 4 classes. Only 10% of the women attended 5 yoga classes. 44% of the antenatal women who were practicing yoga attended only 3 yoga classes.

Table 4: Distribution of preterm or term deliveries

Term/ Preterm			
Out come	Group		Total
	Yoga	Control	
Term	50	48	98
Pre Term	0	2	2
Total	50	50	100

All the patients in the yoga arm delivered at term. Whereas 96% in the control arm delivered at term and 4% of the patients had preterm delivery, but this was not statistically significant as the p value was >0.5.

Table 5: The bishop's score among the antenatal women in yoga group and control group

Bishop Score	Group		Total
	Yoga	Control	
< 5	28	28	56
> 5	19	20	39
Total	47	48	95

As per the result there is no significant difference in Bishop's scoring among the two groups.

Table 6: The onset of labour among the yoga group and the control

Labour	Group		Total
	Yoga	Control	
Spontaneous	33	33	66
Induced	14	17	31
Total	47	50	97

The onset of labour is comparable in both the groups. 70% of the antenatal women doing yoga went into spontaneous labour. 34% of induced labour in the control group were noted. In the yoga group only 30% were induced labour.

Table 7: Distribution of mode of delivery

Mode of Delivery			
Delivery	Group		Total
	Yoga	Control	
NVD	20	36	56
LSCS	17	10	27
Instrumental	13	4	17
Total	50	50	100

The percentage of patients went in for lscs was 34 % in the yoga group where as it was 20% in the control group. Only 66% of women doing yoga had a vaginal delivery out of them 26% was instrumental delivery. Whereas in the control group 80% had a vaginal delivery. This finding was also not statistically significant,

Table 8: Distribution of Instrumental Delivery

Delivery Instrumental			
	Group	Total	
Instrumental	Yoga	Control	
VACUUM	12	3	15
FORCEPS	1	1	2
Total	13	4	17

Vacuum assisted delivery was significantly high among the yoga patients.

Table 9: Indications for lscs

LSCS	Group		Total
	Yoga	Control	
CPD	1	2	3
NPL	1	1	2
ARREST	2	2	4
FETAL DISTRESS	3	5	8
MSL	4	0	4
CONDYLOMA	1	0	1
DTA	1	0	1
FAILED	1	0	1
MATERNAL WISH	1	0	1
TRANSVERSE LIE	1	0	1
MOBILE HEAD	1	0	1
Total	17	10	27

The common Indication for LSCS in yoga patients were meconium stained liquor in early labour and fetal distress.

Table 10: Duration of active phase of labour

Duration	Group		Total
	Yoga	Control	
<= 2 HRS	3	0	3
2 - 3 HRS	16	7	23
3 - 4 HRS	10	16	26
> 4 HRS	4	17	21
Total	33	40	73

There is significant difference in the duration of active phase among the women practicing yoga and the control group. Majority had an active phase duration of< 2-3 hours in the yoga group when compared to the controls who had an average duration more than 4 hours which was statistically significant.

THE USE OF ANALGESICS

There is no significant difference among both the groups in usage of analgesics .

Table 11: Effect on birthweight

Birth Weight [kgs]	Group		Total
	Yoga	Control	
< 2 .5	2	5	7
2 .5 - 3 .5	43	42	85
> 3 .5	5	3	8
Total	50	50	100

The mean birth weight of the babies born to women practicing yoga was 3.10kg .

MEAN OF CLINICAL PARAMETERS – TABLE 12

Mean duration of active labour , in the yoga group came about 190 minutes ,whereas the mean duration of active phase of labour for the control group was 244 minutes which was statistically significant.

Table 12: Mean of clinical parameters								
		Mean	SD	95% CI for Mean		Minimum	Maximum	p value

DISCUSSION

This study which was conducted in a Tertiary hospital in Tamilnadu was done with the objective to analyse the effect of yoga on antenatal outcome. We enrolled 100 antenatal patients-of which fifty underwent yoga classes and fifty had routine antenatal care and the outcomes were analysed and the results were given above.

The age group of the antenatal patients who did yoga and the control group was similar in our study. All the patients practicing yoga had a term delivery which is similar to the study by Narendran et al (2005) where preterm deliveries were significantly low. In our study there was no significant difference in the Bishop's score at admission in the yoga and control group. There was no data to compare this.

There was also no difference in the onset of labour for both the groups.28% had induced labour in the yoga group and 34% in the control group in our study. This is similar to the study by Jahdi et al (2017) where there was a decreased percentage of labour induction in the yoga group.

In our study 34% of the yoga group patients had caesarean delivery while only 20% of the control group had caesarean delivery. This is in contrast to the study by Jahdi et al (2017) and Satyapriya Maharana et al in 2013 who showed reduced incidence of caesarean delivery after yoga therapy i.e.15% versus 40% in the control group.Since the mode of delivery has got multifactorial contribution ,it is difficult to compare it in these two groups. Even though the mode of delivery is not significantly altered, larger sample size is required to conclude this fact.

The major advantage noted in our study was the reduced duration of active phase of labour.This is very much significant as the duration of labour is an important factor in patient comfort,experience with childbirth and satisfaction.The reduction in active phase duration is consistent with the studies conducted by Songporn chuntharapat (2008), Sathyapriya M et al (2013) where there was significant reduction in labour duration.

The mean birth weight of the babies born to women practicing yoga was 3.10kg and 2.99kg in the control group which was not statistically significant. This is similar to the study by Maria Pais in 2016 where the mean weight of the yoga group was 3kg and the control group was 2. 7kg.This may be due to the increase gestational age of delivery in the yoga group. This was also consistent with the study by Shamanthakamani Narendran et al. in (2005) where there was significant higher babies with birth weight more than 2.5kg in the yoga group.

CONCLUSION

As per my study antenatal women doing yoga had significant reduction in the duration of active phase of labour than who receive regular care. Although not statistically significant, all of the patients in yoga group had term deliveries and good mean weight of babies. May be a larger study group in the future can give more definitive results.

Abstract

Background: Adnexal torsion is one of the gynecologic emergency conditions requiring prompt diagnosis and surgical treatment to save the ovarian function. This retrospective study is intended to analyze the clinical manifestations and treatment in a tertiary care center.

Methods: This is a retrospective study Case records during five-year period of February 2012-2017 in PSG Institute of Medical Sciences and research, Coimbatore, India.

Results: Adnexal torsion was seen in all age groups and commonly in reproductive age. It was seen in few pregnant patients also. Lower abdominal pain of acute onset associated with nausea and vomiting was the commonest clinical feature. Ovarian cyst and PCOD were the common risk factors predisposing torsion. Though ultra sound was the common modality used, the diagnosis was done based on strong clinical suspicion with surgical confirmation. The ovaries were preserved in some patients of reproductive age group.

Conclusions: Adnexal torsion is one of the gynecologic emergencies. The symptoms and signs are nonspecific and may not have a confirmatory lab or imaging study. Hence a strong clinical suspicion followed by prompt surgical management in both pregnant and non -pregnant patients of any age group saves the ovary and further complications.

