used in this study. The incubation field in BIOCHIP slide has mosaic of six different substrates: primate oesophagus, primate salt split skin, transfected cells with desmoglein 1 (Dsg1), desmoglein 3 (Dsg3), C-terminal globular domain of the bullous pemphigoid antigen 230 (BP230) and recombinant antigenic dots of tetrameric bullous pemphigoid antigen 180–non-collagenous 16 A domain (BP180-NC16A). For BIOCHIP mosaic, 5 ml of blood is taken by venipuncture in a plain test tube. The blood sample is then centrifuged at the rate of 3000 rotations per minute for 10 minutes for serum separation. 50 µL of serum is mixed with 450 µL of buffer [1:10 dilution]. 30 µL of the above mixture is incubated in substrate wells for 30 minutes and washed with a buffer for 5 minutes. After that, fluorescent conjugate 25 µL is added and incubated again for 30 minutes and washed with a buffer for 5 minutes. The slide is then mounted for interpretation under a fluorescent microscope. All the tests were run with the positive controls provided with the kit.

Interpretation

Primate oesophagus shows fine granular fluorescence of intercellular space (ICS) staining pattern in case of pemphigus and linear basement membrane zone (BMZ) staining pattern in pemphigoid diseases. In salt split skin substrate there will be a linear fluorescence pattern in the roof of the split in bullous pemphigoid and floor of the split in epidermolysis bullosa acquisita and rare variants like anti-laminin 332 pemphigoid and anti-P200 pemphigoid. Dsg 1, Dsg 3 and BP 230 transfected cells show fine granular cytoplasmic fluorescence and BP 180 substrate shows diamond-shaped fluorescence in positive cases.

In the case of DIF, an ICS pattern with IgG and/or C3 is diagnostic of pemphigus. A linear BMZ-staining pattern with predominantly IgG and/or C3 points to the diagnosis of pemphigoid. Standards for reporting of diagnostic accuracy for DIF included type of antibody (IgG, IgA or IgM), intensity (1+ to 3+) and pattern of staining (ICS or BMZ pattern). For BIOCHIP reporting was done as per the interpretation described above.

Results

During the study period, 40 patients fulfilled the inclusion criteria, which included 16 males and 24 females. The age of these patients ranged between 19 and 80 years with a mean age of 53.8 years. Among the study participants, a clinical diagnosis of pemphigus was entertained in 18 patients (16 pemphigus vulgaris and 2 pemphigus foliaceus) and bullous pemphigoid in 22 patients based on characteristic clinical findings.

In pemphigus group, DIF showed characteristic ICS pattern with IgG and C3 in 9 patients and IgG alone in 9 patients. In the pemphigoid group, DIF showed a linear BMZ pattern with IgG and C3 in 14 patients, IgG alone in 4 patients and C3 alone in 4 patients [Figure 1a and b].

BIOCHIP mosaic was then probed with sera from these patients. In the pemphigus group, primate oesophagus showed ICS pattern in all 18 patients, Dsg 1 and 3 were positive in 13 patients, Dsg 3 was positive in 3 patients and Dsg 1 was positive in 2 patients. In general, Dsg 1 was positive in 15 patients and Dsg 3 was positive in 16 patients [Figure 2a and b]. In pemphigoid group, primate oesophagus showed linear BMZ pattern in all 22 patients, BP 180 and BP 230 were positive in 14 patients, BP 180 in 3 patients, and BP 230 in 1 patient. Overall BP 180 was positive in 17 patients and BP 230 in 15 patients [Figure 3a and b]. Salt split skin substrate showed a roof pattern in 18 patients and floor pattern in 4 patients [Figure 4a, b and Tables 1, 2].

BIOCHIP mosaic results showed a concordance of 100% in the diagnosis of pemphigus with DIF. In case of the pemphigoid group in comparison with DIF, BIOCHIP showed the diagnosis of bullous pemphigoid in 18 patients. The remaining four patients showed a floor pattern in salt

split skin substrate and was negative for any of the target antigens.

The correlation between BIOCHIP mosaic and DIF in the diagnosis of AIBD was assessed using Spearman's correlation coefficient and it was found to be statistically significant.

Discussion

The diagnosis of AIBD involves a multistep approach-combining clinical feature, histopathology, DIF, IIF or ELISA. However, the gold standard remains the visualisation of autoantibodies in the skin or mucosa by DIF of perilesional skin biopsy.[1] BIOCHIP mosaic-based IIF is a new diagnostic technique that combines a simultaneous assessment of the staining pattern and identification of target antigens in a single field.[2] Studies assessing the validity of biochip have been conducted in Germany, Italy, Turkey, Poland and Australia. There is a need to assess the diagnostic value of the BIOCHIP in population groups of various ethnicities.[2]

Van Beek *et al*. from Germany were the first to evaluate the utility of BIOCHIP mosaic in the diagnosis of AIBD by comparing it with the multistep algorithm described by Schimdt and Zillikens.[1,3] The results of their study concluded that the diagnostic efficacy of the BIOCHIP mosaic was comparable with the conventional multistep procedure in the diagnosis of AIBD.[1]

Tampoia *et al.* investigated the value of the BIOCHIP method by comparing it with two commercially available ELISA tests (MBL, Japan and EuroImmun, Germany) in the diagnosis of pemphigus and pemphigoid.[4] Later Russo *et al.*from Italy and Özkesici *et al.* from Turkey evaluated the utility of BIOCHIP in the diagnosis of AIBD by comparing it with ELISA.[5,6] These studies concluded that the BIOCHIP method has a diagnostic accuracy comparable to ELISA.[4-6] However in the present study, no such comparison was made with ELISA.

Prussmann and co-workers from Germany studied the prevalence of pemphigus autoantibodies in the general population with a total of 7063 participants using the BIOCHIP method. Their study revealed a very low prevalence of autoantibodies in a large cohort of healthy individuals. Also functional analysis revealed differences between pathogenic autoantibodies in diseased individuals and antibodies detected from healthy donors.[7] The present study did not include any healthy controls and samples were collected only from cases of suspected AIBD.

Table: 1 Results of BIOCHIP mosaic in the pemphigus group (*n*=18)

Substrate	Result	Number of patients	Percentage
Primate oesophagus	Intercellular staining pattern	18	100
Dsg 1	Positive	15	83.3
Dsg 3	Positive	16	88.8

Dsg – Desmoglein

Table: 2 Results of BIOCHIP mosaic in pemphigoid group (*n*=22)

Substrate	Result	Number of patients	Percentage
Primate oesophagus	Linear basement membrane zone pattern	22	100
Salt split skin	Roof staining	18	81.8
Salt split skin	Floor staining	04	18.2
BP 180	Positive	17	77.3
BP 230	Positive	15	68.2

BP – Bullous pemphigoid antigen

Russo *etal.* in their study used the serum and salivary samples to detect anti-Dsg autoantibodies for diagnosis of pemphigus and concluded that saliva is not a suitable sample for BIOCHIP.[8] Gornowicz-Porowska *et al.* from Poland compared the original BIOCHIP method with modified BIOCHIP method using monoclonal IgG instead of routine IgG and concluded that modified BIOCHIP has as higher sensitivity and specificity.[9] The present study utilized routine commercial IgG provided with the kit.

Similar to the previous studies, the current study also revealed that Dsg 3 and BP 180 were the commonly detected antigens using BIOCHIP in pemphigus and pemphigoid groups, respectively [Table 3].[1,4-6,8-13]

The higher correlation in pemphigus group could be attributed to the fact that in pemphigus diseases only two main target antigens are there, both of which are present in BIOCHIP substrates; whereas in the pemphigoid group apart from BP 180 and 230, other antigens in the basement membrane zone may be the target, which needs evaluation with immunoblotting.

In the present study, out of 22 patients in the pemphigoid group, four patients showed a floor pattern of staining in salt split skin.These four patients revealed a linear BMZ pattern in primate oesophagus and were negative for any of the target antigens. These cases could be attributed to floor pattern-staining diseases like epidermolysis bullosa acquisita, anti-laminin 332 pemphigoid or anti-P-200 pemphigoid, which needs further evaluation with

AIBD=Autoimmune bullous disease, Dsg=Desmoglein, BP=Bullous pemphigoid antigen.

immunoblotting.[14-16] This finding of floor pattern in 4 out of 22 cases of pemphigoid group using BIOCHIP is a significant observation. In an Indian study by Tirumalae *etal.*, similar findings were noted in four cases that showed either roof or floor positivity on salt split skin substrate with negative results in other substrates. They categorized these cases as unclassified subepidermal diseases.[13]

The advantage of BIOCHIP is that the combination of different substrates in the same field allows for concurrent evaluation of characteristic-staining pattern, identification of target antigens at once. Also, it facilitates distinction among the various types of AIBD. Further, this multiparametric technique is cost- and time-effective compared to the conventional multi-step approach.[17] However, it has limitations in categorisation of pemphigoid diseases due to restricted antibody coating. This could be overcome by testing additional target antigens or immunoblotting.

The literature search revealed only a few studies investigating the validity of the BIOCHIP IIF in the diagnosis of AIBD. These studies had concluded that the BIOCHIP method has a high degree of sensitivity and specificity in the diagnosis of AIBD.[2] The results of the present study show that the diagnosis of AIBD by BIOCHIP is showing a statistically significant correlation with that of DIF.

Limitations of this study include small sample size, lack of control group and no comparison made with ELISA.

Conclusion

BIOCHIP mosaic shows a good correlation with DIF. BIOCHIP mosaic is a non-invasive, rapid diagnostic technique that can detect the characteristic-staining pattern and target antigens in a single miniature incubation field and can be used as firstline tool in the diagnosis of AIBD.

Brief Report

Comparison of Efficacy of Autologous Platelet-Rich Fibrin versus Unna's Paste Dressing in Chronic Venous Leg Ulcers: A Comparative Study

G. Yuvasri, Reena Rai

Department of Dermatology, PSG Hospitals, Coimbatore, Tamil Nadu, India

Abstract

Background: Chronic venous leg ulcers are difficult to treat and recurrences are common. Among various modalities of treatment, platelet-rich fibrin (PRF) has shown promising results in ulcer healing by providing necessary growth factors. Unna's paste dressing has also proven to enhance wound healing. **Aim:** The aim of this study is to compare the efficacy of autologous PRF versus Unna's paste dressing in chronic venous leg ulcer patients and to compare the mean reduction in ulcer area at the end of 4 weeks. **Materials and Methods:** Twenty patients with chronic venous leg ulcers were randomly divided into two groups. Group 1: Patients received PRF dressing which was repeated every week for 4 weeks. Group 2: Patients received Unna's paste dressing once a week for 4 weeks. The ulcer size was assessed with the help of photographs, and ulcer area was measured. **Results:** The mean reduction in the area of the ulcer size in the PRF group was 86.03% and in the Unna's paste group was 71.97%, which was not statistically significant with a *P* value of 0.223. **Conclusion:** We conclude that though there was no statistical significance between the groups, PRF showed a significant reduction in ulcer size.

Keywords: *Platelet-rich fibrin, Unna's paste, venous leg ulcer*

Introduction

Venous ulcers are the most common cause of chronic leg ulcers. The chronicity and high recurrence rate of venous ulcer are the two fundamental factors causing grave impact on patients' well-being.[1] One of the reasons for chronicity of the ulcer has been attributed to lack of growth factors and nutrients which are essential for wound healing.

A major revolution in the treatment of leg ulcer is cellular therapy, where the patient's own blood is used, which contains various cytokines and growth factors. Platelet-derived products such as platelet-rich fibrin (PRF) have shown promising results in wound healing.

Another dressing for chronic leg ulcer is zinc oxide paste (Unna's paste). It has re-epithelialization and anti-inflammatory properties which can enhance wound healing. Hence, we conducted an open-label randomized study to compare the efficacy of PRF and Unna's paste dressing in chronic venous leg ulcers.

Materials and Methods

A total of 20 patients were randomly divided into two groups based on the inclusion and exclusion criteria. Patients suffering from chronic venous ulcers of the lower extremity for more than 6 months, attending the outpatient department of Dermatology Venereology and Leprosy, and having an ulcer area of 1 cm × 1 cm to 5 cm × 5 cm were included in the study.[2] A thorough clinical examination and ultrasound venous Doppler were performed to confirm the diagnosis of venous ulcer. Ethical clearance was taken from the Institutional Ethics Committee.

Patients with ulcers of less than 6 months duration and of other etiology such as arterial ulcer, diabetic ulcer, neuropathic and vasculitic ulcers; patients with osteomyelitis affecting the area of the ulcer; patients with exposed tendons or bones; patients with infection; and patients receiving anticoagulants/antiplatelet drugs/bleeding diathesis were excluded from this study.

All patients in our study continued using compression stockings.

Preparation of platelet-rich fibrin

Procedure

After obtaining informed consent, 10 ml of the patient's blood was withdrawn into the vacutainer without any anticoagulant and immediately centrifuged (to prevent blood from clotting) at 3000 rpm for 15 mins. After 15 mins, a fibrin gel appears in the center of the vacutainer with red blood cells (RBCs) at the base and acellular plasma above. The PRF obtained was removed with the help of a toothed forcep and placed on the ulcer after removing the adherent RBCs. On an average, 10 ml of whole blood yields about 2.5 ml of the clot.[2]

Dressing procedure

Group 1: The measurements of the ulcer were taken. The PRF gel was then placed on the ulcer floor and covered with a sterile gauze piece (primary dressing), which was, in turn, covered with a sterile gauze pad (secondary dressing) held in place with a sterile roller bandage. The dressing was removed after 1 week. This treatment was repeated every week for 4 weeks.[2]

Preparation of Unna's paste

Procedure

Sixty grams of zinc oxide was mixed with 100 ml of glycerine and stirred well. This mixture was heated for 10–20 mins.

Dressing procedure

The measurements of the ulcer were taken. Ulcers were covered with a gauze impregnated with Unna's paste which was in turn covered with a sterile gauze-pad followed by a sterile roller bandage. This dressing was left in place for 1 week. This treatment was repeated every week for 4 weeks.

Measurements documentation

The greatest length and the greatest breadth were measured using a thread and a scale (the clock face method). This was done before starting the treatment, before repeating the treatment each time at weekly intervals, and after the treatment was completed (the final measurement). Digital photographs in both groups were taken before starting the treatment and after the treatment was completed.[2]

Results

A total of 20 patients enrolled in the study met the inclusion and exclusion criteria. The result was assessed on the basis of the ulcer area reduction. The mean reduction in the ulcer area in the PRF group was 7.50% after the 1st week, 35.04% after the 2nd week, 62.23% after the 3rd week, and 86.03% after the 4th week [Table 1]. However, in the Unna's paste group, the mean reduction in the ulcer size was 14.80%, 29.57%, 56.16%, and 71.97%, respectively [Table 2]. The overall mean reduction in the ulcer area was 86.03% in the patients treated with PRF dressing compared to 71.97% in the patients treated with Unna's paste dressing [Figure 1]. There was a complete closure of the ulcer in four patients (40%) in the PRF group [Figure 2a and b; 3a and b]. There was no case of complete closure of the ulcer in the Unna's paste group [Figure 4a and b; 5a and b].

Statistical analysis using independent *t*-test and Chi-square test showed no significant reduction of the ulcer size between both groups [Table 3].

Discussion

Wound healing is a complicated process which involves a cascade of events such as clotting, neutrophil chemotaxis, epithelialization, angiogenesis, and scar formation. Any interruption in these events leads to failure of wound closure whereby an acute wound is converted to a chronic one. Chronic ulcers are difficult to treat.[3] Therefore, an ideal dressing which offers nutritional support has a significant impact on wound repair leading to complete closure of the wound.

PRF offers the growth factors necessary for wound healing, and have been used in various fields of medicine and surgery. The derived PRF acts as a biodegradable scaffold for cell migration, proliferation, and differentiation, and

Unna's paste	10	71.97	29.358	

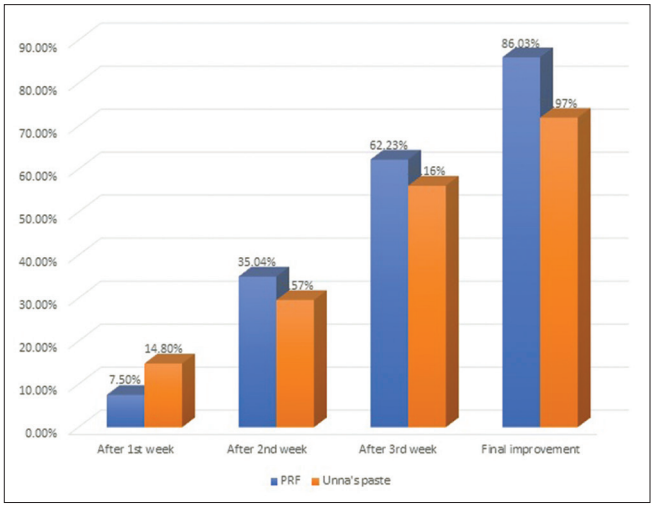

Figure 1: Bar diagram showing percentage of size reduction with platelet-rich fibrin and Unna's paste dressing

delivers growth factors.[4] Platelets trapped within the three-dimensional mesh ensures slow and continuous release of growth factors over time which lasts until the 28th day.[5] Various growth factors such as platelet-derived growth factor help in angiogenesis, neutrophilic chemotaxis, and collagen synthesis; transforming growth factor-beta helps in regulating fibroblast proliferation and deposition of bone matrix; insulin-like growth factor-1 and fibroblast growth factor enhance proliferation and differentiation of osteoblast and activate protein synthesis; vascular endothelial growth factor aids angiogenesis and endothelial cell migration; epidermal growth factor exerts collagen secretion and epithelial mitogenesis; and connective tissue growth factor helps in cartilage regeneration.[6,7]

Unna's paste dressing has a dual action, one by its anti-inflammatory and antibacterial action and offers graded compression.

Various studies with PRF and Unna's paste dressing for chronic venous leg ulcers have shown good results.

A randomized controlled trial conducted by Somani *et al*.[2] compared the efficacy of PRF and saline dressing in chronic venous leg ulcers concluded that the mean reduction in the area of the ulcer size in PRF group was 85.51% and in the saline group was 42.74% which was statistically significant.

Similarly in another randomized controlled study, Goda[8] compared PRF dressing and conventional dressing for venous ulcers. He concluded that the mean percentage of wound reduction was higher in the PRF group than the control group which was statistically significant.

A randomized double-blinded study was conducted by Stromberg and Agren[9] to compare the efficacy of local zinc oxide gauze compress and a placebo. It showed 83% improvement in the zinc oxide group when compared to the placebo group which showed only 42% improvement. Therefore, they concluded that zinc oxide accelerates wound healing.

A case series by Parboteeah and Brown[10] concluded that zinc paste therapy along with compression bandage is more efficacious in the treatment of venous leg ulcers that are difficult to treat with other therapies.

Luz *et al*.[11] conducted a study wherein 43 venous ulcer patients were randomized into two groups. Out of 43 patients, 32 patients in Unna's boot group showed a significant reduction in the ulcer when compared to 11 patients in the control group who received simple dressing. They concluded that though there was no statistical significance between the groups, Unna's boot group showed better improvement at the end of 3 months.

Conclusion

In conclusion, the reduction in ulcer size was better in PRF group (86.03%) when compared to Unna's paste

Brief Report

Comparison of Efficacy of Autologous Platelet-Rich Fibrin versus Unna's Paste Dressing in Chronic Venous Leg Ulcers: A Comparative Study

G. Yuvasri, Reena Rai

Department of Dermatology, PSG Hospitals, Coimbatore, Tamil Nadu, India

Abstract

Background: Chronic venous leg ulcers are difficult to treat and recurrences are common. Among various modalities of treatment, platelet-rich fibrin (PRF) has shown promising results in ulcer healing by providing necessary growth factors. Unna's paste dressing has also proven to enhance wound healing. **Aim:** The aim of this study is to compare the efficacy of autologous PRF versus Unna's paste dressing in chronic venous leg ulcer patients and to compare the mean reduction in ulcer area at the end of 4 weeks. **Materials and Methods:** Twenty patients with chronic venous leg ulcers were randomly divided into two groups. Group 1: Patients received PRF dressing which was repeated every week for 4 weeks. Group 2: Patients received Unna's paste dressing once a week for 4 weeks. The ulcer size was assessed with the help of photographs, and ulcer area was measured. **Results:** The mean reduction in the area of the ulcer size in the PRF group was 86.03% and in the Unna's paste group was 71.97%, which was not statistically significant with a *P* value of 0.223. **Conclusion:** We conclude that though there was no statistical significance between the groups, PRF showed a significant reduction in ulcer size.

Keywords: *Platelet-rich fibrin, Unna's paste, venous leg ulcer*

Introduction

Venous ulcers are the most common cause of chronic leg ulcers. The chronicity and high recurrence rate of venous ulcer are the two fundamental factors causing grave impact on patients' well-being.[1] One of the reasons for chronicity of the ulcer has been attributed to lack of growth factors and nutrients which are essential for wound healing.

A major revolution in the treatment of leg ulcer is cellular therapy, where the patient's own blood is used, which contains various cytokines and growth factors. Platelet-derived products such as platelet-rich fibrin (PRF) have shown promising results in wound healing.

Another dressing for chronic leg ulcer is zinc oxide paste (Unna's paste). It has re-epithelialization and anti-inflammatory properties which can enhance wound healing. Hence, we conducted an open-label randomized study to compare the efficacy of PRF and Unna's paste dressing in chronic venous leg ulcers.

Materials and Methods

A total of 20 patients were randomly divided into two groups based on the inclusion and exclusion criteria. Patients suffering from chronic venous ulcers of the lower extremity for more than 6 months, attending the outpatient department of Dermatology Venereology and Leprosy, and having an ulcer area of 1 cm × 1 cm to 5 cm × 5 cm were included in the study.[2] A thorough clinical examination and ultrasound venous Doppler were performed to confirm the diagnosis of venous ulcer. Ethical clearance was taken from the Institutional Ethics Committee.

Patients with ulcers of less than 6 months duration and of other etiology such as arterial ulcer, diabetic ulcer, neuropathic and vasculitic ulcers; patients with osteomyelitis affecting the area of the ulcer; patients with exposed tendons or bones; patients with infection; and patients receiving anticoagulants/antiplatelet drugs/bleeding diathesis were excluded from this study.

All patients in our study continued using compression stockings.

Preparation of platelet-rich fibrin

Procedure

After obtaining informed consent, 10 ml of the patient's blood was withdrawn into the vacutainer without any anticoagulant and immediately centrifuged (to prevent blood from clotting) at 3000 rpm for 15 mins. After 15 mins, a fibrin gel appears in the center of the vacutainer with red blood cells (RBCs) at the base and acellular plasma above. The PRF obtained was removed with the help of a toothed forcep and placed on the ulcer after removing the adherent RBCs. On an average, 10 ml of whole blood yields about 2.5 ml of the clot.[2]

Dressing procedure

Group 1: The measurements of the ulcer were taken. The PRF gel was then placed on the ulcer floor and covered with a sterile gauze piece (primary dressing), which was, in turn, covered with a sterile gauze pad (secondary dressing) held in place with a sterile roller bandage. The dressing was removed after 1 week. This treatment was repeated every week for 4 weeks.[2]

Preparation of Unna's paste

Procedure

Sixty grams of zinc oxide was mixed with 100 ml of glycerine and stirred well. This mixture was heated for 10–20 mins.

Dressing procedure

The measurements of the ulcer were taken. Ulcers were covered with a gauze impregnated with Unna's paste which was in turn covered with a sterile gauze-pad followed by a sterile roller bandage. This dressing was left in place for 1 week. This treatment was repeated every week for 4 weeks.

Measurements documentation

The greatest length and the greatest breadth were measured using a thread and a scale (the clock face method). This was done before starting the treatment, before repeating the treatment each time at weekly intervals, and after the treatment was completed (the final measurement). Digital photographs in both groups were taken before starting the treatment and after the treatment was completed.[2]

Results

A total of 20 patients enrolled in the study met the inclusion and exclusion criteria. The result was assessed on the basis of the ulcer area reduction. The mean reduction in the ulcer area in the PRF group was 7.50% after the 1st week, 35.04% after the 2nd week, 62.23% after the 3rd week, and 86.03% after the 4th week [Table 1]. However, in the Unna's paste group, the mean reduction in the ulcer size was 14.80%, 29.57%, 56.16%, and 71.97%, respectively [Table 2]. The overall mean reduction in the ulcer area was 86.03% in the patients treated with PRF dressing compared to 71.97% in the patients treated with Unna's paste dressing [Figure 1]. There was a complete closure of the ulcer in four patients (40%) in the PRF group [Figure 2a and b; 3a and b]. There was no case of complete closure of the ulcer in the Unna's paste group [Figure 4a and b; 5a and b].

Statistical analysis using independent *t*-test and Chi-square test showed no significant reduction of the ulcer size between both groups [Table 3].

Discussion

Wound healing is a complicated process which involves a cascade of events such as clotting, neutrophil chemotaxis, epithelialization, angiogenesis, and scar formation. Any interruption in these events leads to failure of wound closure whereby an acute wound is converted to a chronic one. Chronic ulcers are difficult to treat.[3] Therefore, an ideal dressing which offers nutritional support has a significant impact on wound repair leading to complete closure of the wound.

PRF offers the growth factors necessary for wound healing, and have been used in various fields of medicine and surgery. The derived PRF acts as a biodegradable scaffold for cell migration, proliferation, and differentiation, and

Comparison of Efficacy of Autologous Platelet-rich Fibrin versus Saline Dressing in Chronic Venous Leg Ulcers: A Randomised Controlled Trial

Anirudh Somani, Reena Rai

Department of Dermatology, Venereology and STD, PSG Institute of Medical Sciences and Research, Coimbatore, Tamil Nadu, India

Abstract

Background: Venous leg ulcer is a chronic condition, and various treatment modalities are available. Platelet-rich fibrin (PRF) is one of the newer modalities and it contains fibroblast growth factor (GF), vascular endothelial GF, angiopoitin and platelet-derived GF which enhances the wound healing. Hence, we conducted a randomised controlled trial to compare the efficacy of PRF versus saline dressing in chronic venous leg ulcers. **Aim:** This study aims to compare the efficacy of autologous PRF with saline dressing in patients with chronic venous leg ulcer and to compare the mean reduction in ulcer area at the end of 4 weeks. **Materials and Methods:** Fifteen patients with chronic venous leg ulcers of >6 months duration having an ulcer area of 1 cm × 1 cm to 5 cm × 5 cm were taken into the study and were randomly divided into two groups. Group 1: Patients received PRF dressing. Ten millilitres of patient's blood was taken and centrifuged at 3000 rpm for 15 min. A fibrin clot obtained in the middle of the tube was removed and used for dressing over the wound surface. It was repeated every week for 4 weeks. Group 2: Patients received saline dressings once a week for 4 weeks. The assessment of the ulcer size was done with the help of photographs, and ulcer area was measured. **Results:** The mean reduction in the area of the ulcer size in PRF group was 85.51%, and the mean reduction in the area of the ulcer size in Saline group was 42.74% which was statistically significant with a $P < 0.001$ and $t = 4.11$. **Conclusion:** We conclude that PRF dressing can be used as it is effective, inexpensive, safe and an outpatient procedure.

Keywords: Platelet-rich fibrin, saline, venous ulcers

Introduction

Various modalities of treatment for venous ulcers include compression stockings, good wound care and sometimes surgical therapies. The treatment is often difficult and is generally associated with high recurrence rate.[1-3] Dressings play a major role in healing of these ulcers. Moist occlusive dressings with saline are known to improve wound healing. Platelet concentrates have been widely used in regenerative medicine to promote wound healing as they contain transforming growth factor (GF) *F*, platelet-derived GF, vascular-endothelial GF, platelet derived epidermal GF, insulin-like GF-I and basic fibroblast GF. Hence, we conducted a study to compare the efficacy of autologous platelet rich fibrin (PRF) over saline dressing in chronic venous leg ulcers.

Materials and Methods

Selection and description of participants

A total of 15 patients were randomly divided into two groups on the basis of inclusion and exclusion criteria.

Inclusion criteria

Patients suffering from chronic venous ulcers of the lower extremity for more than 6 months, with an ulcer area varying from 1 × 1 cm to 5 × 5 cm attending the out-patient Department of Dermatology Venereology and Leprosy were included.

Address for correspondence: Dr. Reena Rai, Department of Dermatology, Venereology and STD, PSG Institute of Medical Sciences and Research, Coimbatore - 641 004, Tamil Nadu, India. E-mail: drreena_rai@yahoo.co.in

Exclusion criteria

Ulcers of >6 months duration, size less than 1 sq cm or more than 5 sq cm and neuropathic, arterial, diabetic or vasculitic ulcers vasculitis. Patients with infected ulcers, osteomyelitis affecting the area of the ulcer , ulcers with exposed tendons or bones Ulcers with exposed tendons or bones.Patients receiving anticoagulants/antiplatelet drugs/bleeding diathesis were also excluded from the study.

Materials and Methods

The patients were divided into two groups; Group 1: Nine patients with chronic venous ulcer receiving PRF dressing weekly for 4 weeks. Group 2: Patients with chronic venous ulcer receiving saline dressings weekly for 4 weeks.

Preparation of platelet rich fibrin

Procedure

After obtaining consent, 10 ml of the patient's own blood was withdrawn into the vacutainer without any anticoagulant and immediately centrifuged (to prevent blood from clotting) at 3000 rotations per minute for 15 min. After 15 min, a fibrin gel appears in the centre of the vacutainer [Figure 1], in between the red blood cells (RBCs) which are settled at the base and acellular plasma above. The PRF obtained was removed with the help of a toothed forceps and was placed on the ulcer after removing the adherent RBC's [Figure 2]. On an average, 10 ml of whole blood yields about 2.5 ml of clot.

Dressing procedure

Group 1: The measurements of the ulcer were taken. After 15 min, the vacutainer was removed from the centrifuge machine. A sterile non-toothed forceps was used to remove the PRF gel. With the help of an 11 number blade, the RBC clot adhering to the PRF gel was scraped off. The PRF gel was then placed on the ulcer floor and covered with a sterile gauze piece (primary dressing), which was, in turn, was covered with a sterile gauze pad (secondary dressing) held in place with a sterile roller bandage. The dressing was removed after 1 week. The PRF remnants were removed with water and sterile gauze. This treatment was repeated every week for 4 weeks.

Group 2: The measurement of the ulcer was taken. The ulcer was covered with a sterile gauze soaked in saline (primary dressing), which was in turn covered with a sterile gauze pad (secondary dressing) and was covered with a sterile roller bandage. This dressing was left in place for 1 week. This treatment was repeated every week for 4 weeks.

Measurements documentation

The greatest length and the greatest breadth were measured using a thread and a scale (the clock face method). This was done before starting the treatment, and before repeating the treatment each time at weekly intervals and after the treatment was completed (the final measurement). Digital photographs were taken before starting the treatment, before repeating the treatment each time at weekly intervals and after the treatment was completed.

Results

A total of 15 patients meeting the inclusion and exclusion criteria were enrolled in the study. All the patients were suffering from chronic venous ulcers. The result was assessed on the basis of ulcer area reduction. The mean ulcer area reduction after 1 week in the PRF group was 26.27%, after 2 weeks it was 46.25%, at 3 weeks it was 77.08% and after 4 weeks it was 85.51% [Table 1]. Whereas in the saline group, it was 14.55%, 23.24%, 34.78% and 42.74%, respectively [Table 2]. The overall mean reduction in the ulcer area was 85.51% in the patients with PRF dressing compared to 42.74% in the patients treated with saline dressing [Bar Diagram 1]. There was a complete closure of the ulcer in five patients (55.55%) in the PRF group [Figures 3-6]. There was no case of complete closure of the ulcer in the saline group [Figures 7-10].

Statistical analysis showed a significant reduction in the ulcer size in the PRF group compared to the saline group [Table 3].

Discussion

PRF is an autologous platelet and leucocyte-rich fibrin material and is an important advancement in regenerative medicine. It

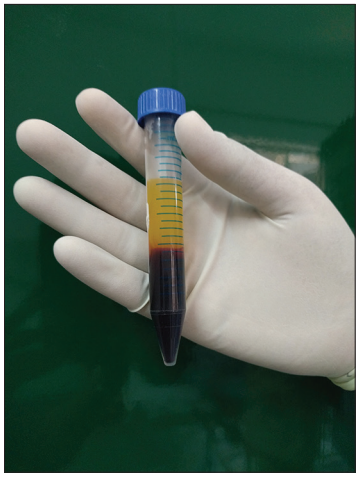

Figure 1: Vacutainer with platelet-rich fibrin clot

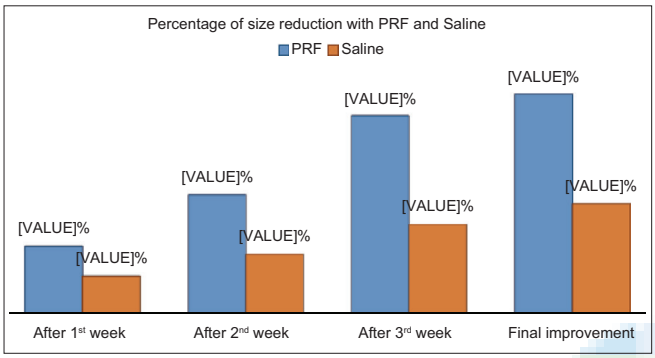

Figure 2: Platelet-rich fibrin placed on the ulcer

[Downloaded free from http://www.jcasonline.com on Thursday, May 4, 2017, IP: 104.247.118.34]

forms an organised network where the platelets and leucocytes are concentrated leading to the sustained release of various GFs, resulting in wound healing. Hence, it can also be used for the treatment of venous ulcers.[4]

A study conducted by Margolis *et al*. which included 26,599 patients, concluded that patients who were treated with products derived from platelets, tend to heal faster than patients who were treated without the products derived from platelets. He also concluded that even though the ulcers that were treated with these derivatives were bigger and deeper than the other groups these showed better improvement at the end of 12 weeks.[5] Our study showed similar results where ulcers treated with PRF showed better and faster improvement when compared to saline dressing.

Bar Diagram 1: The bar diagram above shows the comparison of the mean improvement in PRF group and Saline group after every week and also after the treatment for 4 weeks

In another study, Anitua *et al*. showed that healing increased significantly with the help of PRF. She also concluded that it not only helps in supplying the required GFs but also by forming fibrin matrix which helps in cell migration, it also helps in neo-vascularisation.[6] In this study, there was a mean reduction of ulcer size of 85.51% in the group treated with PRF at the end of 4 weeks.

In another study Mazzucco *et al*. concluded that healing is improved and is much faster when the wound is treated with platelet-rich gel. He stated that this also helps to reduce the hospital stay. In his study, he demonstrated that in patients who were treated with platelet-rich gel the wound healed in 3.5 weeks and the wounds which were not treated with platelet-rich gel took 6 weeks.[7] In our study, 55.55% of patients treated with PRF had complete closure at the end of 4 weeks, whereas no patient treated with saline had complete closure.

In another conducted by Saldalamacchia *et al*., it was concluded that the use of PRF had significant effectiveness in the treatment of ulcers. He stated that the use of PRF had better reduction of area of ulcer when compared with the basic wound care without the use of PRF. He concluded that though in his study he treated the patients with PRF for a short time it showed good improvement.[8] Similarly, in our study, we found mean reduction

Figure 10: Patient 4 after 4 weeks of treatment with Saline dressing

Table 3: Group statistics

Variables	Number of patients	Mean	SD	*t*	*P*
Saline	6	42.74	18.52	4.11	<0.001
PRF	9	85.51	20.45		

The study was statistically significant with the $P<0.001$. SD: Standard deviation, PRF: Platelet rich fibrin

origin had total closure in only 44% of patients. Hence, he proved that PRF was very efficacious in the treatment of venous ulcers.[4]

In many studies, there was no significant improvement in the ulcers treated with saline dressing.[5,7-9] Our study showed 42.74% reduction in ulcer size when treated with saline dressing, however, this was less when compared to the 85.51% ulcer area reduction in the PRF dressing group.

Although we had good reduction in the ulcer size in the patients treated with PRF, we need to validate the results with a larger sample size.

Conclusion

This procedure is simple, patient-friendly, cost-effective, painless and can be performed as an outpatient procedure. We would like to conclude that the use of PRF dressings as an adjuvant therapy in the treatment of chronic venous ulcer shows great potential to achieve complete closure of ulcers and can successfully be used as a routine procedure in the management.

ABSTRACT

Introduction; Depression is an illness that may affect and be affected by diabetes mellitus. The clinical guidelines for older adults with diabetes mellitus have recognized this by recommending screening for and management of depression in diabetic elderly people. The aim of this study was to find out the prevalence of depression using PHQ -9 questionnaire among elderly diabetics in peripheral primary health care centres attached to a Private medical college. **Objectives:** 1. To find out the prevalence of depression among elderly diabetics 2. To find out the factors associated with depression among elderly diabetics **Methodology:** This cross sectional study was conducted among known diabetics above 60 years of age attending the NCD clinic of Peripheral health centres at Peelamedu, Vedapatti, Neelambur during December 2017 – April 2018. The socio demographic factors and morbidity factors such as fasting blood sugar, duration of diabetes, history of hypertension, past history of diabetes related complications, hours of sleep were included to find out the association with levels of depression. **Results:** Among the study population, 40.4 % were having the signs of depression in which the majority have only minimal symptoms of depression. The factors such as Female Gender, Fasting blood sugar >126 mg/dl and hours of sleep < 7 hours found to be statistically significant association with depression. **Conclusion:** The prevalence of depression using PHQ 9 is 40.4% and the factors such as female gender, fasting blood sugar more than 127 mg/dl and sleep at night less than 7 hours were found to have statistically significant association with depression.

Key word: Depression, PHQ-9, Screening, Prevalence, Elderly diabetics.

INTRODUCTION

Depression is an illness that may affect and be affected by diabetes mellitus. Depression is an independent risk factor for the onset of type 2 diabetes mellitus. It negatively affects the course of diabetes and is associated with increased risk of complications, hyperglycemia, and mortality. Depression may exert its negative effect through hormonal, neuronal, or immune system changes that directly affect the body's ability to produce or use insulin or, the effect of depression may be indirect, by resulting in poor self-care behaviours, such as overeating, drinking alcohol, not exercising, skipping medications, or failing to keep medical appointments. Thus, identifying and treating depression in diabetes is strongly recommended.[1]

Evidence suggests that depression may relate to poorer glycaemic control[2] and that poorer control predicts a poorer course of depression in adult samples.[3]There is some evidence that depression does not prospectively predict worsening of blood glucose control in the elderly, but more research needs to be done to understand this relationship in this group.