Keywords: Abdominal pain, Ovary, Torsion, Ultrasound

Introduction

Adnexal torsion is one of the gynecological emergencies affecting females of all ages. Ovarian torsion is defined as rotation of ovary or adnexa with the vascular pedicle on its axis resulting in arterial, venous,or lymphatic obstruction.[1]

It often presents as intermittent acute abdominal pain exacerbated by positional shifts.[2] Approximately 70% have symptoms of nausea and vomiting mimicking other surgical causes of pain like acute appendicitis or renal colic. So, the clinical scenario can lead to misdiagnosis.[3]

In addition, the conventional ultrasound may not be conclusive and the diagnosis can become difficult. Delay in diagnosis and treatment leads to necrosis of the affected ovary.

The aim of the study was to analyze the clinical manifestations and management done during the past five years.

Methods

A Retrospective analysis of 47 medical records with surgically confirmed cases of adnexal torsion was done. The clinical parameters taken for analyses taken were age, medical history, clinical manifestations and examination findings. In clinical presentation the type of abdominal pain with associated clinical findings were noted.

Additionally, whether the condition was associated with fever and leukocytosis was also noted. The imaging performed with its findings, operative details and histopathological reports of the specimens were also analyzed.

[illegible]

Clinical findings

The total number of patients with ovarian torsion were 47 in number. The median age of our patients was 22 years (18days-66years). There were 5 (10.6%) patients in premenarchal age group, 41 patients (87.2%) in reproductive age group and 1 (2.1%) in postmenopausal group. Acute onset of pain was the common symptom present in all patients (100%). The abdominal pain was diffuse and nonspecific in 21patients (44.6%), localized to right side in 19 patients (40.4%), and on the left side in 7 patients (14.8%). The next common symptom was nausea and vomiting seen in 37 (78.7%) patients followed by fever in 5 (10.6%) patients. A mass was palpable in 14 (29.7%) and tenderness elicited in 17 (36.17%) of the cases.

There were 3 (6.3 %) patients in early pregnancy with torsion.

Lab investigations revealed leukocytosis in 18 (38.2%) and anemia in 4 (8.5%) cases.

In all cases ultrasound along with Doppler was performed and torsion was reported in 25 patients (53.19%). 11 cases (23.4%) had minimal free fluid in pouch of Douglas. Ovarian cyst was reported in 31 cases (65.9%) in ultrasound. Of that 16 patients (51.6%) had cyst size of 5- 10cms, 11 patients (35.4%) had cyst size of more than 10cm and 4 patients (12.1%) had cyst size of less than 5cms. The contralateral ovary showed features of PCOD in 5 (10.6%) patients.

Operative findings

Of 47 patients with adnexal torsion, right adnexa was involved in 27 (57.4%) cases followed by 20 (42.5%) cases on left side. The risk factors like tubal ligation was noted in 3 (6.3%) cases, previous surgery adhesions in 1 (2.1%) patient.

Isolated fallopian torsion was seen in 3 (6.3%) in patients.

Detorsion with oophoropexy was done in 8 (17%) patients, ovarian cystectomy was done in 20 (42.5%) patients, unilateral salpingectomy in 3 (6.3%) patients, unilateral salphingo oophorectomy in 11 (23.4%) cases and total hysterectomy with bilateral salphingo oophorectomy in 5 (10.6%) patients. The patients with conserved ovaries were found to have normal ovarian function and asymptomatic on follow-up.

[illegible]

[illegible]	[illegible]	[illegible]
Serous cyst adenoma	6	12.77
Serous cyst adenofibroma	1	2.13
Serous cyst adeno carcinoma	1	2.13
Mucinous cyst adenoma	2	4.26
Teratoma	2	4.26
Follicular cyst	1	2.13
Corpus luteal cyst	4	8.51
Paraovarian cyst	5	10.63
Endometriotic cyst	1	2.13
Total specimens with haemorrhagic necrosis	17	36.17

Histopathological examination was done in all excised specimens and results are shown in Table 1. The common finding seen in specimens was hemorrhagic necrosis (36.1%) and the common benign tumor noted was serous cyst adenoma in 6 patients (12.7%).

[illegible]

Adnexal torsion is the reported to be the fifth most common gynecological emergency condition encountered with a prevalence of 2.7%.[4] Though it is fifth most common emergency it poses difficulty to diagnose clinically due to nonspecific presentation. The lower quadrant abdominal pain described in adnexal torsion is of sudden onset usually following exercise or jerky movement. It is described as sharp, stabbing or less frequently crampy.[5] The ultrasound findings of ovarian torsion may change depending on the duration and degree of torsion (Complete or incomplete) and the presence or absence of ovarian mass.[6,7] The other adnexal pathologies like endometriosis, hemorrhagic cysts, ectopic pregnancy, pelvic inflammatory disease form complex adnexal mass and make it difficult to differentiate sonographically.[4,8,9]

All age groups are susceptible to develop adnexal torsion though it is commonly seen in reproductive women.[3,10-12] Majority of our cases in this study also were in younger reproductive age group (Table 2). It commonly occurs in normal ovaries in young children.[13] Torsion was seen in 5 (10.6%) of our cases in premenarchal age group. Our youngest patient was 18 days neonate, prenatally diagnosed to have an ovarian cyst. Oltmann SC et al reports occurrence of 16% in infant population.[14] It was less common in post-menopausal women in this study.

The most common symptom seen in all our cases (100%) was acute onset of abdominal pain. Other studies also reported the increased incidence of acute abdominal pain.[12,15] In respect to site of pain 21 (44.6%) cases had diffuse pelvic pain, 19 (40.4%) cases had pain on right flank and 7 (14.8%) cases on the left flank. The site of pain may not always denote the site of torsion because twisted adnexal masses are often midline, positioned cranial to the uterine fundus of abdominal pain.[1] The next

common symptom in this study was nausea and vomiting seen in 37 (78.7%) cases similar to other studies.[11,14] In this study palpable mass was seen in 14 (29.7%) cases and tenderness was demonstrated only in 17 (36.1%) cases and was similar to another study.[12] Other symptoms like vaginal bleeding and urinary symptoms reported in other studies were not noted in this study.[11,16]

Table 2: Comparison of clinical presentation and management in various studies

Parameters	Present study	Comparison study	Comparison study

Radical surgery	40.30%	45.70%	53.30%

Adnexal torsion can occur rarely in pregnancy. The incidence reported is 1 in 5000 and occurs more frequently in the first trimester in patients that underwent treatment for infertility with in vitro fertilization or ovarian stimulation.[17] Present study had 2 cases of adnexal torsion in first trimester and one case in second trimester of pregnancy. Similar case series also reports torsion common in first trimester and less common in second and third trimesters.[18] The diagnosis of torsion in pregnancy becomes more challenging and also there is tendency to go for conservative approach. Adnexal torsion requires surgical intervention in pregnancy with preservation of corpus luteum. Organ preservation is important for the continuity of the pregnancy and a study by Oelsener et al reports performing detorsion in all 40 cases of torsion regardless of the macroscopic appearance.[19]

Fever and leukocytosis was seen in 5 (10.6%) and 18 (38.2%) cases respectively. Nurith et al reports incidence of fever in 20% and leukocytosis in 43 % of cases.[15] Fever and leukocytosis occurs due to adnexal mass necrosis. Four patients had anemia, and of that one had 6gm%, 2 cases had 7gm% and one had 8gm% which is similar to another study.[11] Anemia is usually rare in cases with ovarian torsion and may be seen in few patients due to occurrence of hemorrhagic necrosis.