In interactions with the health care system, the presence of depression may influence decisions made by health care providers concerning medical outcomes (e.g., blood glucose and blood pressure). For example, providers may set goals that are easier to achieve, yet are less stringent, when they believe that depression will interfere with a patient's ability to adhere to a stricter regimen. Depression can also have an effect on patients' own goals and preferences for treatment, because depressed patients may feel too hopeless or helpless to embark on the lifestyle changes that are most beneficial for diabetes self-care.

Thus, in many different ways, diabetes may become more difficult to manage for elderly people who are also depressed, and depression may become more difficult to resolve in those who have diabetes, resulting in higher health care utilization and medical costs for those with this comorbidity.[4] The clinical guidelines for older adults with diabetes mellitus have recognized this by recommending screening for and management of depression in diabetic elderly people.

Tools such as the short form of the Geriatric Depression Scale, the Patient Health Questionnaire-9, and the newly

developed Depression and Suicide Screen are useful. [5] The present study used PHQ – 9 questionnaire to arrive at a provisional diagnosis of depression as patients with minimal symptoms (score 5-9), minor depression (score 10-14), moderate Major depression (score 15-19), severe major depression (score >20).

The objectives of this study were to find out the prevalence of depression using PHQ -9 questionnaire among elderly diabetics in peripheral primary health care centres attached to a Private medical college and to find out the factors associated with depression.

METHODOLOGY

The Department of community medicine of PSG Institute of Medical sciences and Research has one Urban (Peelamedu) and Two Rural health training centres (Vedapati and Neelambur) to deliver primary health care to people. These centres have basic laboratory services to manage Non communicable diseases (NCD). All these three centres run NCD clinic on a particular day of the week and maintain NCD register. This cross sectional study was conducted among known diabetics above 60 years of age attending the NCD clinic of Peripheral health centres at Peelamedu, Vedapatti, Neelambur during December 2017 – April 2018. By purposive sampling, 104 elderly diabetics who came for review during the study period at NCD clinic were selected. All registered diabetics above 60 years of age attending the NCD clinic were included and those who were on treatment for pre-existing major and minor mental illness were excluded.

After obtaining approval from Institutional Human Ethics Committee, informed consent obtained from the patients at NCD clinics of peripheral health centres. Study Questionnaire with PHQ-9 administered to the patients till the sample size of 100 reached. Questionnaire contains the following items i.e. Socio demographic variables, fasting blood sugar, presence of hypertension, complications related to diabetes and hours of sleep at past night to find out the association of above factors on depression among the study population.

Those patients found to be having depression will be followed up based on degree of depression at the peripheral health centres. Proportions, test of statistical significance (Chi square) and odds ratio with 95% confidence interval (CI) using SPSS version 24 were calculated.

RESULTS

Table 1: Distribution of study population at Peripheral Health Centres

Peripheral Health centres	Study population	Percent (%)
UHTC (Peelamedu)	46	44.2
VHTC (Vedapatti)	29	27.9
NHTC (Neelambur)	29	27.9
Total	104	100

The present study intended to find out the prevalence of depression among elderly diabetics and the factors associated with depression. There were 104 elderly

* Statistically significant (p< 0.05)

diabetics (Table. 1) included in the study. Among the study population, 40.4 % were having the signs of depression (Table.2), of which 24% have only minimal symptoms of depression (Table.3).

The socio demographic factors i.e. age, gender, education, income per capita per month and morbidity factors such as fasting blood sugar, duration of diabetes, history of hypertension, past history of diabetes related complications, hours of sleep and PHQ -9 score are shown in Table.4.

Each of the above variables were categorized into two to find out the statistically significant (p< 0.05) association with depression among the study population using chi square test (Table. 5) in SPSS version 24. The factors such as Female Gender, fasting blood sugar >126 mg/dl and hours of sleep < 7 hours found to be statistically significant association with depression in the present study.

DISCUSSION

In the present study the prevalence of depression among elderly with diabetes mellitus was found to be 40.4%. The study conducted by SA Black et al showed that 31.1% of the older diabetic individuals reported high levels of depressive symptoms. [6] Prevalent major depressive episodes were present in 15.4% of the subjects with diabetes, which was significantly higher than in nondiabetic subjects in a study conducted among community-dwelling elderly persons with diabetes mellitus by P. de Jonge et. al. [7] In a study conducted by Manjiri D Pawaskar et al. among Medicare enrolled elderly population with type 2 diabetes mellitus, 17% had depressive symptoms. [8] In a study conducted by Kee-Lee Chou et al, on Prevalence of depression among elderly Chinese with diabetes, 26% of elderly diabetics reported elevated levels of depressive symptoms. [9] Elderly female diabetics are more among depressed (OR 3.2, 95%CI: 1.40-7.48) than men in this study which is statistically significant. Finkelstein EA et al reported diagnosed annual prevalence rates of major depression more among elderly female diabetics. In our study there is no significant association between the subjects with duration of diabetes less than 10 years and more than 10 years whereas in a study done by Yu-Ling Bai et al. a significant difference was found for depression scores between subjects with diabetes for <1 year and those with diabetes for >10 years.[10] Elderly with high Fasting blood sugar >127 mg/dl have higher risk of depression (OR 2.5, 95%CI: 0.99-6.33) than those with Fasting blood sugar <126 mg/dl in the present study. PJ Lustman et al reported in the meta analytic review of 24 studies that Depression is associated with hyperglycemia in patients with type 1 or type 2 diabetes[3]. However, association of depression with hyperglycemia in elderly diabetics is not documented. Elderly diabetics who slept more than 8 hours at night had lesser risk of depression (OR 0.279, 95%CI: 0.08-0.89) than those who slept less than 7 hours at night in this study. The factors such as age, education,

© Community Medicine Faculties Association-2019
NJRCM: www.commedjournal.in

income, marital status, past history of diabetes related complications and hypertension were not found to be significant in this study. This study has few limitations like very small sample size, FBS is taken as an indicator for glycemic control instead of Hb A1C and PHQ 9 administered by different doctors at three health centres.

Conclusion:

This cross sectional study among elderly diabetics in primary health centre setting of a private medical college revealed that prevalence of depression using PHQ 9 is 40.4% and the factors such as female gender, fasting blood sugar more than 127 mg/dl and sleep at night less than 7 hours were found to have statistically significant association with depression.

Comparing 24-hour symptom triggered therapy and fixed schedule treatment for alcohol withdrawal symptoms – A randomized control study

Raghuthaman Gopal, Sushith Sugathan Chennatte, Shilpa S.

PSG Institute of Medical Sciences & Researchm, Peelamedu, Coimbatore, Tamil Nadu, 641004, India

1. Introduction

Acute alcohol withdrawal symptoms are common in patients who are dependent on alcohol. While most of them develop only mild withdrawal symptoms like anxiety, insomnia, tremors, nausea, tachycardia, and diaphoresis, 5–15% develop withdrawal seizures and about 5 % develop delirium tremens (Lerner and Fallon, 1985; Guthrie, 1989). It is estimated that 2–10% of patients with delirium tremens die due to metabolic, cardiovascular or infectious complications. Hence it is prudent to manage alcohol withdrawal symptoms effectively.

As supported by meta-analyses reviews, benzodiazepine is the most effective medication in treating alcohol withdrawal symptoms and preventing complications (Mayo-Smith, 1997; Holbrook et al., 1999). The severity of withdrawal varies among patients, which warrant appropriate benzodiazepine dosing. Also, many patients have only minimal withdrawal symptoms which could be managed safely without using benzodiazepines (Naranjo et al., 1983; Shaw et al., 1981). However, in clinical practice, benzodiazepines are empirically predetermined and administered for all the patients. A better approach of management is symptom-triggered therapy, where patients are monitored using a structured scale (Clinical Institute Withdrawal Assessment for Alcohol scale - CIWA-Ar), and benzodiazepines are administered according to severity of the withdrawal symptoms (Sullivan et al., 1991; Wartenberg et al., 1990).

Symptom-triggered therapy reduces the risk of under medicating or overmedicating a patient with benzodiazepines and results in less total benzodiazepine dosage and shorter duration of treatment. This has been confirmed by 3 randomized controlled trials (Saitz et al., 1994; Daeppen et al., 2002; Sachdeva et al., 2014). In all these trials, the investigators used CIWA-Ar assessments throughout the detoxification phase which was more than 3 days. In resource crunch settings, 1–4 hourly rating with CIWA-Ar for the entire detoxification phase may not be feasible. As withdrawal symptoms start emerging within a few hours after stopping alcohol, we hypothesize that structured 1–4 hourly assessments with CIWA-Ar during the first day of detoxification alone could predict the required effective dose of benzodiazepine and the amount received on the first day could be effectively tapered down in the subsequent days.

We conducted a randomized controlled trial comparing the efficacy of 2 detoxification regimens: 1) 24 h structured assessment with CIWA-Ar scale to initiate Symptom Triggered Therapy and 2) Fixed Schedule Treatment.

2. Methods

2.1. Study population

This study was conducted in the de-addiction ward which is part of the psychiatry department of PSG Institute of Medical Science and Research, a tertiary teaching medical college hospital. All consecutive patients between the ages of 16 and 65 years, who got admitted and met the DSM IV criteria for alcohol dependence syndrome when interviewed using Structured Clinical Interview, 1998 schedule for Diagnostic and Statistical Manual IV (SCID IV), were included in the study.

Patients with delirium which was not due to alcohol withdrawal were excluded from the study. Patients with co-morbid Axis I psychiatric disorders and with other co-morbid substance use disorders except nicotine were also excluded. We got written informed consent from the patients and the family members who had accompanied the patients. Patients who were not having capacity to give consent because of delirium were included only if their key family members gave valid consent. Our study was approved by the human ethics board of our institution.

2.2. Measurements

The eligible patients were personally interviewed by one of the postgraduate trainees (SS or S) to get details regarding their demographic characteristics, medical comorbidities, and use of substances by using a semi-structured proforma. We used a translated Tamil version of Severity of Alcohol Dependence Questionnaire (SADQ) to assess the severity of dependence (Stockwell et al., 1994).

We randomized the consecutive recruited patients using computer generated randomization technique into 2 detoxification regimes: 1) 24 h Symptom Triggered Treatment (24 HR -STT) and 2) Fixed Schedule Treatment (FST). We used Tamil translated version of the CIWA-Ar scale for administering benzodiazepines in the 24 HR-STT

group.

Detoxification regimes:

1) 24 h Symptom Triggered Treatment (24 HR -STT):

We gave a structured training to all the nursing staff in the psychiatry ward in administering CIWA – Ar scale. A didactic lecture was followed by a live demonstration of administering CIWA – Ar on 3 patients with different levels of withdrawal symptoms. Later, the nursing staff were shown a video showing an interview conducted to rate CIWA – Ar on 2 different patients in withdrawal state, and the nurses were asked to rate on CIWA – Ar independently. We found that the single measure intra class correlation co-efficient was 0.898 indicating a high level of agreement for all the items of CIWA – Ar (Venkateswaran Rajaraman, 2017).

For the first 24 h, a nursing staff or a resident on the ward administered CIWA-Ar every one hour and if the score came below 10 for three consecutive ratings, then the rating was done once in 4 h. Whenever the score was greater than or equal to 10, that patient was given chlordiazepoxide 20 mg (or lorazepam 1 mg, if there was liver dysfunction). The total amount of benzodiazepine received on the first day was given on the 2nd day as divided doses and from 3rd day onwards chlordiazepoxide was tapered by 10 mg every day (1 mg per day, in case of lorazepam).

2) Fixed Schedule treatment (FST):

The clinician who admitted the patient, based on the clinical factors, decided the initial dose of benzodiazepine (chlordiazepoxide or lorazepam) and from 3rd day onwards the benzodiazepine dosage was tapered (chlordiazepoxide: 10 mg per day/ lorazepam: 1 mg per day) and stopped.

2.3. Outcome measures

The total dose of benzodiazepines administered and the duration of detoxification in both the treatment groups were our primary outcome measures. An independent investigator, who was blind to the treatment allocation, administered CIWA-Ar rating for both the groups, every morning between 8 a.m. and 10 a.m., for a period of 7 days. This measured how effectively withdrawal symptoms were treated in both the groups. We also estimated for any new onset delirium tremens and seizures during the detoxification period.

2.4. Sample size calculation

Before launching the current study, we did a pilot study on a group of 25 patients who got admitted with alcohol dependence syndrome. We found that for the entire detoxification period, they needed average139.6 mg (SD = 70.44) of chlordiazepoxide, which was decided by Fixed Schedule Treatment method, to manage withdrawal symptoms, over the mean duration of 6.11 ± 1.9 days. We proposed that by adopting 24 h Symptom Triggered Treatment the total dose of chlordiazepoxide should be reduced by at least 50 mg to be considered as clinically meaningful. Using the formula, $2 \times [SD] \times (Z\alpha + Z\beta) /$ Mean difference (Kim, 2016), we found that to observe a significant group difference with 90 % power and an alpha of 0.05 (two-tailed), we needed a sample size of 31 patients in each group. Considering a drop-out rate of about 30 %, we estimated that we would require a sample size of 40 in each group.

2.5. Statistical analyses

We tested for normality of continuous variables by examining their histograms and with Shapiro-Wilks test. Student *t*-test was used to compare continuous variables like age, monthly income, SADQ total scores, and number of detoxification days between the two regimens. We used Mann Whitney *U* test to compare CIWA-Ar baseline scores,

total benzodiazepine dose, daily benzodiazepine doses, duration of detoxification and daily CIWA-Ar scores between the two treatment regimens. Chi-square test was used to examine associations between categorical variables. All the patients who were randomized were included in the analysis and for the patients who dropped out, we used last observation carried forward analysis.

3. Results

3.1. Sample characteristics

All the patients who were screened for this study were males and spoke Tamil language. At the stage of screening one patient refused to give consent; we recruited consecutive 80 patients who fulfilled our inclusion criteria and randomized into the 2 detoxification groups: 24 h Symptom triggered treatment (24 HR –STT) = 40 and Fixed Schedule treatment (FST) = 40. Eleven patients (24 HR –STT = 3 and FST = 8) dropped out of the study as they got discharged before completion of their detoxification and their data till drop out were used in the analyses (Fig. 1).

Mean age of the subjects was 40.21 years (SD = 9.54), 83.8 % were married and were earning on an average Rs. 14,805(SD = 13,019.27) per month. The mean score on severity of alcohol dependence questionnaire (SADQ) was 29.65(S.D = 9.83), which amounts to moderate dependence. Demographic characteristics like age, marital status and monthly earnings were similar in both 24 HR –STT and FST groups. The last intake of alcohol was within 12 h prior to the initial assessment and all patients were within the withdrawal period. At the baseline assessment, there were also no differences in severity of dependence, severity of withdrawal symptoms and number of patients with delirium tremens between the 2 groups. None of the patients had withdrawal seizures or hallucinations. All the patients received Thiamine (oral and intramuscular) and oral vitamin B complex. None of the patients received antipsychotics or benzodiazepines other than chlordiazepoxide and lorazepam (Table 1).

3.2. Benzodiazepine and treatment outcome

Lorazepam was used for detoxification in 5 patients (24 HR –STT = 1 and FST = 4) and for the rest of the patients chlordiazepoxide was used and all of them received the same brand of benzodiazepines by oral route. While all the patients in the FST group received benzodiazepines, 12 patients (30 %) in the 24 HR –STT group didn't need any benzodiazepine. Among patients who received benzodiazepines, the median total dose (chlordiazepoxide equivalence) was 95 mg lower in 24 HR –STT group than FST group, which was statistically significant. During the first 6 days of detoxification, the amount of benzodiazepine received on each day was significantly lower in 24 HR –STT group than FST group. Also, the duration of detoxification was significantly shorter in 24 HR –STT than in FST. Median scores of CIWA Ar, as assessed by an independent assessor, in both the groups were similar and low suggesting that the withdrawal symptoms were effectively managed (Table 2).

3.3. Delirium tremens

The clinical diagnosis of Delirium Tremens was made based on ICD 10 Classification of Mental and Behavioural disorders: Clinical descriptions and diagnostic guidelines. At baseline 9 patients had delirium tremens (24 HR –STT = 5 and FST = 4) and during the detoxification phase, 2 patients developed delirium tremens (24 HR –STT = 1 on 3rd day; FST = 1 on 2nd day). Among patients with delirium tremens, those who were in 24 HR –STT group needed 135 mg more total chlordiazepoxide mean dose than FST group; but this difference didn't reach statistical significance. Among patients without delirium tremens, 24 HR –STT group needed 168.18 mg lesser total chlordiazepoxide mean dose than FST group, and the difference was statistically significant (Table 3).

4. Discussion

Our data supported our hypothesis that using 24 h Symptom Triggered Treatment, in patients who are withdrawing from alcohol, can result in: less benzodiazepine dose, shorten detoxification period and avoid unnecessary benzodiazepines, without incidence of any withdrawal related complications.

4.1. Benzodiazepine use

FST and 24 HR –STT groups were similar in demographic and alcohol related variables (severity of dependence and withdrawal symptoms as measured by SADQ and CIWA-Ar scales respectively).

24 HR –STT group received significantly less chlordiazepoxide equivalence dose (median 115 mg) than FST group (median 210 mg). The results are consonant with other studies which had compared Symptom triggered treatment with Fixed schedule treatment: Saitz et al. (1994) (100 mg versus 425 mg of chlordiazepoxide), Daeppen et al. (2002) (37.5 mg versus 231.4 mg of oxazepam) and Sachdeva et al. (2014) (9.5 mg versus 19.9 mg of lorazepam). In our study, patients in the 24 HR – STT group had significantly shorter duration of detoxification (120 h) than patients in the FST group (144 h) ($p = 0.0001$). Again, this finding is consonant with the earlier studies: Daeppen et al. (2002) (20 versus 62.7 h), Saitz et al. (1994) (9 versus 68 h) and Sachdeva et al. (2014) (47.8 versus 146 h). While these studies (Saitz et al., 1994; Daeppen et al., 2002; Sachdeva et al., 2014) had used the CIWA-Ar rating for first 3 days, we had used it only for the first 24 h, but we were able to achieve similar results. Thus restricting CIWA-Ar rating to only first 24 h of detoxification is more time efficient and effective at the same time.

Another statistically significant finding favouring the 24 HR-STT

Table 3
Treatment outcome among patients with and without delirium tremens.

	24 Hrs Symptom Triggered Treatment (24 HR –STT)	Fixed Schedule Treatment (FST)	Statistic Mann-Whitney U test
Total Chlordiazepoxide equivalent dose (mg) Mean (Median) ± SD			
Patients with Delirium Tremens (n = 11)	635 (560.00) ± 184.15	500 (620.00) ± 237.38	U = 12 P = 0.583
Patients without Delirium Tremens (n = 69)	88.53 (50.00) ± 98.60	255.71 (210.00) ± 249.16	U = 181.000 P < .0001

group was that 30 % of patients in this group did not require any benzodiazepine, where as all the patients in the Fixed Schedule Treatment group received benzodiazepines during detoxification even though the severity of baseline withdrawal score in both these groups were comparable. Two studies have reported even a higher percentage of patients who didn't require benzodiazepines: Daeppen et al. (2002) - 60.7 % and Foy et al. (1988) - 46 %.Thus using symptom triggered treatment helps to identify patients who can be safely managed without prescribing benzodiazepines.

Using benzodiazepines for alcohol withdrawal, by whatever method, doesn't seem to result in benzodiazepine abuse or dependence. In our study, benzodiazepines were stopped in a very short period in both the groups (24 HR –STT: 3.90 (5) ± 3.19 days and FST: 6.35 (6) ± 2.05 days). Shree Shilpa et al. (2019) found that, among 109 Benzodiazepine abusers in a psychiatric setting, none of them were prescribed for alcohol withdrawal.

4.2. Course of withdrawal

Even though the median dose and duration of detoxification was lesser in the 24 HR-STT group, the withdrawal symptoms were effectively controlled in both the treatment groups as shown by very low CIWA-Ar ratings from the 2nd day as assessed by an independent rater, who was masked about the treatment allocation.

4.3. Implementation of STT

Administration of CIWA-Ar is simple to learn and we have successfully trained nursing staff and residents in using this (Venkateswaran Rajaraman, 2017). A physician could advice nurses to assess patients using CIWA-Ar at regular intervals on the first day of hospital admission.

The implementation of symptom triggered treatment for alcohol withdrawal in an in-patient unit includes not only training of the personnel but also the choice of patients who need symptom triggered treatment. Studies have shown inappropriate use of symptom triggered treatment in general hospital settings due to indiscriminate use of CIWA-Ar without properly establishing two important selection criteria for STT, such as the diagnosis of alcohol dependence and the communication ability of the patient (Hecksel KA et al., 2008).The authors in the study had identified that patients with medical comorbidities were more likely to be wrongly initiated on symptom triggered treatment when the above mentioned criteria were overlooked. Also, Bostwick and Lapid (2004) had reported in their case studies of 4 medically complicated patients, in which physicians had overlooked the period of abstinence in patients with remote history of alcohol use. This had resulted in inappropriate use of CIWA-Ar scale when the patient was not in withdrawal. Therefore, even though the CIWA-Ar scale is easy to administer and nurses can be trained to administer benzodiazepines according to symptom triggered regimen, physicians have to meticulously assess and establish the alcohol dependence criteria and current state of withdrawal in the patient before initiating symptom triggered treatment protocol.

4.4. Limitations

Generally studies exclude patients younger than 18 years; in our study, in the inclusion criteria we had set the age range as 16–65, however the age of recruited patients ranged from 24 to 65 (Mean: 40.21 ± 9.55). Not being a double blind study was our biggest limitation; but by carefully adhering to the study protocol, we tried to overcome any investigator bias. Also, in the Fixed Schedule Treatment group, the doses of benzodiazepines were decided by the primary treating psychiatrists who were not part of the investigative team and they were unaware of our hypotheses. The tapering of doses were different for chlordiazepoxide (10 mg per day) and lorazepam (1 mg per day); however it is unlikely to affect the result as out of 80 patients, only 5 had received lorazepam (24 HR –STT = 1 and FST = 4). During

the study, none of the patients suffered from any known adverse effects due to chlordiazepoxide or lorazepam; however not having a structured assessment for adverse effects is a limitation. But, dropout rates were less in the 24-HRSTT group than the FST group thus favoring the symptom triggered treatment.

To assess the severity, we used Severity of Alcohol Dependence Questionnaire (SADQ); however we didn't capture the type and exact quantity of alcohol consumed. Complicated withdrawal symptoms like delirium tremens, withdrawal seizures and alcoholic hallucinosis were poorly represented in our sample and thus findings may not be generalizable for use in these conditions, for which further studies are needed. We had not captured the physical parameters in a meaningful way which could be analysed and presented.

The study setting happened in a psychiatry ward where we have psychiatry residents and nursing staff with psychiatry skills. Hence, the efficacy of such interventions may not be the same in other medical settings.

5. Conclusion

Symptom triggered treatment using CIWA-Ar scale for the first 24 h seems to be a favourable, safe and effective method of detoxification for alcohol related withdrawal symptoms among hospitalized patients, where nursing staff or residents are trained in using the CIWA-Ar to administer the benzodiazepines.

PHENOMENOLOGY OF DELIRIUM IN DECOMPENSATED LIVER DISEASE PATIENTS-A PROSPECTIVE OBSERVATIONAL STUDY

B Lakshmi Dorai[1]*, G Raghuthaman[2]

[1]Department of Psychiatry, Vinayaka Mission's Kirupananda Variyar Medical College and Hospital, Salem

ABSTRACT

Background: Decompensated liver disease (DCLD) is associated with various cognitive changes. The present study aimed to estimate the prevalence, phenomenology, and course of delirium in decompensated liver disease patients. **Methods**: This prospective observational study was done on 111 patients admitted to the gastroenterology department with the diagnosis of DCLD. Richmond Agitation Sedation Scale (RASS) and confusion assessment method (CAM) were used to detect delirium for the first five consecutive days. Patients detected to be having delirium were administered a delirium rating scale (DRS) for the next seven days to evaluate the features of delirium. Descriptive analysis was carried out by mean and standard deviation for quantitative variables, frequency, and proportion for categorical variables. For normally distributed quantitative parameters, the mean values were compared using an independent sample t-test. Categorical outcomes were compared between study groups using the chi-square test. coGuide version V.1.0 was used for statistical analysis. **Results:** The prevalence of delirium among patients with DCLD was 34 (30.63%). All delirious patients continued to have delirium symptoms for the initial three days. Six patients remitted as early as the fourth day of DRS assessment, while nine patients continued to have delirium symptoms even by the seventh day of evaluation. **Conclusion:** Nearly one-third of patients with DCLD presented with delirium. They presented with insomnia, cognitive deficits, motor retardation, and minimal psychotic symptoms. Many patients completely recovered from delirium within a week, but a few had delirium up to the seventh day.

Keywords: delirium, Hepatitis, hepatic encephalopathy, cirrhosis

Introduction

Delirium is a complex neuropsychiatric disorder and a potentially life-threatening acute brain dysfunction. Among the various causes of delirium, decompensated liver disease (DCLD) is an important one. [1] The literature on DCLD has dealt in-depth with various cognitive changes associated with it. Various terms are given for it as hepatic encephalopathy, minimal hepatic encephalopathy, episodic and persistent encephalopathy.[2] During the natural course of DCLD like fatty liver (steatosis), followed by inflammation ofthe liver tissue (hepatitis), scar tissue formation (fibrosis), and finally, destruction of liver architecture (cirrhosis) cause a decrease in the number of functional liver cells resulting in an inability to remove toxic substances from the blood. As a result, ammonia and manganese accumulate in the brain leading to structural

changes in the astrocytes. These factors contribute to altered neurotransmission and brain dysfunction.

Based on psychomotor features, two clinical subtypes of delirium have been described; hyperactive and hypoactive.[3] Some patients fluctuate between these two and fall into the third subtype called mixed delirium.[4] Hyperactive delirium is characterized by agitated behaviour with increased psychomotor activity.[5] Alcohol withdrawal is a classic example of hyperactive delirium. Patients with hypoactive delirium are quiet and lethargic with decreased psychomotor activity.[5] Probably, these phenotypes signify different forms of neurologic dysfunction. However, as of now, clinically, there is no substantial understanding to pinpoint the aetiology.[6]

The prevalence of cognitive changes among patients with decompensated liver disease (DCLD) ranges from 30%-60%. The annual risk of a patient with DCLD developing hepatic encephalopathy is 20%, and 60%-80% of the patients with DCLD have some form of cognitive impairment during their lifetime.[7] Survival probability among DCLD patients who developed encephalopathy was 42% at one year and 23% at three years.[8] Prompt identification and management of this condition reduces mortality, morbidity and also shortens hospital stay.[9] Literature available includes studies on clinical profile, plasma ammonia levels in patients with liver failure with or without hepatic encephalopathy (HE) and prognostic factors associated with HE.[10–12] Longitudinal studies are found to be looking into the phenomena of all-cause delirium.[13] Though there are Indian studies on all-cause delirium [14], studies looking specifically at hepatic encephalopathy (HE) are rare. Hence, the current study aimed to study the phenomenology and course of delirium in decompensated liver disease patients. The objectives were to estimate the prevalence of delirium in patients admitted with decompensated liver disease and determine the association between delirium with clinical and laboratory parameters.

MATERIALS AND METHODS

Study population and study site: The study was conducted on patients admitted in the ward and ICU of a PSG Institute of Medical Science and Research, Coimbatore, with decompensated liver disease (DCLD) (based on clinical examination and supportive laboratory test reports).

Study design: Prospective observational study.

Study duration: Eight months from May 2013 to January 2014.

Inclusion Criteria:

1. Patients who were diagnosed with decompensated liver disease (DCLD).
2. Age between15 to 80 years.

Exclusion criteria:

1. Patients who were having severe mental disorders and mental retardation.
2. Patients on ventilators.
3. Patients were having severe impairment in vision (blindness) and hearing as they could not undergo the psychological tests.

Sample size: The sample size was calculated assuming the prevalence of delirium as 20% as per the study by FF Poordad et al.[15] The other parameters considered for sample size calculation were 8% absolute precision and a 95% confidence level. The following formula was used for sample size calculation.

$$n = \frac{Z^2 P(1-P)}{d^2}$$

Where n = Sample size, Z= Z statistic for the level of confidence, P= Expected prevalence of proportion (if the expected prevalence is 20%, then P= 0.2), and d = Absolute precision (if the precision is 8%, then d=0.08). The required number of subjects as per the calculation mentioned above was 97. To account for a non-participation rate of about 4% (four subjects), it was decided to sample about 111 subjects into the study.

Sampling method: All the eligible subjects were recruited into the study by consecutive sampling until the sample size was reached.

Ethical considerations: The Institutional Human Ethics Committee, PSG Institute of Medical Sciences & Research , Coimbatore approved the study, and the proposal approval number is 13/064. Written informed consent was obtained from the patient, and most were not capable of giving informed consent due to episodes of delirium at entry. Consent from the nearest key family member was taken in these cases.

Data collection tools and clinical examination

Patient proforma: Consists of data regarding socio-demographic profile, substance use details, clinical and laboratory parameters. A single examiner (psychiatrist) administered all the scales.

Various scales used for measurement:

SADQ (severity of alcohol dependence questionnaire)

The Severity of Alcohol dependence questionnaire was developed by Addiction Research Unit at Maudsley Hospital in 1983. It covers five aspects of alcohol dependence like Physical withdrawal symptoms, Affective withdrawal symptoms, relief in drinking, the frequency of alcohol consumption, and the speed with which onset of withdrawal symptoms occurs. It focuses on the last six months of heavy alcohol drinking. It takes 2-5 minutes to administer this questionnaire.[16]

RASS (Richmond Agitation Sedation Scale)

In our study, we use this scale to assess the level of consciousness of the patient. The Richmond Agitation Sedation Scale was developed at Virginia Commonwealth University in Richmond by a multidisciplinary team, and it can be performed in less than 20 seconds and requires minimal training.

CAM-ICU (confusion assessment method)

Confusion Assessment Method- ICU was developed by Sharon Inouye et al. in 1990, subsequently revised in October 2010. It is a bedside assessment tool, even usable by non-psychiatrists. This was designed mainly for ICU patients who are critically ill, with or without a ventilator, and unable to talk. It takes 5-8 minutes to assess the presence or absence of Delirium.[17]

The Delirium Rating Scale-Revised 98 (DRS-R-98) and administration of various scales:

The timings for data collection were scheduled between 5-7 pm because it is well known that delirium worsens during evening hours. The severity of alcohol dependence questionnaire (SADQ) was used on patients with a history of alcohol use. Each of the patients was administered RASS and CAM-ICU scales daily for five days to detect delirium. If a patient was detected to be having delirium on any of those five days, from that day onwards DRS-R-98 scale was administered. The onset of delirium was considered as the primary outcome variable. Data collection was scheduled between 5-7 pm of all the seven days of the study period (every 24 hours) to avoid overlap of symptoms and better capture of signs. DRS-R-98 scale is a validated scale with a high inter-rater reliability score ranging from 0.66–0.99, specificity ranging from 79%-88%, and sensitivity of 83%-88%. It is a 16-item clinician-rated scale, and it has two sections. First, 13 items are for assessing delirium symptoms severity, and the next 3 are diagnostic items. First, 13 items are rated from 0-3 points, and diagnostic items are rated from 0-2.[18]

Statistical Methods: The onset of delirium was considered as the primary outcome variable. Symptoms at different follow-up periods were considered as the primary explanatory variable. Demographic variables (like age, gender), clinical variables, and laboratory parameters were considered other study-relevant variables. Descriptive analysis was carried out by mean and standard deviation for quantitative variables, frequency, and proportion for categorical variables. For normally distributed quantitative parameters, the mean values were compared using an independent sample t-test. Categorical outcomes were compared between study groups using the chi-square test. P-value <0.05 was considered statistically significant. The coGuide version V.1.0 was used for statistical analysis.[19]

RESULTS

In our study, the prevalence of delirium among patients with DCLD was 30.63% (34). 94 (84.7%) were males in the study sample, and 17(15.3%) were females. More than half of the study group had been diagnosed with alcohol-induced DCLD 64(57.7%). The majority of patients with DCLD had portal HTN91(82%), ascites 43(38.7%), and oesophagal varices 36 (32.4%) were almost equally distributed in the entire sample. Among111 patients, 71 patients (64%) had a history of alcohol consumption in their lifetime. The number of patients using nicotine in the form of smoking was 48(43.2%), and in the form of tobacco, chewing was noted only in 10 (9%) of patients. Among the patients who had a history of alcohol consumption in their lifetime, around 36 (50%) consumed alcohol within one month before hospital admission. (Table 1)

Patients continued to have sleep disturbance throughout one week of delirium. Sleep disturbances seen were sleep-wake cycle disruption, insomnia, day-night

reversal, and frequent daytime naps. From the fourth day onwards, psychotic symptoms (delusions, perceptual abnormalities, and thought disorder) started

Table 1: Summary of demographic variables and clinical parameters (N=111)

Petameters	Summary
Gender	
Male	94 (84.7%)
Female	17 (15.3%)
Age	53.6 ± 8 years
DCLD subtypes	
DCLDalcohol-induced	64 (57.7%)
DCLD-cryptogenic	15 (13.5%)
DCLD- other types	32 (28.8%)
Manifestations of DCLD	
Portal hypertension	91 (82%)
Ascites	43 (38.7%)
Esophageal varices	36 (32.4%)
Mean total bilirubin	6.58 ± 0.25
Mean SGPT	49.31 ± 5.33
Mean SGOT	84.38 ± 9.45
Mean alkaline phosphatase	133 ± 20.15
Mean proteins total	6.27 ± 0.18
Substance use	
Alcohol	71 (64%)
Nicotine (smoking)	48 (43.2%)
Nicotine (Chewable)	10 (9%)
Last drink of Alcohol consumption (n=71)	
0 to 30 days of admission	36 (50.7%)
between 30 to 90 days of admission	8 (11.2%)
>90 days of admission	27 (38.0%)
SADQ severity of alcohol dependence (no=51)	
Mild	3 (5.8%)
Moderate	28 (54.9%)
Severe	20 (39.2%)
The onset of Delirium (no=34)	
Day 1	23 (67.6%)
Day 2	7 (20.5%)
Day 3	4 (11.7%)
Last drink (N=71)	
<7 days	26 (36.62%)
>7 days	45 (63.38%)

Patients continued to have sleep disturbance throughout one week of delirium. Sleep disturbances seen were sleep-wake cycle disruption, insomnia, day-night reversal, and frequent daytime naps. From the fourth day onwards, psychotic symptoms (delusions, perceptual abnormalities, and thought disorder) started reducing and were absent on the sixth and seventh days. On day 7, patients continued to have the following symptoms; sleep disturbance 9 (100%), motor retardation 4(44.4%). The cognitive deficits which continued were disorientation, inattention, visuospatial deficits, short-term memory loss, and long-term memory loss. (Table 2)

We looked for association with hepatic encephalopathy by considering various parameters like age, gender, the severity of DCLD presentation, alcohol use, and LFT values. We compared these parameters between delirious and non-delirious patients. There were no statistically significant differences between delirious and non-delirious in various parameters like age, gender, the severity of DCLD presentation, and LFT parameters like (SGPT, SGOT, alkaline phosphatase, total protein, GGT) (p-value >0.05) except for bilirubin, which showed statistical significance. (Table 3)

DISCUSSION

In our study, the prevalence of delirium in patients with decompensated liver disease was 30.63%. Among the various causes of decompensated liver disease, alcohol-induced DCLD was seen in most patients (57%). While analyzing the association, none of the factors like age, gender, alcohol, or severity of liver dysfunction was associated with delirium except for bilirubin in DCLD patients.

The mean age of the participants was 53.6±8 years, and 84.7% were males, and 15.3% were females. A study on cirrhotic hepatitis C patients had a mean age of 57.8 ± 7 and 63%, and 37% were males and females, respectively.[20]

Our study was comparable to other studies on cognitive changes in decompensated liver disease (30%-60%) in the prevalence of delirium.[21] Overt hepatic encephalopathy occurs in approximately 30%–45% of cirrhotic patients and 10%–50% of patients with the transjugular intrahepatic portosystemic shunt.[22] Minimal hepatic encephalopathy, characterized by

Table 2: Course of each symptom of delirium in 7days period

SL. No	Day 1	Day 2	Day 3	Day 4	Day 5	Day 6	Day 7

subtle motor and cognitive deficits, affects approximately 20%–60% of patients with liver disease.[8] The true incidence and prevalence of hepatic encephalopathy is difficult to establish because of

Figure 1: Course of Delirium as evaluated by Delirium rating scale (DRS)

considerable differences in the aetiology and severity of hepatic encephalopathy and the varying tools in diagnosing.

Unlike the previously used scales like West-Haven Criteria, PSE-syndrome test (Portosystemic encephalopathy Syndrome Test and Repeatable Battery for the Assessment of Neuropsychological Status (RBANS) test, which detects cognitive changes rather than delirium, we have used RASS and CAM-ICU, which detect delirium due to any cause. Unlike previous scales (which need physicians and psychologists to assess), nursing staff can administer these scales with minimal time and monetary resources.

To the best of our knowledge, this is the first study to look into the breadth of the phenomenology of delirium in patients with DCLD. Our study describes delirium in detail by tracing out and defining 13 of its symptoms over seven days (Table 3). By unfolding how exactly each of these symptoms remitted in a week, this study also portrays the course of delirium.

On meticulously observing the symptoms of delirium, sleep disturbance is present in all patients, and it is present throughout delirium. Sleep disturbance includes sleep-wake cycle disturbance, day-night reversal, nocturnal disturbance only, or frequent daytime naps. Sleep-wake inversion or the combination of restless nights and excessive daytime sleepiness were first described as a sign of overt HE by Sherlock et al.[23] Similar findings were recorded in studies with both insomnia and fragmented sleep with multiple night awakening sin cirrhosis patients.[24]

The next glaring symptom is disorientation, where the person is disoriented to time, place, and person in increasing order of severity. While recovering, the patient first gets oriented to person, and the last thing he gets oriented to is time. Almost 100% of the patient had disorientation on day one. Similar results were shown in studies where almost all participants showed disorientation features.[25] A recent longitudinal study of the phenomenology of delirium showed the prevalence of disorientation in all visits to be 81% with DRS-R-98 and 69% with the cognitive test for delirium (CTD).[13] Another longitudinal study (Fan et al. 2005) has suggested that psychomotor abnormalities and sleep-wake cycle disturbances present mainly in the early course of a delirium.[26] In contrast, disorientation, inattention, impaired memory, and sleep disturbances are present throughout delirium (McCusker et al., 2003).[27]

Another important area in delirium symptoms is cognitive deficits. Cognitive deficits consist of inattention, memory impairment, visuospatial disturbances. The cognitive symptom was one of the persistent symptoms patients had while getting discharged. Studies were done in the past, giving weightage on how to detect delirium in patients with a

subclinical presentation, mainly in cognitive deficits.[9] A study done to assess all-cause delirium's phenomenology using the MDAS scale showed an increased prevalence of perceptual disturbances (e.g., hallucinations) and delusions. In contrast, the present study showed less prevalent symptoms for perceptual disturbances and delusions.[28] The difference may be due to the scales used in both studies and the latter used only for DCLD patients.