Ultrasound as a modality to diagnose torsion is found to have a senstivity of 63%-95% due to difficulty in interpretation.[1,14,20] Normal adnexal appearance is common in 69% of premenarchal patients.[21] Some studies[9,20] show enlarged ovary with multiple peripheral follicles as sign of torsion with a sensitivity of 64-74%. So, to improve the detection rate further studies have focused on blood flow using doppler.[22] Since there is possibility of arterial flow in cases of partial type or early adnexal torsion it led to further studies to improve detection rate to 88-95% by focusing on twisted pedicle described commonly as whirlpool sign.[1,23] In present study torsion was diagnosed using ultrasound with doppler in 53.19% of our cases. The ultrasound finding showing presence of ovarian cyst in 31 (65.9%) cases suggests that it is the common risk factor in most of our

cases, especially if the size was 5-10cm in 16 (51.6%) followed by size >10cms in 11 cases (35.4%) and size of <5cm in 4 (12.9%) cases. Ovarian cyst as common risk factor was reported by Oltmann SC et al.[24] It was noticed polycystic ovary in 5(10.6%) cases as the next common risk factor. In young women polycystic ovary is reported to be a common risk factor for adnexal torsion.[11]

Regarding the side of torsion our study showed right side was involved in 27(57.4%) cases and on left side in 20 (42.5%) cases. Other studies also similar findings. This could be because of long right ovarian ligament or presence of sigmoid on the left side.[12,14] Isolated tube torsion was seen in three (6.3%) cases. No specific risk factors like hydrosalpinx was seen in our cases.

Previously oophorectomy or salphingo oophorectomy was the preferred procedure fearing the possibility of gangrenous transformation and sepsis. Now recently the studies show preserved ovaries maintains its function on follow up.[25] In present study 8 (17%) cases had undergone detorsion and oopheropexy, 20 (42.5%) had ovarian cystectomy, 3 cases (6.3%) had unilateral salphingectomy, 5 cases (10.6%) had hysterectomy with bilateralsalphingo oophorectomy, and 11(23.4%) cases underwent unilateral salphingo oophorectomy. In total, conservative surgery was done in 59.5% of patients and radical surgery in 40.3% of patients (Table 2). Removal of adnexa was performed in patients having a gangrenous mass and ovarian preservation was done in cases having edematous or bluish black ovaries. On follow up patients with preserved ovaries were comfortable, was asymptomatic and showed evidence of ovarian function.

Histopathology examination (Table 1) showed benign conditions in most specimens and were associated with hemorrhagic necrosis commonly. The common benign tumor was serous cyst adenoma followed by mucinous cyst adenoma and teratoma. One of patients diagnosed as malignancy had torsion following the completion of third cycle of presurgical chemotherapy. But the pain was misdiagnosed as ureteric colic and was treated conservatively before taking up for surgery. There are other case series reporting the rarity of malignant tumour undergoing torsion.[24]

□□□□□□□□□□

Diagnosis of adnexal torsion is a challenge to both clinician and radiologist due to its nonspecific clinical and radiological findings. So, it requires strong clinical suspicion and radiological expertise. Early diagnosis and surgical management saves the ovary, thereby preserving its function.

Efficacy of intermittent iron versus daily iron in antenatal women

Dr. TV Chitra, Dr. Seetha Panicker and Dr. Grace Wesley

DOI: https://doi.org/10.33545/gynae.2020.v4.i4a.614

Abstract
Aim: This study was done to determine if alternate day oral iron as effective as daily oral iron in antenatal women including those with mild anemia.
Methods & Material: A prospective randomised trial was done in 215 antenatal women attending a tertiary centre in South India. Group 1 received 100mg of elemental iron daily and group 2 received 100mgs of elemental iron on alternate days. Haemoglobin was estimated in all the trimesters and change in Haemoglobin from baseline and at 32-34 weeks were estimated. Side effects and neonatal outcomes were analysed. Further analysis were done within groups depending upon the Haemoglobin levels.
Results: There was no difference in Haemoglobin levels between the two groups. The response was better in patients with mild anemia in both groups, however when iron was given daily in mildly anemia women the increase in Haemoglobin was better than alternate iron therapy.
Conclusion: Intermittent iron is as effective as daily iron.

Keywords: Haemoglobin, daily iron, intermittent iron, iron therapy in pregnancy, anemia in pregnancy

Introduction

Anaemia complicating pregnancy is one of the most common medical disorders of pregnancy. The WHO [1] has defined anaemia as a Haemoglobin less than 11gms/dl in the first and third trimester and a Haemoglobin of less than 10.5gms/dl in the second trimester. Any Haemoglobin less than the 5th percentile for a given gestation is defined as anaemia by CDC [2]. Globally about 58.25 million women are found to be anaemic during pregnancy and 95% of them belong to the developing world [3]. In India as per the population based survey in 2016 it was found that about 50% of pregnant women were anaemic [4]. Anaemia is a direct and an indirect cause of maternal mortality and causes around 13% of all maternal deaths and about 20% in South East Asia [5].

As part of a global strategy to prevent anaemia, WHO has recommended that all pregnant women be given 60mgs of elemental iron with 400mgs of folic acid every day prophylactically[6]. However in the event of iron deficiency anaemia, higher doses are prescribed. Oral iron is associated with many undesirable side effects causing poor compliance. An ideal dosing schedule is yet to be found, which patients will not default and yet give the desired results.

There has been lot of research in iron metabolism over the past two decades.

First is the presence of protein Hepcidin which regulates iron absorption [7], second is the mucosal turn over time which is said to occur once in 3 to 5 days. Thus after a given dose, further supplementation with iron until turn overtime is completed might lead to impaired absorption since the cells are already saturated [8]. Excess iron may cause oxidative stress and other side effects [9]. This has changed the thinking that intermittent iron might work as well. Subsequent to this there are many studies which state that iron two or three times per week or even once a week might be all that is required. Most of these studies have been done in pregnant women who had normal haemoglobin levels.

The WHO in a recent guideline has suggested administration of weekly iron of 120mgs with 2.8mgs of folic acid in pregnant women in areas where the prevalence of anaemia is less than 20% [10].

In India, the practise is still to administer daily iron during pregnancy. Being an area where the prevalence of anaemia is high, it would be worthwhile to know the efficiency and advantages of intermittent iron and hence this study was conducted to determine the usefulness of intermittent iron in both mildly anaemic and non anaemic pregnant women.

Materials and Methods

This was a prospective observational study conducted at a teaching hospital in South India. 215 pregnant women attending the antenatal OPD were randomly recruited for this study. 105 pregnant women from Unit 1 were assigned to daily iron and formed group 1 and 110 pregnant women from Unit 2 were given alternate day iron and were assigned as group 2. During the first visit between 10 to 14 weeks investigations like CBC, Peripheral smear and serum ferritin were done. This helped to rule out thalassemia which is not very uncommon in this area. Ferrous tablets containing 100mgs of elemental iron and 500mgs of folic acid was used after completion of 13 weeks and continued till delivery.

Exclusion criteria: Were Haemoglobin less than 9gms in the first trimester, history of haemtological disorders like sickle cell or thalassemia and history of autoimmune disorders.

Inclusion criteria: All patients attending OPD from at least 12 weeks of pregnancy. The patients were asked to take iron at night before food or at least one hour after food. They were asked to report if they had any side effects like vomiting, diarrhoea, heart burn or constipation. Repeat Haemoglobin was done in the second trimester and around 32 to 34 weeks to assess the Haemoglobin status of the individual. If the Haemoglobin fell to less than 8gms they were advised parenteral iron. Haemoglobin was done using Coulter LH 780 Haematology Analyser method. The maternal and fetal outcomes were noted.
Patients who did not have their delivery in our institution and if the Haemoglobin levels were not done in the third trimester, were excluded from the final analysis and two patients who were given parenteral iron were also excluded from final analysis.

Statistical Analysis

The categorical variables were analysed using chi square test and the continuous variables were analysed using test and ANOVA. P value of .005 was taken as significant. Both groups were compared in regard to mean change from baseline Haemoglobin to Haemoglobin at the 2nd and 3rdtrimester.
The groups were further subdivided into three groups based on Haemoglobin levels. Group A had Haemoglobin level between 9 to 11gms, Group B had Haemoglobin levels between 11.1 to 13gms and Group C had Haemoglobin levels more than 13gms and analysis done within the subgroup with regards to the change in Haemoglobin levels in the first and last trimester.

Results

Total of 215 pregnant women were included in this study 105 in the daily group and 110 in the alternate group. A total of 173 women, 80 in group 1 (daily Iron) and 93 in group 2 (alternate day Iron) were analysed and the attrition was mainly due to change of place for delivery, or incomplete data and investigations. Table 1 shows the age distribution in both groups and Table 2 shows the parity.

Table 1: Age

Age Yrs	Daily Regimen	Alternate Iron
<20	1	3
	1.3%	3.2%
21-25	34	31
	42.5%	33.3%
26-30	36	48
	45.0%	51.6%
>30	9	11
	11.3%	11.8%
Total	80	93

Table 2: Parity

	Daily Regimen	Alternate Iron
Primi	53	62
	66.25%	66.66%
Multi	27	31
	33.75%	33.33%
Total	80	93

The distribution of age and parity were similar in both groups. Table 3 shows the mean Haemoglobin levels in all trimesters in both groups which showed that the mean Haemoglobin levels were almost identical in both groups. The levels were higher in the first trimester and third trimester and slightly lower in the second trimester as expected due to haemodilution.

Table 3: Mean Hemoglobin in all trimester

Trimester		Daily regimen (N=80)	Alternate regimen (N=93)
1st trimester	Mean Hb	11.553	11.983
	SD	(1.2447)	(1.1462)
2nd trimester	Mean Hb	11.138	11.271
	SD	(0.9611)	(0.8489)
3rd trimester	Mean Hb	11.3065	11.382
	SD	1.1487	1.1218

The relationship between the Haemoglobin level and the ferritin level is shown in Fig1.

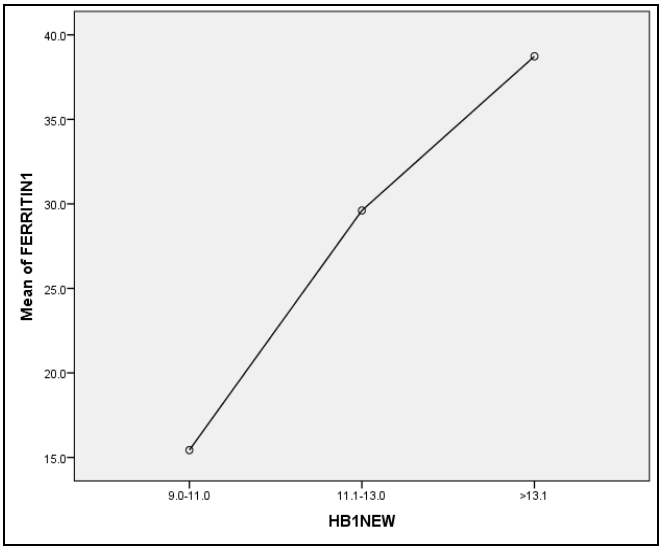

Fig 1: Relationship between the Haemoglobin level and the Ferritin level

38 women had ferritin levels less than 12ngm/dl. 24 in the daily group and 14 in the alternate group had ferritin less than 12 ngm/dl.
Table 4 shows the side effects of oral iron in both groups. Side effects were much lesser in the alternate iron group and so also was the compliance, which was found to be significant statistically with a P value of <001.

Table 4: Side effects

Side effects	Daily regimen (N=80)	Alternate regimen (N=93)
Vomiting	38	5
Constipation	30	8
Diarrhoea	2	1
Metallic taste	5	2
Bloatedness	10	2

Both groups were analysed as subgroups with the Haemoglobin levels in each trimester as shown in Table 5. This table shows that the response and Haemoglobin rise was better in women with mild anemia in both groups and the rise in Haemoglobin was better in the daily group.

Table 5: Analysis of haemoglobin in different sub groups in all trimesters

Hb gm/dl		1st trimester	2nd trimester	3rd trimester
9.0-11.0	Daily regimen N=26	10.085	10.872	11.1960
	Alternate regimen N=22 cases	10.395	10.629	10.9719
11.1-13.0	Daily regimen N=45 cases	11.996	11.107	11.2500
	Alternate regimen N=55 cases	12.169	11.375	11.3611
>13.1	Daily regimen N=9 cases	13.578	12.033	11.9625
	Alternate regimen N=16 cases	13.525	11.756	12.0333
Total	Daily regimen N=80 cases	11.553	11.138	11.3065
	Alternate regimen N=93 cases	11.983	11.271	11.3823

There were no preterm deliveries and the birth weight of babies was similar as shown in Table 6.

Table 6: Birth weight

	Hb	Number	Mean birth weight
Daily regimen (N=80)	9.0 – 11.0	25	3.0548
	11.1 - 13.0	45	2.9983
	>13.1	9	3.2938
	Total	80	3.0487
Alternate regimen (N=93)	9.0 – 11.0	22	3.0514
	11.1 - 13.0	55	2.9898
	>13.1	16	2.9106
	Total	93	2.9908

Discussion

In our study 80 women with a mean Haemoglobin 11.5gms/dl were given daily iron and 93 women with a mean Haemoglobin of 11.93gms/dl were given alternate iron. The third trimester Haemoglobin was 11.30gms/dl in the daily group and 11.38gms/dl in the alternate group showing that in both the treatment groups the Haemoglobin was almost the same.