Psychotic symptoms experienced were thought disorder, delusions, and perceptual abnormalities. Delusions predominantly seen were persecutory. Perceptual abnormalities ranged from illusions to hallucinations, predominantly auditory. We also found that psychotic symptoms were the first to remit among all the delirium symptoms. More prevalent symptoms such as hallucinations, illusions, and delusions were seen in patients with the activated subtype in a study done by Ross et al.[14]

Delirium was fully remitted in 11 patients within a week, but 14 patients got discharged within seven days while still having some features of delirium. Three of these patients requested discharge for personal reasons, and four patients got discharged against medical advice. The remaining seven patients were discharged from the hospital side when they still had minimal delirious features (like motor retardation and cognitive deficits).

This study also tried to analyze the association of delirium following hepatic encephalopathy with other factors. Age, gender, marital status, socio-economic status, and education did not significantly affect delirium. Moreover, on generally comparing LFT results between delirious and non-delirious patients, patients with delirium showed significantly more deranged bilirubin values. This is also supported by previous studies.[29]

The main strength of our study was that the participants were followed up by a week to assess the course of delirium in decompensated liver disease in detail.

Limitations: We don't have data on patients who had a more extended hospital stay in which delirium could have developed after five days (stopped visiting DCLD patients on the fifth day itself according to our study protocol). We did not consider other parameters associated with delirium, like biochemical parameters (electrolyte, ammonia, arterial blood gas, etc.), cardiac or renal parameters. Also, pharmacotherapy was not assessed, such as benzodiazepines for alcohol withdrawal that could have precipitated encephalopathy in some patients.

Conclusions: We conclude by saying that a significant number of patients having DCLD present with delirium. They present with insomnia, cognitive deficits, motor retardation, and minimal psychotic symptoms. Many patients completely recovered from delirium within a week, but few had delirium for more than one week. No significant association was seen in delirium patients with liver function tests and alcohol consumption except for bilirubin.

ABSTRACT

Background: Specific learning disorder in general called as dyslexia is a neuro developmental disorder, which occurs more commonly in males (Male:Female ratio is 4:1), there are evidence to suggest role of prenatal gonadal hormone exposure in neurodevelopment. However, studies on association between 2nd to 4th digit ratio and dyslexia are mixed. Objective: To compare the 2nd and 4th digit ratio (2D:4D) of both hands between children with dyslexia and children without dyslexia.
Methodology: A case control study, recruited 30 children with dyslexia and 30 age and education matched normal controls, after getting informed consent from their parents. Collected socio demographic details, applied CARS, Schonell's reading and spelling test, followed by detailed evaluation by psychiatrist and clinical psychologist, including psychological testing to confirm the diagnosis of dyslexia. The digit length of index and ring finger on both hands of all children were measured using Vernier Calliper by direct method.
Results: In both the hands 2D:4D ratio was more in children with dyslexia than normal children, but the difference was not significant (p – 0.146). Analysis of only male samples showed digit ratio is higher in dyslexic children than normal children; which were significant (p – 0.03).
Conclusion: Our study does not support an association between digit ratios and dyslexia; however, trend towards higher ratio in dyslexia especially in male children are interesting and needs further exploration. Need more studies in this area to form a definite conclusion.

Keywords: Dyslexia, Specific learning disorder, Digit ratio, 2D:4D, Biomarker.

INTRODUCTION

Dyslexia is a neuro - developmental disorder, Prevalence of dyslexia ranges from 4 % to 17%. The prevalence is higher in males (Male: Female ratio is 4:1),[1]. This suggests there could be some factors that is different in either sex which plays a role in the development of this disorder. The neurobiology of dyslexia remains largely unknown but evidence suggests that neuronal migration and axon guidance pathways may be disrupted in dyslexia [2].

Normal brain is sexually dimorphic, due to the influence of gonadal hormones on neurodevelopment during antenatal period. Aberrations in neurodevelopment due to gonadal hormonal imbalance are one of the mechanisms for developing dyslexia. The relation between imbalance in gonadal hormones and dyslexia is very complex.

The absence of testosterone leads the central nervous system to develop passively, in a primarily female fashion, while the presence of testosterone induces the masculinization of the brain, indicating that the sexual dimorphism of the brain is mediated by the epigenetic action of gonadal steroids [3]. Geschwind and Galaburda suggested that testosterone inhibited the growth of certain areas of the left hemisphere and

facilitated the growth of the same areas in the right hemisphere. As a result, language skills would be negatively affected and hand preference would tend to shift toward the left. In extreme forms, this abnormal cortical development would render an individual incapable of handling effectively the linguistic tasks required for reading and writing [4]. Ramus, based on animal studies demonstrated that rodents with induced ectopias and microgyri exhibit learning deficits. Focal cortical abnormalities in specific areas of left perisylvian cortex are the primary cause of dyslexia. When foetal testosterone exposure is high, cortical disruption propagates to the thalamus, provoking additional sensory impairments as a consequence of the conjunction of high fetal testosterone exposure and ectopias or microgyri [5]. A study showed high prenatal testosterone may impair developing auditory perceptual processes and phonological processing in the left hemisphere. These impairments in phonology in turn can adversely affect development in reading [6].

But it's not possible to measure the prenatal gonadal hormone exposure directly. Hence, we need to evaluate it indirectly using an indicator which could predict gonadal hormones concentration in utero. The digit ratio is the ratio of the lengths of different digits, typically as measured from the basal / proximal crease of the finger to the tip of the finger. Androgen and Estrogen differentially regulate the network of genes that controls condrocyte proliferation, leading to differential growth of digits in males and females [7].

The ratio between the length of the 2nd and 4th digits is: (a) fixed in utero; (b) lower in men than in women; (c) negatively related to testosterone and sperm counts; and (d) positively related to estrogen concentrations [8]. 2D:4D ratio may be used as an indicator and predictive factor in a variety of disorders associated with a disturbed testosterone/estrogen hormone balance like Gender identity disorder, Autism, Dyslexia, Migraine, Stammering, Immune dysfunction, Infertility [8].

The existing literature shows mixed results regarding the relation between digit ratio and dyslexia; there is also ongoing debate whether 2nd digit to 4th digit ratio is a reliable indicator of prenatal gonadal hormones exposure. Few researchers even question the proposed role of gonadal hormones in the development of dyslexia. This is an interesting area and has a wide scope for research. There are many studies on digit ratio in autism, but only very few studies in dyslexia. Hence this study is planned to examine the relationship between 2nd digit to 4th digit ratio and dyslexia. A reliable finding in this area of research would have a very significant clinical implication; this has prompted us to carry out this study.

The objective of the study was to compare the 2^{nd} to 4^{th} digit ratio (2D:4D) of both hands between children with dyslexia and children without dyslexia.

METHODOLOGY

Hypothesis

Children with specific learning disability (Dyslexia) will have smaller 2^{nd} digit to 4^{th} digit ratio compared to children without dyslexia.

Subjects and Procedure

We screened all children aged between 5 and 18 years old, who attended psychiatric outpatient department in PSG institute of medical sciences and research, between May 1st 2014 and July 31st 2014. PSG institute of medical sciences and research is a tertiary care general hospital. A final year MBBS student who got trained in applying Schonell reading test, Schonell spelling test and Childhood Autism Rating Scale administered these tests on all children. All children were evaluated in detail by a psychiatrist; the diagnosis of dyslexia and the type of dyslexia was confirmed only after further psychological testing by the child psychologist. We consecutively recruited 30 children with dyslexia who fulfilled the inclusion and exclusion criteria.

Control group had 30 age and education matched children who visited hospital for non psychiatric problems or were recruited from the community. Control group didn't had any academic difficulties or psychiatric problem according to parents, Schonell reading test, Schonell spelling test and childhood autism rating scale was administered to all children in control group as well, child suspected to have dyslexia or autism were referred to psychiatry for further evaluation.

Children were included in the study after getting informed consent from their parents and only if the child was willing to participate in the study. Children with autism, Asperger's syndrome, mental retardation,

attention deficit hyperactivity disorder, schizophrenia, medical or surgical condition which would interfere with measurement of digit length e.g., contractures, trauma, amputation etc, were excluded from the study. Children who were recruited for the study, the length of their index finger and ring finger (from the basal crease to the tip of the finger) of both the hands is measured using Vernier Calliper by direct method, which is an accurate as well as easy method to measure the digit length [9].
The study was approved by Institutional human ethics committee, PSG institute of medical sciences and research.

Materials

1. **Semi structured proforma:** This Proforma is used to get basic details of the cases and controls. It includes the name, age, sex, education medium, syllabus, socio economic status, height, weight, IQ, co morbidity.
2. **Childhood Autism Rating Scale (CARS):** It is a tool for assessing autism. This is scored based on the interview with the primary care giver and observation of the child. The child is diagnosed as having autism if they score above 30 [10].
3. **Schonell reading test:** A reading test that determines the reading age, however it does not test reading comprehension. The reading age is calculated from the number of words read correctly and compared to the student's chronological age to see if the student is reading at the level for their age, or are reading either below or above level for their age [11].
4. **Schonell spelling test:** A spelling test that determines the spelling age. It comprises of 100 words, and the child is asked to write 30 words (applicable for their class).The spelling age is calculated from the number of words wrote correctly and compared to the student's chronological age to see if the student is writing at the level for their age, or are writing either below or above level for their age [12].

STATISTICAL ANALYSIS

Statistical analysis was done using the Statistical package for social sciences (SPSS) version-18. Continuous variables were assessed using the unpaired t-test and categorical variables were assessed using the chi-square test. P value of less than 0.05 is considered as statistically significant.

RESULTS

Table 1 – Socio-demographic variables

		CASE (N=30)	CONTROL (N=30)	p Value
Age (Mean, SD) in years		11.60 ± 3.328	13.40 ± 2.568	0.092
Education (Mean, SD) in years		6.90 ± 2.998	8.50 ± 2.610	0.470
Sex	**Female**	3	18	0.001
	Male	27	12	
Medium	**English**	28	27	0.640
	Tamil	2	3	
Syllabus	**CBSE**	1	29	0.313
	Samachir	0	30	
SES	**Lower middle**	0	6	0.010
	Upper middle	27	24	
	Upper	3	0	

The mean age of cases and controls were 11.6 years and 13.4 years respectively, the difference in age between the 2 groups was not statistically significant. There is no statistical difference between the 2 groups on other socio demographic profiles like education, medium, syllabus and socioeconomic status. Most of the children

on either group were from upper middle socioeconomic class, studied in English medium and their syllabus was samachir, which is the most popular syllabus in the state of Tamil Nadu, India.
The children with dyslexia were predominantly males (90% of the cases) were as in control group only 40 % were males; this was statistically significant (p = 0.001).

Table 2: 2D:4D ratio between male and female children

Male Vs Female (n-39) (n-21)		t	df	Sig. (2-tailed)	Mean Difference	95% CI of Difference	
						Lower	Upper
Rt hand 2D:4D	Equal variances assumed	-0.761	58	0.450	-0.01239	-0.04498	0.02020
	Equal variances not assumed	-0.674	29.596	0.506	-0.01239	-0.04994	0.02517
Lt hand 2D:4D	Equal variances assumed	-0.761	58	0.450	-0.01239	-0.04498	0.02020
	Equal variances not assumed	-0.674	29.596	0.506	-0.01239	-0.04994	0.02517

Taken all 60 children together and divided them into 2 groups based on sex, male children had lower 2nd to 4th digit ratio on either hand when compared to controls, shown in (table 2), but the difference is not significant (p = 0.506).

Table 3: 2D:4D ratio between SLD and control groups

SLD Vs Control (n-30) (n-30)		t	Df	Sig. (2-tailed)	Mean Difference	95% CI of Difference	
						Lower	Upper
Rt hand 2D:4D	Equal variances assumed	1.490	58	0.142	0.02283	-0.00784	0.05349
	Equal variances not assumed	1.490	33.222	0.146	0.02283	-0.00833	0.05398
Lt hand 2D:4D	Equal variances assumed	1.490	58	0.142	0.02283	-0.00784	0.05349
	Equal variances not assumed	1.490	33.222	0.146	0.02283	-0.00833	0.05398

The comparison of 2nd to 4th digit ratio using independent t test between children with dyslexia and normal children showed that the mean digit ratio on both hands is more in children with dyslexia than normal children, which is in contrary to our hypothesis, however this was not statistically significant (p = 0.146). Our sample predominantly contained children with writing disorder (23/30 children). So, we decided to compare the 2D: 4D ratios between children with writing disorder only and controls.
As shown above in (table 4) the 2nd digit to 4th digit ratio in both right and left hand was higher in children with writing disorder than control group, but this again was not significant (p = 0.134). The sub-analysis comparing children with writing disorder and controls yielded a result similar to dyslexia group in general. Since the number of children with reading and mathematics disorder were very few, it was not possible to do a separate analysis on them. As dyslexia is more common in males and testosterone is expected to play a major role, a separate analysis was done comparing the digit ratio between male children with and without dyslexia.
The 2nd to 4th digit ratio on either hand was higher in male children with dyslexia compared to male children without dyslexia; the difference was statistically significant with a p value of 0.03. This is shown in (table 5).

Table 4: 2D:4D Ratio between dysgraphia children and controls

Dysgraphia Vs Control (n-23) (n-30)		T	Df	Sig. (2-tailed)	Mean Difference	95% CI of Difference	
						Lower	Upper
Rt hand 2D:4D	Equal variances assumed	1.372	51	0.176	0.02404	-0.01115	0.05923
	Equal variances not assumed	1.533	35.936	0.134	0.02404	-0.00776	0.05585
Lt hand 2D:4D	Equal variances assumed	1.372	51	0.176	0.02404	-0.01115	0.05923
	Equal variances not assumed	1.533	35.936	0.134	0.02404	-0.00776	0.05585

Table 5: 2D:4D Ratio in male children

Male children Case Vs Control (n-27) (n-12)		T	Df	Sig. (2-tailed)	Mean Difference	95% CI of Difference

	Equal variances not assumed	2.456	12.001	0.030	0.05263	0.00594	0.09932

DISCUSSION

There are very few studies in this area, to best of our knowledge this is the first study in India looking into the relation between 2nd digit to 4th digit ratio and dyslexia. We have taken 30 children with dyslexia (cases) and 30 normal age and education matched controls. There was a significant difference between the two groups with respect to gender distribution, predominance of male children in dyslexia group could be explained by the general prevalence of dyslexia, which is more common in males (Male: Female ratio is 4:1) and ours being a consecutive sampling.

The current study did not show any difference in the 2nd to 4th digit ratio between children with dyslexia and normal children, neither the right hand comparison nor the left hand comparison between groups showed significant difference, which is in contrast to the observation made by Manning et al 2002 who reported 2nd digit to 4th digit ratio is low in dyslexia compared to Non dyslexic individuals. But our finding is in concurrence with the findings of two other studies, which also reported no association between 2D:4D ratio and dyslexia. A study done in Netherland on children with dyslexia with a phonological deficit showed no evidence for an association between reading disabilities and the 2nd digit to 4th digit ratio, also showed no support for the assumed relation between the 2nd digit to 4th digit ratio and prenatal testosterone[10]. Another study showed digit ratios were sexually dimorphic 'male lower than female' pattern, no difference in digit ratio between dyslexic and normal reading children. Digit ratios were not related to any sensory measure.[11]

The present study showed that 2nd to 4th digit was lower in children without dyslexia than in children with dyslexia, which is contrary to our own hypothesis that 2nd to 4th digit ratio will be low in dyslexic children compared to normal children, and contradicts those studies which shows an association between digit ratio and dyslexia. This finding is difficult to explain by any existing literature on dyslexia and digit ratio. However similar finding was reported in a study on 2nd to 4th digit ratio among 107 individual across all departments and all academic grades, who completed an Internet-based questionnaire on autism or dyslexia in self and family members, the study showed an association between autism and lower 2nd digit to 4th digit ratio, whereas interestingly dyslexia was associated with a higher 2nd to 4th digit ratio in that study [12].

Males had a lower digit ratio compared to females irrespective of being dyslexic or not, points in favour of the concept of sexual dimorphism in digit ratio as suggested by a study [13], however could not agree fully because the difference was not significant.

Some of the theories put forward to explain dyslexia and digit ratio are testosterone theory in the context of cerebral lateralization with testosterone suppressing certain areas in left hemisphere, Extreme male brain theory which suggests excess masculinization of brain leading to dyslexia.

In this study there is no difference in the digit ratio between left hand and right hand nor there do any association of digit ratio in either of this hand and dyslexia. Comparison of only male samples between groups also revealed a higher ratio in children with dyslexia than normal children; this was significant ($p = 0.03$). These findings are in contrast to theories explaining dyslexia and digit ratio.

Our finding does not support an association between digit ratio and dyslexia; neither has it supported the cerebral lateralization theory or extreme male brain theory. The reasons could be digit ratio depends on the production of testosterone and sensitivity of digits to foetal testosterone, which can vary across different ethnic groups, this can explain why there is no difference in digit ratio between groups but this can't explain the reason for lower ratio in controls.

May be there is no real association between dyslexia and digit ratio as supported by studies, 2nd to 4th digit length may not be an indicator of prenatal gonadal hormone exposure 14 and most of the studies supporting the association has not directly compared dyslexia with normal children, it was either done on children with family history of dyslexia or comparing individuals in different academic fields [12]. So, findings in these studies could be influenced by some confounding factors.

Strength of the study

The sample in our study is homogenous and it's a direct comparison between children with dyslexia and without dyslexia. We recruited the children consecutively so any bias in sampling is avoided. Exclusion of comorbid condition like autism, Asperger's syndrome etc which could have confounded the findings if present, as studies also show an association between these disorders and digit ratio.15 All children in dyslexia group were evaluated in detail by a psychiatrist and clinical child psychologist. Using direct method to measure digit ratio by Vernier Calliper, which is an accurate as well as easy method to measure digit length.

Limitations of the study

The findings of this study should be interpreted with caution because of small sample size, possibility of type II error could not be ruled out. The investigator was not blind to the diagnosis, however any bias in measurement was unlikely as the results contradicts our own hypothesis. Measurement was done by a single investigator; having 2 or 3 persons to measure the digit could have added more reliability and validity to the findings. Controls were recruited based on the parents report on their children's academic performance, physical and mental status, not evaluated by psychiatrist or clinical psychologist, it's possible that children with subtle psychological disturbance are missed and mistakenly recruited as normal controls. Despite all these limitations, the finding of this study is unique and cannot be dismissed.