WHO recommends 30-60mgs of elemental iron for all pregnant women depending on the prevalence of anaemia. This lower dose of 30mgs by WHO supersedes the previous recommendation of 60mgs taking into account the side effects and iron pharmokinetics [11].

The National iron plus initiative of India recommends iron folic acid [IFA] supplementation of 100 mg elemental iron and 500 mgs of folic acid every day for at least 100 days starting after the first trimester at 14–16 weeks of gestation for all non-anemic pregnant women followed by the same dose for 100 days postpartum [12].

Currently intermittent iron supplementation has been accepted for prophylaxis except in antenatal programmes for which debate is still ongoing.

In the past few years many studies have proven the hypothesis that intermittent iron is as effective as daily iron in terms of Haemoglobin change with the added advantage of having less side effects and being cost-effective. In spite of this information the change to intermittent therapy has not yet been implemented, maybe, since the prevalence is so high and further studies are warranted.

Cochrane in 2015 reviewed 21 trials of daily iron versus intermittent iron and stated that while there was no difference between groups for any maternal or fetal outcomes, the intermittent groups had less side effects [13].

Pena-rosa [14] suggested that women receiving intermittent iron had similar maternal and fetal outcomes. Study by Mukhopadhyay [15], Goonewardene [16] and ZInatossadaat [17] in have all suggested that intermittent iron is as effective as daily dosing.

Our study also proved that intermittent iron was as good as daily iron.

The second observation was that in patients who were found to have Haemoglobin between 9 to 11gms/dl, the rise in Haemoglobin was better in these patients with mild anaemia than non-anaemia and a mean increase of 1.1gm/dl was noted in daily group and 0.60gms/dl in the alternate group. The patients in the group with Haemoglobin between 11.1 to 13gms/dl and more than 13gms/dl did not show an increase, but showed a slight fall in Haemoglobin level from baseline.

There were two observations different in our study when compared to many studies. The first observation was that post treatment Haemoglobin did not show an increase from baseline as many studies have shown. However Adaji [18] in his Nigerian study between once and twice daily dosing has shown a fall in baseline Haemoglobin from 11.1gms/dl and 11gms/dl to 10.2gms/dl and 10.5gms/dl respectively in both arms. Similar fall in Haemoglobin has been noted by Okwara [19] who showed a fall from 11.2gms/dl in the first trimester to 10.4 gms/dl in the third trimester. In our study too, in the daily group the fall in Haemoglobin level was 0.2gms/dl and was 0 .6gms/dl in the alternate day group which was not statistically significant.

The second observation was that Haemoglobin improvement was better in women with anaemia in both groups. Although the final Haemoglobin was not very different in both groups, daily iron proved to be slightly better than alternate iron. The maximum oral dose per day is only 160mgs/day. Hence doubling the dose to twice daily is not beneficial, anaemic women would do well by just once daily dosing

Intake of iron is generally associated with untoward side effects like vomiting, constipation, dark stools, diarrhoea and a metallic taste in the tongue. A few rare myths discovered during the study was the belief that babies might be darker or be heavier which lead to women refraining from taking the medications. Side effects were less when given on alternate days, making women more compliant. According to a study by Khalafalloh [20] the side effects of oral iron include gastro intestinal disturbances characterised by colicky pain, vomiting, diarrhoea and constipation which occurred in about 50% of patients. Many patients taking more than 30mgs of iron per day have side effects causing them to discontinue the medication. In our study two women had to be given parenteral iron both belonging to the daily iron group since they experienced severe nausea and vomiting with oral iron.

Slon [21] *et al.*, Shatrugnaan [22] and Beard [23] and Souxa [24] have all corroborated the fact that increasing dose frequency also increases the side effects.

Preterm labour and low birth weight are common when Haemoglobin is less than 9gms or more than 13gms. Haemoglobin above the upper limit can give rise to decreased plasma expansion and is associated with poor pregnancy outcomes. In our study there was no preterm babies and no difference in birth weight in both groups, neither was there any growth restricted babies.

Conclusion

Intermittent dose seems convenient compared with daily dosing. There was no difference in Haemoglobin levels when administered daily or on alternate days. This regime was more cost effective and had less side effects and better compliance. Intermittent iron can also be practised for anaemic pregnant women since the absorption is better, however the improvement is better with daily iron. There is no benefit in increasing the dose to twice or thrice daily since required benefit was seen even with a daily dosing

Abstract

Background: Autoimmune disorders are chronic multisystem disorders affecting women of their reproductive age. Pregnancy among these women is complicated by the disease itself. Flaring up of disease, uteroplacental insufficiency due to vasculitis and drugs used for treatment are main reason for unfavourable pregnancy outcomes. The objective of this study was to analyze the pregnancy complications and outcome among 113 cases of autoimmune disorders.

Methods: This study is a retrospective analysis of case records of pregnant women with autoimmune disorders. This study was conducted at PSG IMSR and Hospital, Coimbatore, and Tamil Nadu from July 2012 to June 2018. The case sheets were retrieved from medical record department and the details such as type of disease, maternal age, parity, status of disease at conception, treatment taken during pregnancy, maternal complications and fetal complications were collected and analyzed.

Results: During 6-year period there were 113 pregnant women with autoimmune disorders, and they were studied of their previous and present pregnancy outcome. The disease incidence was 7.01% per 1000 deliveries. 40.7% were less than 25 years age group and 71.6% were multigravidae. We had forty-one patients (36%) who were positive for APLA syndrome which were the maximum number of patients with auto immune disorder in pregnancy and 37 patients (32.7) with SLE. We had significant numbers of maternal and fetal complications for common disorders. Most of the rare auto immune disorders were diagnosed before pregnancy and these pregnancies were managed by multi-disciplinary approach, and continued on immunomodulators throughout pregnancy, hence maternal and fetal complications were less for them.

Conclusions: Adequate pre-conceptional counseling, vigilant monitoring during pregnancy and post-partum will avoid pregnancy related complications and have favorable outcomes.

Keywords: Autoimmune disorder, Fetal complications, Immunomodulators, Maternal complications, Pregnancy outcome, Pre-conceptional counseling

Introduction

Autoimmune disorders are chronic multisystem disorders which are characterized by tissue damage and inflammation due to alteration of adaptive immune response in the absence of trigger.[1] Its prevalence is between 7.6%-9.4%.[2] Since most of the autoimmune disorders are diagnosed frequently during reproductive age in females, these women are at high risk not only during pregnancy but also during postpartum.[3] When compared to females without autoimmune disorders, these women carry more incidence of miscarriages in all trimesters, preeclampsia, intrauterine growth restriction, premature rupture of membranes, placental insufficiency, preterm labour, low birth weight and have increased caesarean section rates.[4] Though these pregnancies carry

high incidence of adverse effects, improved care in terms of pre-conceptional counselling and continuation of treatment throughout the pregnancy and post-partum have improved the outcome of pregnancies.[5]

M□□□□ □□

This study is a retrospective analysis of a total 113 case records of pregnant women with autoimmune disorders. This study was conducted at PSG IMSR and Hospital, Coimbatore, Tamil Nadu from July 2012 to June 2018. The case sheets were retrieved from medical record department and the details such as type of autoimmune disorder, maternal age, parity, status of disease at conception, treatment taken during pregnancy, maternal complications like pregnancy induced hypertension, gestational diabetes mellitus, thrombotic events, anemia, renal flares, thrombocytopenia, preterm labour, mode of delivery, indications for caesarian section and fetal complications like abortion, anomalies, intra uterine fetal demise, low birth weight, intra uterine growth restriction, oligohydramnios, need for admission to neonatal intensive care unit, low Apgar score were collected and analyzed.

Inclusion criteria

- All primigravidae and multigravidae who are known case of autoimmune disorder and all primigravidae and multigravidae who are diagnosed with autoimmune disorder during present pregnancy.

Exclusion criteria

- Pregnant mothers without autoimmune disorders.

□□□□ □□□

During this period of 6 years (2012-2018), there were 113 pregnant women with autoimmune disorders and study was carried out based on their previous and present pregnancy outcomes. The incidence of autoimmune disorders in pregnancy was 7.01% per 1000 deliveries.

Table 1 shows the number of pregnancies with autoimmune disorders in our study.

Takayasu	3 (60%)	-	1 (20%)	-	-	-	4 (80%)	-
Sjögren syndrome	-	1 (25%)	-	-	-	-	3 (75%)	□□

In our study, most of the patients were below 30 years of age. Table 2 shows the age group distribution. Multigravida (71.6%) were more in number than primigravida (28.3%) in our study.

Parity distribution is shown in Figure 1.

Table 3 shows the most common autoimmune disorders in our study and their maternal complications.

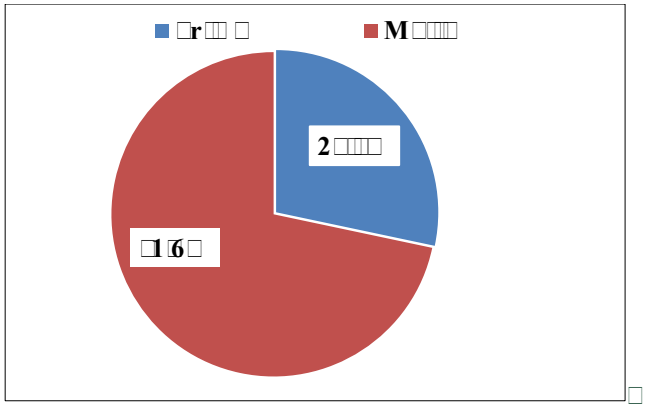

Table 3: Maternal complications in previous pregnancy.

Disorder	Number	Percentage
APLA	26 (63%)	9 (21.9%)
SLE	22 (59%)	5 (13.5%)
ITP	4 (36%)	-
Takayasu	-	1 (20%)
Sjögren syndrome	3 (75%)	-

Two patients diagnosed with SLE had abnormal doppler changes at 32 weeks and 34 weeks respectively and underwent caesarean section. The most common indication for caesarean section was non-progression of labour followed by previous section.

Table 4 shows fetal complications in previous pregnancy for more common disorders in our study.

Table 4: Fetal complications in previous pregnancy.

Disorder	IUGR	Abortion	Stillbirth
APLA	7 (17%)	2 (4.8%)	1 (2.4%)
SLE	13 (35%)	6 (16%)	5 (13.5%)
ITP	2 (18%)	-	1 (9%)
Takayasu	3 (60%)	-	-
Sjögren syndrome	-	2 (50%)	-

Table 5 shows the fetal complications in the current pregnancy for same disorders.

Table 5: Maternal complications in current pregnancy.

Disorder	Current	Previous
Pre-eclampsia	10.8%	13%
GDM	16%	NA
Renal flare	8%	NA
Anemia	7.3%	21%
C-section	43%	53%
Preterm labour	21%	21%

Table 6: Fetal complications in current pregnancy.

Abortion in previous conception	59%	46%
IUD	13.5%	8%
IUGR	35%	32%
LBW	24.3%	22%
NICU admission	13.5%	15%

APLA

Obstetric antiphospholipid antibody syndrome (OB-APS) is defined according to the updated Sydney classification criteria developed by expert consensus agreement in 2006.[6] APLs include the lupus anticoagulant, anticardiolipin IgG and IgM and anti-β2-glycoprotein I antibody. In addition to the detection of aPLs on at least two occasions more than 12 weeks apart, OB-APS is defined by any one of the following adverse pregnancy outcomes: 1) otherwise unexplained recurrent pregnancy loss before the 10th week of gestation, 2) otherwise unexplained fetal death ≥10 weeks of gestation, 3) preterm birth before 34 weeks of gestation due to preeclampsia or placental insufficiency.[7] Other OB-APS complications include catastrophic APS, thrombosis, HELLP syndrome (hemolysis, elevated liver enzymes, and low platelet count), IUGR, fetal distress, premature rupture of membranes, and thrombocytopenia.[8] It has been recognized that among the three aPLs, lupus anticoagulant (LAC) is the primary predictor of poor pregnancy outcome in women both with or without SLE, and with or without other aPLs.[9] Among the 41 patients with APLA, 20 patients were positive for lupus anticoagulant antibody, 11 were positive for anticardiolipin antibody and 10 had anti-β2-glycoprotein I antibody.

In our study, 31.8% of patients with primary APLA and 4.4% of patients with secondary APLA with associated SLE were diagnosed. The incidence of pre-eclampsia among APLA positive patients in our study was 4.8% whereas in Wijeyaratne study, it was 10.9%.[10] Similarly the incidence of GDM in our study was 31% as compared to 19.2% in Wijeyaratne study. In our study 2.4 % had preterm labour and 17% of patients underwent cesarean section. In regard to fetal complications, 63% of patients in our study had previous one or more abortions which was comparable to Wijeyratne study (59.8%). The incidence of IUD in previous pregnancy was 21.9.%. The incidence of low birth weight babies was 12% and babies requiring NICU admission was 2.4% respectively.

SLE

Systemic lupus erythematosus (SLE, or “lupus”), affects females in a 9:1 ratio to males.[11] The adverse pregnancy

outcomes observed with lupus are well known, and include increased rates of intrauterine growth restriction (IUGR), preterm birth and fetal loss, as well as the syndrome of neonatal lupus (NL), associated with trans placental passage of auto antibodies. The risks for thrombosis, infection, thrombocytopenia, and transfusion were each 3- to 7-fold higher for women with systemic lupus erythematosus. Lupus patients also had a higher risk for cesarean sections (odds ratio: 1.7), preterm labor (odds ratio: 2.4), and preeclampsia (odds ratio: 3.0) than other women. Women with systemic lupus erythematosus are more likely to have other medical conditions, including diabetes, hypertension, and thrombophilia, that are associated with adverse pregnancy outcomes.[12]

High disease activity at the time of conception or in the months preceding conception is an independent predictor for increased risk of adverse pregnancy outcomes including prematurity, IUGR and fetal demise. This has led to the current recommendations that lupus patients achieve 6 months of disease quiescence prior to attempting conception.[13] Maternal and fetal complications associated with SLE were compared with Eman et al study.[14] These are shown in table 6 and 7 respectively.