CONCLUSION

This study does not support the association of 2nd digit to 4th digit ratio and dyslexia; neither do the theories put forward to support such an association. However, this study has certain limitations, we need more studies in this area with a larger sample size to overcome above limitations and form a definite conclusion.

The finding children with dyslexia having a higher digit ratio than controls especially in male samples are interesting and needs further exploration.

ABSTRACT

Background: Insight is awareness of one's symptoms, illness, and need for treatment. In bipolar disorder, insight is better in bipolar depression and nonpsychotic depression when compared with mania and psychotic depression. Insight impacts on medication adherence. In our study, we measured and compared with various clinical parameters of insight. The aim of this study is to assess various dimensions of insight recovery prospectively in bipolar affective disorder patients with treatment and drug compliance. **Materials and Methods:** Patient's insight was assessed using Mood Disorder Insight Scale (MDIS) at baseline, 1st, 3rd, and 6th months. Their insight was then compared with various sociodemographic profiles and correlated with number of mood episodes, family history of mental illness, and 6-month MDIS scores. **Results:** Depression patients scored better in insight components ($P = 0.001$). The good compliance group attributed their symptoms to their illness than the poor compliance group ($P = 0.013$). The MDIS scores were gradually improving from baseline to 6 months ($P \leq 0.001$). There was no relationship between insight and the number of episodes ($P = 0.788$). **Conclusion:** Depressive episode patients had better insight during the baseline, which improved during 6 months follow-up compared with manic patients. Among various components of insight, insight on the attribution of symptoms was a predictor of good compliance. Progression of insight was steady and proportionate to the duration of treatment in depressive episode patients.

Keywords: Bipolar affective disorder, depression, insight, mania

The bipolar affective disorder is common and disabling disorder and is associated with considerable morbidity.[1] It is a mood disorder that is characterized by episodes of depression, mania, hypomania, and mixed episodes, with a period of inter-episodic recovery. The World Health Organization estimated that bipolar disorder was the 46th greatest cause of disability and mortality in the world among 291 diseases and causes of injuries. Insight is defined as the awareness of one's illness, the ability to recognize the symptoms of the illness and the need for treatment. Insight of a patient can be categorized into absent insight, partial insight, and full insight.[2-5]

Insight is being highlighted as state-dependent component in a few studies. In disorder like bipolar affective illness, impairment in insight fully resolves. There are few studies which highlight that insight does not resolve completely even in the euthymic state. The more the number of episodes especially manic episodes, the lesser is the insight recovery. However, psychotic depression is associated with less insight than nonpsychotic depression. Insight continues to be poor in chronic illness like schizophrenia. Nowadays, more attention has been given to insight of the patient toward mental illness. There are many

studies, which were being done which evaluated the relationship between insight and course and outcome of the illness, compliance to medications and the severity of psychopathology. The prevalence of good insight in remitted bipolar affective disorder patients is only 47%.[6] In another study, the prevalence of absent insight was 39.09% in the schizophrenia group, 36.36% in the bipolar disorder with psychotic symptoms and 9.37% in bipolar disorder without psychotic symptoms.[7]

The bipolar affective disorder is usually associated with noncompliance and poor outcome.[8,9] Insight and quality of life, cognitive functions, psychotic symptoms, and the number of episodes in mood disorders are interrelated.[10] Many studies have shown that insight is impaired in the acute phase of illness and insight improves as the patient improves symptomatically. Insight was more impaired during manic episodes when compared with depression.[11] Lack of insight in mania was present for all three components of insight-awareness of illness, social consequences of illness, and therapy benefits.[12] A study has showed that insight of bipolar affective disorder patients and schizophrenia patients were the same during admission. At 6 month follow-up, there was a large difference between both the groups. Bipolar disorder patients had better insight when compared with schizophrenia patients.[13]

Adherence to medications plays a key role in the effectiveness of any treatment. Research on the relationship between insight and adherence to treatment is important because adherence to medication can be modified. Meta-analysis that was done to study the relationship between insight and treatment compliance showed poor insight was associated with poor adherence to medications, which was similar to the literature on schizophrenia patients.[14] Studies on schizophrenia patients showed that patients with more insight have a better long-term outcomes.[15] There are similar researches in bipolar disorder, which showed improvement of insight from baseline and follow-up was related to better outcomes of illness and quality of life.[16]

Various scales are available for the assessment of insight. However, most of the scales were validated to measure insight in psychotic illness. Mood Disorder Insight Scale (MDIS) is a short and self-report instrument, includes all the components of insight and it is specifically modified for affective disorder patients. The MDIS was derived from the insight Scale for psychosis which was developed by Birchwood *et al.*, 1994. This scale measures three aspects of insight-awareness of mental disorder, attribution of symptoms, and need for treatment. Hence, we used this scale, which specifically measures insight in bipolar affective disorder in our study.

Most of the studies on insight were done in schizophrenia patients. Very few studies were done on bipolar disorder patients. There are only very few studies which have studied insight in various phases of illness. In disorder like bipolar affective illness impairment in insight fully resolves. The more the number of episodes especially manic episodes, the lesser is the insight recovery. Insight continues to be poor in chronic illness like schizophrenia.

An earlier study reported a 94% prevalence of impaired insight in symptomatic patients in various psychiatric illness such as depression, manic, and bipolar I patients. The prevalence of insight in remitted patients is 47%.[6]

A prospective study on insight in various phases of bipolar illness, observed that insight was impaired in mania when compared with the euthymic state. Insight was better in patients who had single episode of mania or depression; this insight was similar to preepisode insight. However, patients with multiple episodes of illness in 2 years had poorer insight when compared with insight of patients with less number of episodes.[7,17,18]

Very limited number of studies had compared insight with sociodemographic and clinical variables such as age, educational status, gender, marital status, and family history of mental illness. Most of the studies that have been done in insight are cross-sectional study. There are very few prospective studies on insight in bipolar disorder patients.

Therefore, the aim of this study is to assess insight recovery in bipolar affective disorder patients admitted in the psychiatry ward. We also assessed the correlation of insight about awareness of illness, attribution of symptoms to illness and insight recovery with various phases of bipolar affective illness.

MATERIALS AND METHODS

Participants and procedures

This is a prospective study. Participants of our study were both male and female gender for >12 years. These patients were admitted and were undergoing in-patient treatment in PSG Hospitals, a 2000-bedded tertiary hospital at Coimbatore, for Bipolar affective disorder either in depression or manic phase. These patients were admitted between the period of April 2016 and 2017. The participants were diagnosed with bipolar affective disorder using the International Statistical Classification of Diseases (ICD-10) criteria by the treating consultant. Patients having comorbid mental retardation and other Axis 1 psychiatric disorder except nicotine dependence, patients who did not respond for at least three telephonic calls in

[Downloaded free from http://www.industrialpsychiatry.org on Tuesday, March 16, 2021, IP: 59.92.30.139]

the follow-up and patients <12 years old were excluded from our study.

We recruited 50 consecutive in-patient bipolar affective disorder patients based on the ICD-10 criteria. Nine patients were excluded as per the exclusion criteria. Five of them had follow-up elsewhere, two patients did not give consent and two patients had mental retardation. Informed consent in the local language (Tamil) was obtained from primary caregiver for those patients who were not able to give consent. Once the patient became euthymic informed consent was obtained from the patient as well. The personal identification data such as name, age, gender, educational qualifications, and socioeconomic data of all the participants were recorded. Data related to psychiatry illness such as the number of past episodes and family history of mental illness was also recorded.

Once the patient got admitted, the severity of the present episode was measured using rating scales. The severity of affective symptoms was assessed by the Youngs Mania Rating Scale (YMRS) and Hamilton Depression Rating Scale (HAMD) for mania and depression, respectively. Baseline Insight was assessed using MDIS. Then, the patient was treated according to their clinical diagnosis by the consulting psychiatrist. One month after discharge, the insight was assessed using the MDIS scale and recorded. Then again, at the 3rd and 6th months of follow-up insight was measured using MDIS. The total scores of insight were calculated at baseline, 1st month, 3rd month, and 6th month and compared for improvement in insight.

Drug compliance was assessed clinically from the patient and reliable informant. During follow-up, the course of the illness was assessed, and the escalation of the dose of psychotropics or addition of a new psychotropic medication is also assessed. Patients who missed the follow-up are contacted through telephonic calls, encouraged to attend outpatient department and Insight assessed. Patients who did not respond for at least three telephonic calls were considered as dropouts [Figure 1]. The study was approved by the Institute Human Ethics committee of PSG IMSR and Hospital.

Assessment

Data were collected using the following instruments.

Semi-structured pro forma

The sociodemographic profile of the patient, details of substance use, diagnosis, and clinical details (compliance of medications, the severity of illness using YMRS and HAMD scales, number of past episodes, and family history of psychiatry illness) were assessed.

Mood Disorder Insight Scale

MDIS is a short and self-report instrument. This scale has eight questions which are read by the interviewer and the patient is asked whether their response is agree, disagree, or unsure for each of the eight items in the questionnaire. Depending on the response, the scores are calculated. The total score is 16. The MDIS was derived from the Insight Scale for psychosis, which was developed by Birchwood. This scale has good test–retest reliability and internal consistency. The test–retest reliability (coefficient alpha) of the MDIS was 0.95 ($P < 0.01$). This scale for insight includes all the components of insight and it is specifically modified for affective disorder patients. The administration of this scale does not require any special training as this is a self-report questionnaire. This scale measures three aspects of insight-awareness of mental disorder, attribution of symptoms, and need for treatment.

Data analysis

Data were entered into MS Excel and analyzed using SPSS version 20. Qualitative data were summarized as frequencies and percentages. Quantitative data were checked for normality. Normally distributed data were summarized using mean and standard deviation. Nonnormally distributed data were summarized using Median and inter-quartile range. Association between qualitative variables was tested using Chi-square test. Mann–Whitney U test was used to compare the distribution of MDIS scores by level of compliance and phase of disease; mania or depression. Friedman's test was used to check if the MDIS scores changed significantly with time. Correlation between the YMRS score and MDIS at baseline was tested using the Spearman rank correlation test. Statistical significance was interpreted using an arbitrary cut-off of $P = 0.05$.

RESULTS

Descriptive statistics for the study variables and demographics data are shown in Table 1.

The number of episodes ranged from 2 to 7. Fifteen patients had psychotic symptoms in their mood episodes and twenty-six patients had no psychotic symptoms. Family history of psychiatry illness was present in 26.8% ($n = 11$) and absent in remaining 73.2% ($n = 30$). Twenty-three patients (56.1%) of the participants had good compliance and the remaining 43.9% ($n = 18$) had poor compliance [Table 2].

The insight scores between different age group were compared, the *P* value was not statistically significant ($P = 0.318$). The insight scores, according to educational status, were not

[Downloaded free from http://www.industrialpsychiatry.org on Tuesday, March 16, 2021, IP: 59.92.30.139]

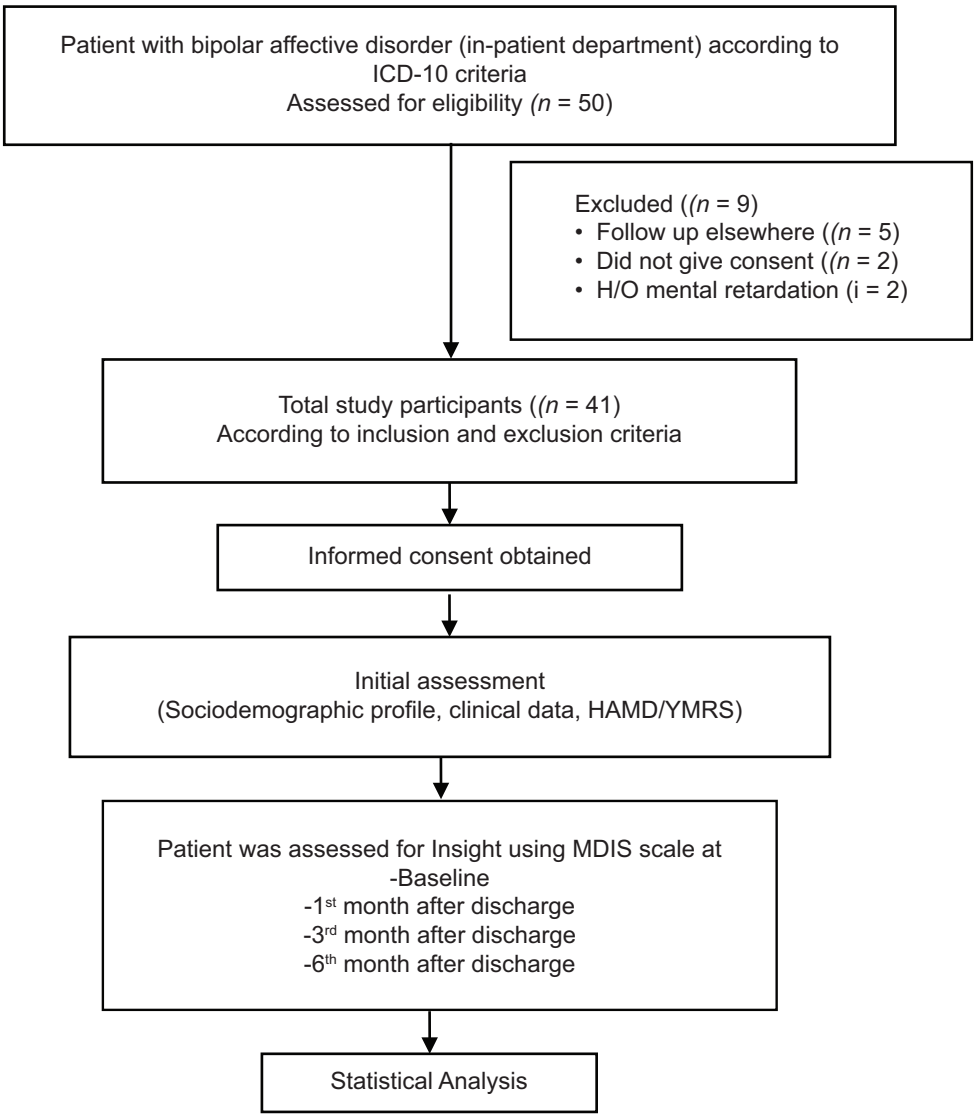

Figure 1: Flow chart

statistically significant ($P = 0.75$). Insight scores did not differ statistically between males and females, P value was 0.552. Insight scores of participants who had family history of mental illness were compared with participants who did not have family history of mental illness also did not have any statistical significance ($P = 0.124$) [Table 2].

The overall scores of the MDIS scale were compared between mania and depression groups, depression patients scored more when compared with manic patients in the insight scale. The more the MDIS score, the better the insight. The P value was also significant $P = 0.001$ [Table 3].

The total scores of MDIS between good compliance and poor compliance group were statistically significant, P value was 0.012. Good compliance group scored better in insight scale than the poor compliance group [Table 4].

In our study, we assessed for the insight score of the participants at baseline, 1st month, 3rd month and 6th month. When these scores were compared from baseline to the end of 6 months, we found that the insight scores were gradually improving. This was statistically significant and P value was < 0.001 [Table 5].

Figure 2 shows the MDIS scores at baseline, 1st month, 3rd month, and 6th month in depressive patients. The MDIS scores of the depressive patient were higher when compared with manic patients. This shows that depressive patients have more insight than manic patients. Figure 3 shows the MDIS scores at baseline, 1st month, 3rd month, and 6th month in manic patients. The MDIS scores of the manic patient were lower when compared with depressive patients indicating manic patients have less insight about illness than depressive patients.

MDIS - Mood disorder insight scale

In Figure 4, MDIS scores were plotted against the period of assessment. The MDIS scores have an increasing trend from baseline to 6 months in the depression group. The progression of insight reached a plateau after 3 months for manic patients.

The number of episodes of illness was compared with MDIS scores. The *P* value was not significant ($P = 0.788$).

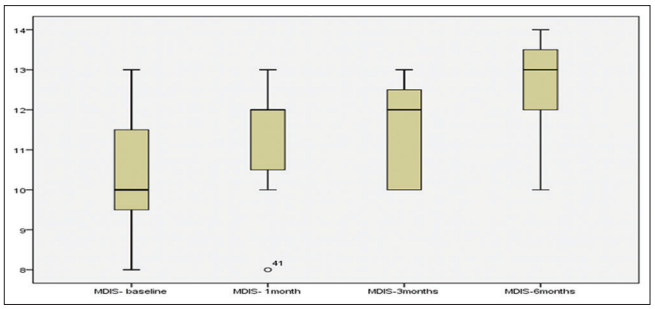

Figure 2: Progression of insight based on Mood Disorder Insight Scale scores at baseline, 1, 3 and 6 months in participants with depression

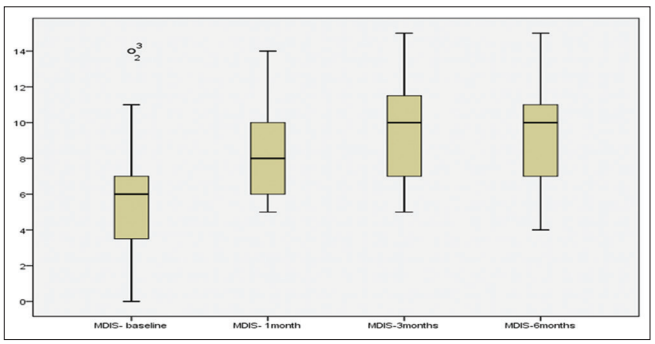

Figure 3: Progression of Mood Disorder Insight Scale from baseline to 6 months in patients with mania

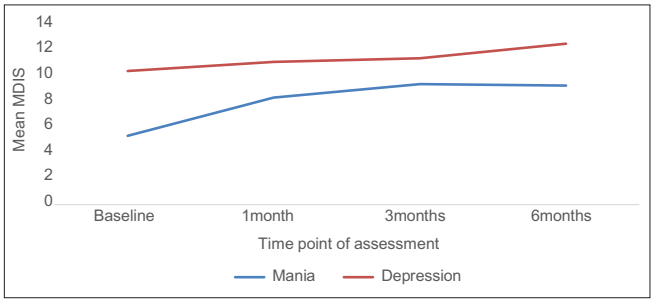

Figure 4: Progression of Mood Disorder Insight Scale from baseline to 6 months in patients with mania and depression

The presence of family history of mental illness was compared with MDIS scores. The *P* value was not significant ($P = 0.701$) [Table 6].

MDIS scores were negatively correlated with both YMRS and HAMD scores, which implies less severe the illness, the better the insight. The correlation with YMRS was statistically significant ($P = 0.003$), whereas with HAMD the correlation was not statistically significant ($P = 0.640$) [Table 7].

DISCUSSION

Insight is a multidimensional and complex phenomenon (Amador *et al.*, 1993). We compared sociodemographic profile (name, age, gender, educational

qualifications, and socioeconomic data) of the participants with MDIS scores. There was no difference in insight between different groups.

In this study, insight scores were lower in females than males ($P = 0.08$), but the P value was not significant. The insight scores were compared with different educational status groups. There was no statistically significant ($P = 0.75$) difference within these groups. On the contrary to our understanding insight did not differ according to the educational status in our study. To our knowledge, no other studies on insight had compared the relationship between educational status and marital status.

Insight scores of participants who had family history of mental illness were compared with participants who did not have family history of mental illness. Though the scores of the participants who had family history of mental illness were higher than the other group, it was not statistically significant.