Six patients had first trimester abortions in the current pregnancy.

Takayasu syndrome

In our study, 60% patients had hypertension complicating pregnancy whereas in Mandal et al study had 92.8%.[15] Caesarean section rate in our study was 60%, whereas in Mandal study it was 71.4%. Intrauterine growth restriction was 60% in our study, which was comparable with Mandal et al study (51.7%).

Schönlein-henoch purpura

Schönlein-henoch purpura (SHP) is a systemic vasculitis that affects vessels of a small caliber.[16] The onset of SHP during pregnancy is very rare. Treatment with orally administered corticosteroids may lead to a beneficial outcome for both mother and newborn.[17] In our study, we had 2 patients diagnosed with Schönlein-Henoch purpura, of which one developed GDM, other had uneventful pregnancy.

Medium vessel vasculitis

Most of the women with medium vessel vasculitis fared well during pregnancy without significant disease progression, but instances of aneurysm rupture, renal insufficiency, pulmonary embolism, and myocardial infarction were reported in Gatto et al study.[18] In our study, one patient diagnosed with medium vessel vasculitis developed myocarditis during pregnancy and she was managed with steroids.

ITP

Nine percent of chronic ITP patients in our study had preeclampsia, whereas Diego et al, study had 8.3%.[19] In our study 9% had preterm labour which was comparable to Diego et al (9.5%) study. Diego et al showed 8.5% of gestational diabetes in the study whereas in our study we had 54% of gestational diabetes which could be explained by ethnicity and usage of steroids.

In Yassaee et al, study occurrence of IUGR was 10.5% whereas in our study it was 18%, among which one baby was admitted in NICU.[20] In Yassaee et al study 57% of patients had moderate thrombocytopenia (more than 50,000) whereas 18% of thrombocytopenia and 9% of anemia were diagnosed in our study.

When comparing the caesarean section rate, Yassaee et al had 81% whereas we had 63%.

Rheumatoid arthritis

In women with well-controlled RA, pregnancy outcomes are comparable to the general obstetric population, whereas in women with higher RA disease activity, there is more chances of less favorable pregnancy outcomes.[21,22]

Akasbi et al, study showed improved maternal and fetal outcome in patients with RA in pregnancy. Similarly, in our study two patients diagnosed with RA had uneventful pregnancy.

Guillain-barré syndrome

Guillain-barré syndrome (GBS) represents a heterogeneous group of immune mediated peripheral neuropathies. A feature common to all GBS variants is a rapidly evolving polyradiculoneuropathy preceded by a triggering event, most often an infection. GBS generally manifests as a symmetric motor paralysis with or without sensory and autonomic disturbances. Delayed diagnosis is common in pregnancy or immediate post-partum period because the initial non-specific symptoms may mimic changes in pregnancy. GBS should be considered in any pregnant patient complaining of muscle weakness, general malaise, tingling of the fingers, and respiratory difficulty.[23,24]

We had one patient diagnosed with GBS who had an uneventful course during pregnancy.

Multiple sclerosis

Multiple sclerosis (MS) is an inflammatory disease in which the fatty myelin sheaths around the axons of the brain and spinal cord are damaged, leading to demyelination and scarring as well as a broad spectrum of signs and symptoms.[25] Pregnancy is typically a stabilizing period in the clinical course of MS. During the

third trimester the MS relapse rate can be 70% lower when compared with the time prior to pregnancy, but exaggeration of the disease is commonly seen postpartum. Presently, there is no evidence that MS patients are more susceptible to pregnancy or delivery related complications, such as ectopic pregnancy, pre-eclampsia, gestational diabetes mellitus, prolonged labour or miscarriage than women in general, nor is their infants more likely to be delivered preterm or to be of low birth weight, have malformations or experiences an early death.[26,27] Mothers with MS required operative delivery more often than healthy mothers, which might be attributed to MS-related symptoms such as neuromuscular perineal weakness and spasticity in addition to fatigue and exhaustion.[28] In our study, we had 3 mothers diagnosed with multiple scelerosis, of them one developed PIH, one had GDM.

Sjögren syndrome

Sjögren syndrome is known to occur predominantly in women. Affected women are likely to experience more complicated pregnancies than are women without the disease.[29] Its effect on pregnancy differs according to the maternal disease, disease activity, and severity of organ damage, antibody profile, and drug treatment.6.

Several studies have reported an increased rate of spontaneous abortion and fetal loss associated with Sjögren syndrome.[30] This may be explained by, first, the age of the patients at the time of concep-tion which usually belongs to an elderly age group and, second, a possible immunologic factor involved in the mechanisms of miscarriage.[31]

In our study, out of four mothers diagnosed with Sjögren syndrome, two had spontaneous abortions.

The outcome of pregnancies in women with Sjögren syndrome can be improved with use of a multidisciplinary approach for management involving an obstetrician who has specialized in high-risk pregnancies, a rheumatologist, and a pediatrician.[32]

Hashimotos thyroiditis

Hashimotos thyroiditis is associated with an increase rate of spontaneous.

Abortions, preterm delivery and increased use of cesarean section.[33] All the three patients diagnosed with Hashimotos thyroiditis underwent cesarean section for non-progression of labour.

Ulcerative colitis

Stephansson et al study concluded that pregnant women with ulcerative colitis had a greater number of preterm births, babies with low birth weight and cesarean section deliveries than those without ulcerative colitis.[34] In our study we had one patient who delivered a low birth weight baby of 2.2 kg. One patient diagnosed with multisystem connective tissue disorder had an intra uterine growth restriction and the same baby had low birth weight.

Von Willebrand's disease

Pregnancy and delivery are considered events predisposing to a high risk of bleeding in women with von Willebrand's disease.[35]

Our patient did not have any complication. All the patients diagnosed with GDM were found to be on steroids.

Among the 113 patients, 3 underwent caesarean section in view of abnormal umbilical artery doppler findings.

Patients previously diagnosed were continued on disease modifying agents and this could be the reason for their successful pregnancy outcome.

Rauto immune disorders were diagnosed before pregnancy and these pregnancies were managed by multi-disciplinary approach, and continued on immune modulators throughout the pregnancy, hence minimizing maternal and fetal complications.

□□□□□□□□□□

In our study, most of the patients were either continued on the same treatment they were taking before pregnancy or were started on treatment once they were diagnosed with autoimmune disorders, and hence they were found to have successful pregnancy outcomes. Therefore, appropriate pre-conceptional counselling, continuation of treatment, intense maternal and fetal monitoring and timely delivery plays an important role in improving the pregnancy outcome.