The overall MDIS scores, when compared between mania and depression groups, showed that depressive patients scored more when compared with manic patients in the insight scale ($P = 0.001$). The individual dimensions of scale were also better among depression than mania, which was statistically significant. Another study which was done to evaluate insight in mania, depression and euthymia in 95 bipolar affective disorder patients showed poor insight among mania patients when compared with depressive patients.[19] The P value was significant 0.001.

Twenty-three patients that is 56.1% of the participants had good compliance and the remaining 43.9% ($n = 18$) had poor compliance. Compliance is a very important part to consider in illness like bipolar affective disorder. Literature on the prevalence of nonadherence also had similar values. The median prevalence of nonadherence is 44.7% in

[Downloaded free from http://www.industrialpsychiatry.org on Tuesday, March 16, 2021, IP: 59.92.30.139]

patients with bipolar affective disorder.[19] In one study that was done to assess the predictors of nonadherence in bipolar affective disorder patients showed treatment nonadherent individuals had more negative attitudes toward medications and reduced insight into illness when compared with treatment adherent individuals.[20] We also compared the MDIS scores between good compliance and poor compliance group. The total scores of MDIS between good compliance and poor compliance group were statistically significant and *P* value was 0.012. Yen *et al.* study[21] showed insight about illness and treatment was positively correlating with adherence to medication in the bipolar affective disorder group and schizophrenia group. So interventions, which concentrated on building insight play a vital role in ensuring good compliance among bipolar patients.

In our study, we assessed for the insight score of the participants at baseline, 1st month, 3rd month, and 6th month. When these scores were compared from baseline to 6 months, we found that the insight scores were gradually improving. This was statistically significant and *P* value was < 0.001. In another prospective study which evaluated the correlation of insight in 65 bipolar disorder patients for 2 years showed insight of the manic patients gradually improved as they returned to the euthymic state.[21]

The average number of episodes in our study among the participants was two. The number of episodes ranged from 2 to 7. In our study, the number of episodes did not make any significant difference in insight of the participants ($P = 0.788$). Similar findings were seen in Cassidy study; on the contrary, showed more the number of episodes, poorer the insight.[22]

Limitations

The sample size is very small in our study, and hence the results cannot be generalized. The initial assessment of insight was not assessed on specifically on the same day after admission for all patients. The treating consultant psychiatrist made a diagnosis of bipolar affective disorder. No separate research diagnostic criteria were used to recruit our patients. With the help of insight scale we have assessed whether the patient is aware of their symptoms in general but have not analyzed about the awareness of individual symptoms. MDIS scale gives only qualitative assessment and not a quantitative assessment.

CONCLUSION

Depressive episode patients had better insight during the baseline, which improved during 6 months follow-up compared with manic episode patients. Among various components of Insight, insight on the attribution of symptoms was a predictor of good compliance during 6 months follow-up than the awareness of mental disorder or need for treatment. Progression of insight was steady and proportionate to the duration of treatment in depressive episode patients. More severe the manic episode poorer was the insight.

Geriatric psychosis

ABSTRACT

Objective: Schizophrenia and related psychotic disorders are predominantly studied in young population. However some individuals do develop psychotic disorder for the first time during their old age. The aim of this study is to look at the clinical characteristics of non-affective, non-organic, late onset psychosis.
Participants and methods: Retrospective chart review study, medical records of all patients registered between 1st of January 2006 and 31st May 2011 at geriatric clinic in NIMHANS, Bangalore was screened, 83 files with a diagnosis of late onset psychosis and meeting the study criteria were systematically analyzed.
Results: The mean age at onset of illness was 67 ± 10 years; 98.8% were married, females formed 67.5% of the sample, commonest phenomenon was delusions followed by hallucinations, 80.5% of the subjects had delusion of persecution, 38.5% had referential delusion, 51.8% had accusative and derogatory auditory hallucinations, negative symptoms was seen only in 2.4% of subjects, none had formal thought disorder. 3.6% had co-morbid Axis II diagnosis.
Conclusion: Despite its rarity non affective, non organic, late onset psychosis forms a distinct group with unique manifestation. Further systematic research is needed for better understanding of this condition.

1. Introduction

Schizophrenia and related Non-Affective psychotic disorders are predominantly studied in adolescence and young adults. However some individuals do develop psychotic disorder for the first time during their old age. Community prevalence estimates for schizophrenia range from 0.1% to 0.5% (Castle and Murray, 1993; Copeland et al., 1992, 1998; Kua, 1992). 1-year prevalence rate of schizophrenia in individuals between ages 45 and 64 is 0.6% (Keith et al., 1991). For individuals over 65 years of age, incidence rate of schizophrenia with first onset after 44 years is 12.6 per 100,000 population per year (Copeland et al., 1998). The Studies on late-onset schizophrenia began with Manfred Bleuler, Late onset schizophrenia constituted 15% of patient whom he examined; 4% of the patients had an onset after 60 (Bleuler, 1943). About 50% of the patients with late-onset schizophrenia had symptoms that were similar to those seen in early onset schizophrenic patients. However he did report certain striking differences; more than 50% of patients had Paraphrenia like symptoms, depressive, anxious, catatonic or confused agitated symptoms, but with less affective flattening (Harris and Jeste, 1988; Jeste et al., 1988, 1995; Mayer et al., 1993; Pearlson et al., 1989; Rabins et al., 1984). Subsequently there are lot of studies on late onset psychosis (LOP), mostly from developed countries of Europe and America, but the research findings in this area is struck with difficulties because neither ICD 10 nor DSM V contain separate codes of diagnosis for 'late onset schizophrenia'; different terms being used to describe a similar illness occurring in old age and using different age cut-off to be called late onset psychosis (LOP) (Howard et al., 2000). But other limitations of existing literature in this field are some studies include patients who had early onset psychosis but grown old, including patients with affective disorder and organic psychosis. Some of these confusions were cleared after The International Late Onset Schizophrenia group came up in the year 2000 with consensus on nomenclature defining Late Onset Schizophrenia and Very Late Onset Schizophrenia like Psychosis. For developing countries like India and China with their large population and increasing geriatric population, late onset psychosis is a major concern. Socio cultural factors like globalization, migration, breaking up of joint families, poorer healthcare facilities etc in developing countries in Asia are certainly different to that of developed countries in Europe and America. There are many

factors that increase the risk of developing psychiatric disorder in elderly like loss of close relatives, social network, previous status in society, sensory functions, functional ability, and health (Skoog, 2008).These psycho socio cultural factors can influence the presentation of individuals with late onset psychosis. Currently there is a paucity of literature on the clinical manifestation of late onset psychosis in Asia especially from India. So the aim of this study is to study the clinical characteristics of non-affective, non-organic, late onset psychosis in an Indian set-up.

2. Methods

2.1. Study design & setting

This is a retrospective chart review study conducted at the Geriatric clinic & Services in National institute of mental health and neuro sciences (NIMHANS) Bangalore, a tertiary care hospital in India, which caters to individuals with psychiatric, neurology and neurosurgery problems. Geriatric clinic is run by a multi disciplinary team which includes psychiatrists, neurologists, neuro psychologists and social workers. All the patients attending geriatric clinic are assessed using a semi structured workup proforma, thorough physical examination, Hindi Mental State Examination scale (HMSE) which is an Indian adaptation of Mini Mental State Examination, Geriatric Depression Scale (GDS), Clinical Dementia Rating Scale (CDR), Neuro Psychiatric Inventory (NPI) and Everyday Abilities Scale for India (EASI). They also undergo basic investigations like complete haemogram with peripheral smear, random blood sugar test, liver function test, renal function test, serum electrolytes and Computerized tomography of brain. Other investigations are done if necessary.

2.2. Study participants

We retrieved and screened medical records of all patients who got registered in the geriatric clinic between 1st of January 2006 and 31st of May 2011. In this study we included medical records of patients diagnosed to have psychosis (Schizophrenia, delusional disorder, acute psychosis, nonspecific psychotic disorder, other psychotic disorder) as per International classification of disease 10th version (ICD-10), who were above 50 years of age at the time of onset of psychosis and those who followed up in geriatric clinic atleast for 3 months. We excluded files of patients whose diagnosis was other than psychosis, who developed psychotic symptoms secondary to affective disorder or substance use or organicity (epilepsy, cerebral tumors etc), dementia, whose age at onset of psychosis was below 50 years, those who had major mental illness in the past and medical records that lacked sufficient data. Finally we selected 83 medical records which satisfied our inclusion and exclusion criteria, these records were analyzed.

This study was approved by NIMHANS Institute ethics committee, written informed consent was not taken as it is a retrospective chart review, and anonymity of all patients was maintained.

2.3. Materials

1. Hindi Mental Status Examination (HMSE) **–** Is an Indian adaptation of *Mini Mental Status Examination* (MMSE) that is being used in epidemiological studies of dementia in India. It contains 23 items which test different components of intellectual capability. The scale has a total score of 31, a score less than 19 is indicative of dementia and warrants a detailed cognitive assessment (Ganguli et al., 1995).

2. Everyday Abilities Scale for India (EASI) –This is brief, reliable and valid scale to assess activities of daily living, with norms, which is appropriate for use in assessing dementia in elderly people in India. This is a 12-item uni-dimensional scale which measures mobility, instrumental and personal care activities, the scale has good internal consistency (Pandav et al., 2002). Each item is scored either 0 or 1, less number of 1 score, in other words lower total scores indicates better functioning.

3. Neuropsychiatric Inventory (NPI) – The purpose of NPI is to obtain information on the presence of psychopathology. The NPI was developed for application to patients with Alzheimer's disease and other dementias, but it may be useful in the assessment of behavioral changes in other conditions aswell. It assesses ten behavioral symptoms including psychotic and affective symptoms and two neurovegetative symptoms. The NPI has been proven to be sensitive to change with treatment, it is available in many languages, has been shown to be valid and reliable in cross-cultural studies (Wood et al., 2000).

4. Geriatric Depression Scale (GDS) – Short version – GDS short version is a 15 item scale.The GDS was found to have a high sensitivity and specificity. The validity and reliability of the tool have been supported through both clinical practice and research. In a validation study comparing the Long and Short Forms of the GDS for self-rating of symptoms of depression, both were successful in differentiating depressed from non-depressed adults with a high correlation (Sheikh and Yesavage, 1986). Scores of 0–4 are considered normal; 5–8 indicate mild depression; 9–11 indicate moderate depression; and 12– 15 indicate severe depression.

2.4. Statistical analysis

Descriptive statistics (frequency, ratio, mean, standard deviation) was used to define the socio demographics and clinical characteristics of the patients. Chi square test and Fisher's exact tests were conducted for to compare the symptomatology between different age groups. Person's correlation test was used to analyze the association between cognitive functions and different variables, with p value of <0.05 considered as significant. The data was analyzed using SPSS version 19.

3. Results

Among the 83 medical records that were reviewed, the mean age of the patient was 69 ± 9 years at the time of initial consultation, and age ranging between 51 and 91 years. The average age at the time of onset of illness was 67 ± 10 years. The mean duration of illness was 2.5 years (SD $\pm$ 2.2 years); 55.4% of the patients were uneducated and 54.2% belonged to low socio economic class.

3.1. Socio demographics and clinical characteristics

The socio demographics and clinical characteristics of the patients are depicted in (Table 1). The sample had female preponderance; with number of females being almost double that of males. Except one person all others were married, most of them followed Hindu religion. Psychosis not otherwise specified (psychosis NOS) was the most common diagnosis in these patients, followed by schizophrenia, delusional disorder and acute and transient psychosis. Interestingly all patients diagnosed with acute and transient psychosis developed illness only at $\geq$60 years. Only 3/83 (3.6%) patients had Axis II disorder (Anankastic personality disorder – 1; Anxious avoidant personality disorder – 1; and Paranoid personality disorder –1) Precipitating factor was noticed in 12% of these patients, with some developing psychosis following a loss of family member, some following hearing or visual impairment etc. Positive family history was found in more than 20% of patients, with nearly 11% of them had either a first or second

Other disorders	1/83	1.2
Co-morbid medical illness	56/83	67.4

SD: Standard deviation, N: total number, Psychosis NOS – Psychosis not otherwise specified.

degree relative with psychosis. Co-morbid medical illness was found in 67.46% of patients; with most common being hypertension followed by Type 2 diabetes mellitus.

3.2. Symptomatology

Delusions and hallucinations dominated their clinical presentation, with acting out behavior secondary to delusions being the commonest reason for bringing the patient for consultation. Thought alienation phenomenon noted in 15.7%, none of the patients reported delusional perception, made phenomenon or somatic passivity. Affective symptoms (sadness, irritability, fear, anxiety, dysphoria and rarely elation) were seen in nearly half of the patients (Table 2**).** Only two patients had negative symptoms, one with apathy, anhedonia, and another patient had asocialization, apathy and anhedonia. One third of patients had verbal/physical aggression and other behavioral disturbance like restlessness, aimless wandering, and disorganization. One third had subjective or objective memory disturbances. No patients had formal thought disorder or expressed any bizarre delusions. Among delusions, delusions of persecution followed by referential delusion were the commonest. 64% of patients had hallucination, out of which half of them had 2nd person auditory hallucination, very few patients had hallucination in other modality (Table 3**).** There was no significant difference in the symptomatology between those with late onset psychosis and very late onset psychoses (where the onset of psychosis was ≥60years) (N = 16 & 67 respectively).

Table 2
Symptomatology.

Symptoms	N = 83 n/N	%
Delusion	73/83	88
Hallucination	53/83	63.9
Thought alienation	13/83	15.7
Made phenomenon	0/83	0

Pseudo hallucination	1/83	1.2

3.3. Cognitive function and activities of daily living

Although one third of the patients had some memory disturbances, their cognitive functions and their ability to function independently remained largely intact (Table 4**)**, with mean HMSE and EASI scores being 24.5 ± 4.9 & 2.3 ± 2.8 respectively. Most patients had an EASI score of 0 indicating they were functioning independently. Cognitive functions were slightly lower in females

Table 4
Cognitive function & Activities of daily living.

	Mean	SD
HMSE (score out of 31)	24.50	±4.9
Female	23.34	±4.4
Male	26.50	±3.5
EASI (score out of 15)	2.3	±2.8
Female	2.5	±2.9
Male	2.1	±2.7

Current age	0.74	
Age at onset of illness	0.67	
Duration of illness	0.83	

HMSE: Hindi Mental Status Examination, EASI: Everyday Abilities. Scale for India, Correlation significant at p* value < 0.05.

compared to males. There is no significant association between cognitive functions and age, age at onset of illness or duration of illness (P values – 0.74; 0.67; 0.83 respectively).

4. Discussion

4.1. Sociodemographics and clinical characteristics

This study evaluated the clinical characteristics of non-affective, non-organic, late onset psychosis in a sample of Indian population seeking care in special clinic. A minimum of 3 month follow up was included as a part of study criteria in order to validate the diagnosis and to allow for any revision after initial consultation. Most participants in this study were above 60 years of age at the time of onset of psychosis, the "age of onset" is defined as a change from a state without psychotic features to a clearly abnormal psychotic state as evidenced by the presence of any of the characteristic symptoms of psychosis according to ICD-10. Female preponderance was noted in overall sample which is comparable to other studies (Castle and Murray, 1993; Harish et al., 1996). Many were uneducated in our sample which could be due to female preponderance and also most of them were from rural background, according to Indian government census in 2001 on literacy rate in India, overall literacy rate works out to be 64.8%, the male literacy rate is 75.3% and that for females is 53.7%, showing a gap of 21.6 percentage points between the sexes at the national level and the gap is more in the rural areas. In our sample almost all were married and had a stable occupation suggesting a good pre-morbid functioning in these patients, in concurrence with other studies done in western countries (Alici-Evcimen et al., 2003; Lacks et al., 2006), the higher marriage rate and fairly good adjustment in occupation may also merely reflect the late onset of illness in this group, this finding good pre-morbid functioning is in contrast to early onset group, with some researchers speculating early onset patients perhaps represents pernicious form of the illness particularly associated with pre-morbid dysfunction (Castle and Howard, 1992; Pearlson et al., 1989). In our study co-morbid Axis II disorder was found only in 3.6% of participants and with only one patient diagnosed to have paranoid personality disorder, our study contradicts other studies which reported as high as 45% of patient with late onset psychosis having paranoid or schizotypal personality (Jeste et al., 1988; Kay and Roth, 1961; Kay et al., 1976). Family history of psychiatric disorder was noted in just over 20% of patients, among which family history of psychosis and mood disorder are 10.8% and 4.8% respectively, family history studies almost all show a familial risk of late-onset schizophrenia lower than that of early onset patients but greater than that of the general population (Howard et al., 1997).

4.2. Symptomatology

In our population delusions and hallucinations are the common symptoms, which are in concordance to other studies (Castle and Howard, 1992; Pearlson et al., 1989) which also reported delusions and hallucinations being common among late onset psychosis. On further analysis of type of delusions we found certain differences when compared to other studies. Though delusion of persecution was the commonest (88%) none of the patients had partition delusion which is in contrast to other studies that reported a high prevalence of this delusion (Howard et al., 1997; Pearlson et al., 1989).In addition only 2.4% had grandiose delusion, whereas other studies reported grandiose delusion in 14%-17% of subjects (Howard et al., 1997; Pearlson et al., 1989).Though accusatory, abusive, 3rd person auditory hallucination and hallucinations in other modalities were noted in our sample, none had running commentary type hallucination which is not in accordance with other studies (Harish et al., 1996; Howard et al., 1997).

In our study negative symptoms was reported in 2.4% of subjects and none had any formal thought disorder which is consistent with an overall lower prevalence of these symptoms in other published reports (Almeida et al., 1995; Howard et al., 1994, 1997; Pearlson et al., 1989). Some affective symptoms was noted in half of these subjects, but they appeared secondary to psychotic symptoms and were not severe enough or lacked associated symptoms that would warrant a diagnosis of mood disorder or schizoaffective disorder. As we all know well even in core schizophrenia it is not uncommon to have depressive or anxiety symptoms, which could in fact be secondary to psychotic symptoms. It is possible to misdiagnose patients with severe depression with psychotic symptoms as late onset psychosis, but in this study we recruited only those patients who followed up for at least 3 months, and we excluded those patients if diagnosis was revised to affective disorder. 3.6% of patients attempted suicide which is a cause for concern, as the intentionality and lethality of such attempts are very high in geriatric population. There was no difference in Symptomatology between sexes. This perhaps suggests that the clinical presentation of late onset schizophrenia is similar in both sexes. Diagnosis wise most patients would fall under the category of Psychosis Not otherwise Specified (Psychosis NOS) as per ICD-10, as our sample is not restricted to schizophrenia.

Memory disturbance either subjective or objective was reported in one third of the subjects despite having a stable cognitive functions and ability to take care of themselves as indicated by HMSE (Mean-24.5) and EASI (Mean-2.3) scores, in our study there was no correlation between cognitive functioning and age, age of onset of illness or duration of illness, this could be because of our strict selection criteria this in turn can validate our initial diagnosis. However it's worth evaluating the longitudinal course of these patients as two of these patients diagnosis was revised to fronto temporal dementia after nearly 1.5 years of follow-up, and there are many studies that suggest late onset psychosis is a prodrome of dementia (Brodaty et al., 1999).

4.3. Strengths

Strengths of this study are it adds to the existing knowledge on late onset psychosis in this part of the world as there is paucity of research in India on this area, relatively large sample size compared to many earlier studies done in west (Jeste et al., 1988, 1995; Pearlson et al., 1989)as well as in India (Harish et al., 1996), stricter diagnostic criteria making the sample more homogenous. We felt compared to late onset psychosis as such (which could be secondary to other cause) non-affective non-organic late onset psychosis forms a distinct group with unique manifestations which warrants further research for better understanding.