Abstract

Background: Thyroid diseases are one of the commonest endocrine disorders affecting women of reproductive age group, and hence constitute one important disorders complicating pregnancy. The objective of this study was to determine the importance of universal screening for hypothyroidism in pregnancy at the first antenatal visit and to formulate whether this routine screening is mandatory in our country.

Methods: This retrospective study was conducted in the year 2018 at PSG IMSR Hospital for all pregnant women who attended the first antenatal visit between Jan 2012 to Dec 2012 after obtaining ethical clearance. Pregnant women who were already taking treatment for hypothyroidism, diabetes mellitus, hypertension and those pregnant women who lost their follow up were excluded from the study.

Results: The incidence of subclinical hypothyroidism among antenatal women were 7.06%. In our study the maternal complications like anemia 12 (8%), preeclampsia 26 (17.3%), gestational diabetes 25 (16.7%), fetal growth restriction 8 (5.3%), Oligohydramnios 13 (8.7%), pre mature rupture of membranes 25 (16.7%), placental abruption in 2 (1.33%), APLA syndrome 2 (1.33%), low birth weight 26 (17.3%) were observed.

Conclusions: Universal screening for hypothyroidism is recommended for all antenatal women especially in iodine depleted country like India.

Keywords: Anemia, Gestational diabetes, Pre-eclampsia, Subclinical hypothyroidism, Thyroxine, Thyroid stimulating hormone

Introduction

Thyroid diseases are among the commonest endocrine disorders affecting women of reproductive age group, and hence constitutes one of the important medical disorders complicating pregnancy.[1] About 2-5% of all pregnant women are reported to have some degree of hypothyroidism.[2] Subclinical hypothyroidism is a prevalent condition which may go unrecognised and has the potential to cause adverse maternal and fetal outcome.[3] Sub clinical hypothyroidism defined as elevated serum thyrotropin level accompanied by normal serum thyroxin concentration. TSH plays a central role in screening and diagnosis of hypothyroidism.

Pregnancy complications with hypothyroidism include increased incidence of preeclampsia, abruptio placentae, anemia, and preterm labour. Unexplained still birth, fetal distress, low birth weight and neonatal hypothyroidism are perinatal complications.[4]

There has been a wide geographic variation in prevalence of hypothyroidism during pregnancy. Reports indicate it varies from 2.5% from the West to 11% from India also it is more in Asian countries compared to the West.[5,6] In a recent study by Dhanwal et al, a high prevalence of hypothyroidism (14.3%) was noted.[7] Looking at these data the purpose of the study was to determine whether

universal screening for hypothyroidism in pregnancy would prove to be beneficial in our country.

The objective of this study was to determine the incidence of hypothyroidism in pregnancy at the first antenatal visit and complications associated to formulate whether routine screening can be recommended in our country.

M□□□□□□

This retrospective study was conducted in the year 2018 at PSG IMSR Hospital for all pregnant women attending the first antenatal visit between January 2012 to December 2012 after obtaining ethical clearance.

Inclusion criteria

- All pregnant women attending the antenatal OPD at the first antenatal visit and who delivered in our hospital.

Exclusion criteria

- Pregnant women who were already taking treatment for hypothyroidism, diabetes mellitus, hypertension and those who lost their follow up in our hospital.

The Sr.TSH is done as a screening tool for hypothyroidism for all antenatal women. The Sr.TSH reference range as per Indian thyroid society guideline 2015 was applied to diagnose hypothyroidism in pregnancy. Sr.TSH upper limit value is in the following range in each of the trimesters:

- First trimester <2.5 mIU/L
- Second trimester <3.0 mIU/L
- Third trimester <3.5 mIU/L

Sr.TSH > 2.5mIU/L in the first trimester were treated with thyroxine supplementation after checking FT3 and FT4.

These patients were subjected to repeat Sr.TSH in second and third trimester and analysed whether they are treated adequately or inadequately based upon the trimester specific upper reference limit. The dose of drug was adjusted if required. More over all the subclinical hypothyroid and low risk (euthyroid) study participants were followed up till delivery and analysed for any maternal complications like preeclampsia, anemia, preterm labour, gestational diabetes, fetal growth restrictions, low birth weight in both the groups.

Statistical analysis

The data was entered in Microsoft excel spread sheet and analysed by Statistical Package for Social science (SPSS version 21) and chi square test.

□□□□□□□

In the present study total number of antenatal women who booked and delivered at PSG Hospital was 2124 of which the total number women with subclinical hypothyroidism were 150 (7.06%). The total number of low risk deliveries (euthyroid) excluding chronic hypertension (10), overt diabetes (19) and overt hypothyroidism (25) were 1920 and these patients were also analysed for maternal complications.

The thyroid gland size increases by 10% in size during pregnancy in iodine-deplete countries and to greater

extent by 10-20% in areas of iodine deficiency. Hence the thyroid hormone production, thyroxin (T4) and tri-iodothyronine (T3) increases by 50%, along with a 50% increase in daily iodine requirement during pregnancy. These physiological changes may result in hypothyroidism during pregnancy in iodine-deficient women.

The prevalence of subclinical hypothyroidism in our study group was 7.06%. A study conducted by Sapna C. Shah et al, in Karnataka shows a prevalence of sub clinical hypothyroidism of 9%.[8] Nambiar et al, conducted a study in Europe among Asian Indian pregnant women and said that the prevalence of hypothyroidism is about 7.2%.[9] In contrast to our study Rajput et al, conducted a study and said that the prevalence of hypothyroidism in pregnancy in northern India is 14.3%.[10]

Table 1 shows the demographic distribution of age, parity and gestational age at the diagnosis of subclinical hypothyroidism. Among the age distribution most of the women were below 30 years of age 109 patients (73%). Among 150 subclinical hypothyroidism pregnant women 85 of them were primi gravid and 65 of them were multigravida. The gestational age at which subclinical thyroidism was diagnosed based upon the TSH value were more in the second and third trimester.

In our study Table 2 shows the maternal complications like anemia 12 (8%), preeclampsia 26 (17.3%), gestational diabetes 25 (16.7%), fetal growth restriction 8 (5.3%), Oligohydramnios 13 (8.7%), pre mature rupture of membranes 25 (16.7%), placental abruption in 2 (1.33%), APLA syndrome 2 (1.33%), low birth weight 26 (17.3%), papillary carcinoma thyroid 1 (0.66%) treated with neck radiation were observed. In our study there were 20 (13.3%) patients who underwent caesarean section. Radha et al, in her study observed the maternal complications in subclinical hypothyroidism like anemia in 18 (36%), preeclampsia in 13 (26%), placental abruption in 2 (4%), caesarean section in 20 (44%), low birth weight baby 28%.[11] Anupama et al, in her study observed that 0.65% women had APLA syndrome, 0.3% had history of neck irradiation.[12]

Table 3 shows the maternal complications correlation between subclinical hypothyroidism and low risk (euthyroid) antenatal women.