4.4. Limitations

Some of the major limitations of this study are its retrospective study design, reliance on medical records to collect details; lack of control groups (like early onset group, late onset group with organic psychosis) that would have helped us to distinguish the clinical features of these groups. One can always question the reliability of determination of symptoms from medical records, as interpretation of psychopathology can vary between individuals, the symptoms which were not mentioned in the medical records were considered as absent, No inter-rater reliability test done, which could have made the data more reliable, and the severity of symptoms could not be assessed. However since we use validated

scales and follow a standard protocol at geriatric clinic in NIMHANS, Bangalore, we hope some of these limitations were reduced.

5. Conclusion

Despite its rarity non affective, non organic, late onset psychosis forms a distinct group and validity of this psychiatry entity is undeniable. Though our study has certain striking similarities with other published research like female preponderance, delusions and hallucinations being the common symptoms, lack of negative symptoms and formal thought disorder, there are subtle variations with respect to the type of delusion and hallucination. Further systematic research is needed for better understanding of phenomenology, epidemiology, biological underpinnings, psychosocial issues, as well as course and outcome of this condition.

Lithium has been used in the treatment of mood disorders but its use is limited for its narrow therapeutic window and renal dys function. We aimed to correlate severity of renal dysfunction with duration of lithium therapy and serum lithium levels. We also analysed patients with Lithium induced renal dysfunction with normal creatinine values, but with abnormal eGFR. **M** **d** We included Bipolar patients who are on atleast 2 years of Lithium therapy & with minimum of 2 serum Creatinine values during treatment, baseline & 6months post-baseline. We recruited 906 patients, only 55 patients qualified for our inclusion criteria. We had 110 creatinine values & we calculated eGFR based on Modification of Diet in Renal Disease study group formula. We correlated duration of lithium therapy, serum lithium levels with average S.Creatinine levels and average eGFR. There was no correlation between duration of lithium treatment with average serum creatinine values (r = -0.17) or average eGFR (r = +0.24).There was no correlation between serum lithium levels with average serum creatinine values (r = -0.04) and average eGFR (r = -0.06).Among 19 patients with high serum creatinine values , almost all except one had Grade 2 renal dysfunction eGFR value Neither the duration of lithium therapy (upto 17 years) , nor serum lithium levels correlated with renal dysfunction. Fifteen percent of patients with normal creatinine levels had early renal dysfunction on eGFR, indicating probably eGFR as an early indicator than creatinine.

Introduction

Lithium has been used in the treatment of mood disorders for several decades. But its use is limited for its narrow therapeutic window and multiple systemic side effects. Various studies were done to find the relationship between the serum lithium levels, duration of therapy, and dosage of lithium carbonate with its clinical responses. Among the available psychotrophics, Lithium remains a key drug especially in maintenance therapy. Lithium needs regular monitoring of serum lithium levels and renal dysfunction because of its narrow therapeutic window, as it is excreted nearly exclusively through the kidneys. The effect on Lithium induced renal dysfunction remains a controversy for more than four decades. Histopathological changes have been demonstrated way back in 1977, concluding chronic renal disease may develop only in patients with renal concentration of lithium reaches toxic level- either periodically or continuously.[1]

The duration of lithium treatment and cumulative dose has been suggested as major determinants of nephrotoxicity, but were only from small case series with

How to cite this article: Syed Ummar Ibrahim, Fathima nasreen jaffar hussain, Jayachandran G, Sureshkumar Ramasamy. A comparative study of effects on working and logical memory in psychiatry patients receiving combined electroconvulsive therapy with pharmacotherapy and pharmacotherapy only. *MedPulse – International Journal of Psychology.* April 2019; 10(1): 01-05. http://www.medpulse.in

multiple methodological issues.[2,3] Previous meta- analysis have shown poor quality, emphasizing the need for large scale studies. [4,5] In the study by Stephen Clos *et al*, no effect was found on rate of eGFR change over time in euthymic BPAD patients on Lithuim maintenance therapy.[6] Lithium causes a modest decline in renal function. However, the available research suggests that ESRD is a very rare complication of long-term lithium treatment, affecting ~1% of patients who have taken lithium for over 15 years.[7] With this above background, we planned for a study aiming for correlation of severity of renal dysfunction with duration of lithium therapy and serum lithium levels. We also did a correlation between socio-demographic variable and severity of renal dysfunction. We also analysed patients with Lithium induced renal dysfunction with normal creatinine values, but with abnormal eGFR.

M□□□□□□□

We included patients with bipolar affective disorder who are on atleast 2 years of Lithium therapy & with minimum of 2 serum Creatinine values during the treatment, one at baseline & atleast one after>= 6 months post-baseline. We excluded patients who were on short duration of lithuim treatment (< 2 years) or who had only one/no serum creatinine value. We also excluded patients who were on not on follow-up at PSG. We retrieved 1296 Serum lithium values of Bipolar affective disorder patients from PSG Hospitals MRD records (2013 – 2017). 522 values were repeat serum lithium values of same patient. Hence 774 patients with all the available lithium values were included. 295 patients excluded , as they were all inpatients and they had another out-patient file. Among the remaining 499 patients, 339 patients were excluded (160 patients were left), as they had one or no serum creatinine value.105 patients were excluded as they did not have serum creatinine values both at baseline and 6months post-baseline. Finally, 55 Patients were analysed for the study. We had 121□creatinine values & we calculated corresponding eGFR based on Modification of Diet in Renal Disease (MDRD) study group formula,[8] eGFR (mL × min^{-1}× [1.73 m^2] $^{-1}$)= 175 × (S_{Cr} standardized [mg × dL^{-1}]) $^{-1.154}$× (age [years])$^{-0.203}$Correction factor: for women × 0.742 for blacks × 1.18 186 x [Plasma Creatinine (µmol/L) x 0.0011312] $^{-1.154}$ x [age (years)] $^{-0.203}$ x [0.742 if female] x [1.212 if black] The following categories of eGFR were considered, as per KDOQI criteria. [9] Grade 1 -> 90 ml/min/1.73 m^2: Grade 2 – 60 to 89 ml/min/1.73 m^2: Grade 3a – 45 to 59 ml/min/1.73 m^2: Grade 3b–30 to 44 ml/min/1.73 m^2: Grade 4– 15 to 29 ml/min/1.73 m^2 : Grade 5–<15 ml/min/1.73 m^2.We analyzed baseline socio-demographic variables , namely, age & sex .We categorized age into adolescence, adults & geriatric population. We also analysed the co-morbidities, duration of follow-up after initiation of study, serum Lithium Level, total serum Creatinine values & total eGFR values. We correlated duration of lithium therapy with patients average S.Creatinine levels and average eGFR. We also correlated serum lithium levels with patients average S.Creatinine levels and average eGFR. We compared patient's serum creatinine level and the corresponding eGFR. We analysed patients having normal serum creatinine (<=1 mg/dl) values with patients having abnormal eGFR.

□□□□□□□□□□□□□□□□□□□□□□□□We analysed duration of lithium therapy, serum lithium levels, average serum creatinine levels , eGFR as a continuous measures. We used Pearsons correlation co-efficient to correlate duration of lithium therapy, serum lithium levels with serum creatinine and eGFR. If the r value is +1, it means a positive correlation and if it is1, it means a negative correlation. We also tabulated normal serum creatinine (<=1 mg/dl) values with abnormal eGFR in varying ranges.

□□□□□□□□

Majority of the patients were men & in adult age group. Majority of patients followed upto 5 years & more than two-fifth followed up more than 5 years. Diabetes was the commonest co-morbidity. Six percentage of patients had serum lithium level in toxic range. Seventeen percentage of patients had serum creatinine value more than one. Thirty percentage of patients had eGFR less than 90.

Table 1: Socio-demographic variables at baseline and Lithium parameters

Socio-demographic parameters & Lithium variables			Mean
Age(yrs)	<18	1 (1.8%)	44.93
	18-65	50 (90.9)	
	>65	4 (7.3)

All the patients, except one had Grade 1 renal dysfunction, eGFR between 60 to 98.

□

□□□□□□□□□□

We did a retrospective study on effect of lithium levels and duration of lithium therapy on renal dysfunction. Majority of the recruited were adult men with diabetes as the common co-morbidity. The duration of lithium therapy, did not correlate with renal dysfunction in-terms of serum creatinine values. Three patients were on treatment for more than ten years, one for even seventeen years. The corresponding eGFR values also did not correlate with duration of lithium therapy. Previous studies and meta-analysis also concluded the same result. In the study by Stefan Clos *et al*, both, duration of exposure to lithium and mean serum lithium level were not significant predictors for eGFR decline. Our study also reveals serum lithium level (which is a marker of adequacy of lithium dose), did not correlate with renal dysfunction, either by creatinine levels or eGFR levels. Previous studies have shown that exposure to lithium (in the absence of episodes of toxicity) is a causal factor and the length of lithium exposure as a predictor of renal dysfunction.[10,11] In contrary, our study did not show correlation. A large UK community sample study by Miney *et al*[12] had a short observation period of 2 years and did not analyse longitudinal changes. In our study patients were on lithium, even for 17 years and the mean duration of lithium was five years. In a UK cohort study, Close and colleagues 13 used diagnostic codes for adverse renal outcomes rather than eGFR. We preferred eGFR as an indicator of renal dysfunction as it is a better predictor than serum creatinine. In an observational study by, Aprahamian and colleagues,[14] a single-blind follow-up study , no significant change in renal function of elderly patients after 4 years of chronic low-dose lithium use , as evidenced by our study. About fifteen patients (15 %), with normal creatinine levels had low eGFR values, indicating eGFR could pick-up renal dysfunction early. Among 19 patients with high serum creatinine values, almost all except one had Grade 2 renal dysfunction eGFR value .A single patient had grade 3 renal dysfunction 9 (eGFR –57).Our study limitations are , retrospective study design which has its own critics. The sample size was small and hence results can't be generalized. Mean duration on lithium was five years; a longer study would be of more credit. We could have had a control population, with which we would have analyzed in a better way. Our study was an observational study , hence only the available creatinine & lithium level were used for analysis.Almost one-third of patients had a co-morbid physical illness , disorders like diabetes and hypertension is known to cause renal dysfunction. Cockcroft-Gault equation is well suited for estimation of GFR changes during pharmacotherapy, instead we used MDRD equation, which is applied in adults with chronic renal disease. The National Kidney Foundation grades chronic kidney disease based on kidney damage (for ≥ 3 months, as defined by structural of functional abnormalities of the kidney, with or without decreased GFR, manifest by either : Pathological abnormalities; or markers of kidney damage, including abnormalities in the composition of the blood or urine, or abnormalities in imaging tests) and eGFR. In our study, we used only eGFR as an indicator of renal dysfunction. The strengths of our study are, we had a strict inclusion criteria, thereby excluded patients an acute phase of lithium treatment

(less than two years of treatment). We included patients only with post-baseline creatinine levels, atleast after 6 months, hence had a minimum renal exposure to lithium.

□□□□□□□□□□

In our study, neither the dosage (analysed with serum lithium level), nor the duration of lithium treatment, caused renal dysfunction. Hence, clinicians prescribing lithium need not be anxious on renal parameters, but need to monitor as per guidelines. We would also recommend clinicians to monitor eGFR than creatinine, to identify renal dysfunction early.

Email: side_ummar@yahoo.com

Abstract Bipolar disorder is potentially a lifelong and disabling condition, which requires long-term pharmacological therapy as maintenance treatment. Lithium is considered as first-line mood stabilizer, followed by Divalproate, both are known to reduce the risk of relapse. However, relapses do occur and these medications are also associated with side effects. We aimed to compare the mood stabilizing effect between Lithium and Divalproate in our prospective study. **Methods** 104 bipolar patients who were euthymic (52 patients each on Lithium and Divalproate therapy) were followed up for one year with periodic evaluation done during initial, 3rd, 6th, 9th and 12th month. Time taken to relapse, severity of mood episode, suicidal risk and functioning were assessed using standardized scales. Compliance to medications and adverse effects were also assessed. **Results** The duration of treatment was for a longer period in Lithium group (p=0.001) and this was the only confounding variable which was significant. Patients who are taking Divalproate had more severe manic episode at the end of 1 year when compared to patients taking Lithium (p=0.041). Patients on Lithium also had lesser suicidal risk (trending towards significance). **Conclusion** There was no difference in terms of frequency of depressive episode, adherence, adverse effects and global functioning between the two groups. But Lithium group patients had less frequent and less severe manic episodes and lower suicidal risk, favoring Lithium to be a better mood stabilizer, with less adverse effects and better quality of life.

Key words Bipolar disorder; Mood stabilizer; Maintenance treatment; Quality of life.

Introduction

Bipolar Affective Disorder (BPAD) is one of the most disabling mental illnesses affecting most productive period of life at the age 15-45years.[1] Lithium carbonate has been a gold standard treatment for past five decades. But it has a narrow therapeutic index and significant adverse effects.[2] Anticonvulsants such as Divalproate sodium, Carbamazepine and Oxcarbamazepine, have been proposed as an alternative, also have more adverse effect profile and their comparative efficacy with Lithium is uncertain.[3-8] Lithium Carbonate as a mood stabilizer has been a superior agent to reduce the risk of relapse and to prevent suicidal behaviours.[2-7] In view of its adverse effects, tolerance becomes an issue; which can interfere with adherence.[4-7] Lithium causes multiple skin reactions, the most common are acne and psoriasis. The prevalence of skin reaction with Lithium ranges between 3-34 %. Some studies have shown high chance of discontinuation of Lithium is due to adverse skin reactions.[9] Anticonvulsants approved by FDA, has the next level of

evidence as a mood stabilizer but their long term safety and efficacy in comparison with Lithium remains uncertain[7] Randomised controlled trails have shown superiority of Divalproate sodium to placebo.[10-11] Divalproate sodium has been comparable with Lithium in Manic episode[11] FDA approved mood stabilisers for the treatment of bipolar affective disorder are Lithium, Divalproate sodium, Carbamazepine and Lamotrigine.[17-20] Mood stabilisers can also be used as monotherapy which was approved by FDA.[21-22] Mania with two or more episodes of depression showed a good improvement with Divalproate sodium than Lithium.[23-24] Lithium and Divalproate sodium showed more effect than any other mood stabilisers during acute phase of mania and in maintenance phase.[25-27] Olanzapine, Risperidone and Quetiapine are FDA approved atypical antipsychotics for the acute phase of mania[17,18,20] According to BALANCE study both Lithium monotherapy and combination therapy with Lithium and Divalproate sodium are more likely to prevent relapse than Divalproate sodium monotherapy, irrespective of baseline severity of illness and is maintained for up to 2 years.[12] Bowden *et al*, in his randomized placebo controlled 12 months trial of Lithium v/s Divalproate sodium, has shown no significant difference between the two groups in terms of time to recurrence of mood episode during maintenance therapy. Compared to placebo, Divalproate sodium has lesser discontinuation rate[13.] Even though open labelled trails favours Divalproate sodium in reducing the frequency and intensity of further episodes, there are less comparative study with Lithium in maintenance therapy.[14-16] Long term outcomes are often poor in patients with bipolar disorder despite treatment; therefore more effective treatments are needed to reduce recurrences and morbidity. Hence, we proposed a prospective comparison study of Lithium and Divalproate sodium in euthymic BPAD patients for a period of at least 1year during the maintenance phase. We aimed to compare the mood stabilizing properties of Lithium and Divalproate sodium in BPAD patients. Our other objectives are to evaluate the time taken for relapse of any mood episodes (mania/depression/mixed episodes), assess the severity of the mood episodes, episodes of deliberate self harm, adherence to study treatment, adverse effects of medications and global assessment of functioning.

M

This is a prospective observational study done in patients with bipolar affective disorder who came to the psychiatry department in PSG Institute of Medical Sciences and Research, Coimbatore, India. A total of 104 bipolar affective disorder patients were recruited from out-patient setting. The study protocol was explained to the participants, and a written informed consent was obtained from the patient. If patient could not consent, it was obtained from the family member and later from the patient when he/she could consent. The study was approved by Institutional Human Ethics Committee.

Men and women aged 18 years and above who received a clinical diagnosis of BPAD (as per ICD-10 criteria) in psychiatry out-patient department were eligible for the study. Patients were initiated or continued on a single mood stabilizer either on Lithium or Divalproate sodium. Only patients who achieved remission within 2 months of follow-up were included in the study. Patients who were already on more than one mood stabilizers (Lithium, Valproate, Carbamazepine, Lamotrigine, Gabapentin and Topiramate) during index diagnosis and medically unstable patients with conditions such as renal failure, liver cirrhosis, severe diabetes, arrhythmia etc. were excluded from the study.

After recruiting the patients as per our inclusion and exclusion criteria, 52 patients who were on Lithium therapy and 52 patients who were on Divalproate therapy, were prospectively followed up for 1 year period. Patients were evaluated by the investigator, following 2 months of euthymic period (index evaluation). During follow up patients were evaluated at 3rd, 6th, 9thand 12th month respectively (periodic evaluation). Patients who are missing on follow up are contacted through telephone and requested to come for follow-up and assessed. As it is an observational study, investigators took no role in modifying the dosage of medications, but it was taken care by the primary incharge treating team. During initial evaluation, a semi-structured proforma (socio-demographic details and other confounding variables) is administered. Diagnosis was confirmed by applying a SCID (Structured Clinical Interview for DSM-IV) version for mood disorder. As per earlier literature available, remission is a state that comes close to being symptom free. By which the euthymic status of the patient was ascertained by applying HAM-D and YMRS rating scales. Typically remission should have a score of ≤ 7 on HAM-D and ≤ 2 on YMRS. Severity of suicidal ideas is assessed by Modified SADPERSONS Scale. Global Assessment of Functioning was assessed using a GAF scale. The dosage of the mood stabilizer could be altered by the primary in-charge team based on serum concentration of the drug/adverse effects, during 1 year maintenance period. Participants who remain on the allotted treatment for 1 year of study were periodically evaluated. Use of other psychotropics was allowed during the study trial (antipsychotics, benzodiazepines).Periodic assessment was done as per the figure 1 given below, for confounding variables, SCID-mood disorder sub-scale,

Young Mania Rating Scale (YMRS)/ Hamilton rating scale for Depression (HAM-D) appropriate to the patient (to access the severity of episode if any), Modified SADPERSONS scale-to see suicidal score, adverse drug reaction and Global assessment of functioning (GAF) scale.

Statistical analyses were conducted using software package SPSS version 20. We compared the efficacy of Lithium and Divalproate sodium with the following variables such as age, gender, marital status and education status, which were expressed in percentage and the presence of any statistically significant difference, was analysed using Chi-square test. Also statistically significant difference between the age of onset, number of previous episodes, previous hospitalisation, polarity of previous episodes, psychotropics and duration of mood stabiliser with that of Lithium and Divalproate sodium was done using Chi-square test. Comparison of duration of illness, time taken for any mood episodes, severity of manic episode/depressive episode, suicidal risk, adherence to medications, adverse effects, global assessment functioning between Lithium and Divalproate sodium was done using analysis of variance; p-values <0.05 was considered as significant.

Table 1: Comparison of socio-demographic and confounding variable between Lithium and *Divalproate sodium group*:

Variables		Lithium	Divalproate sodium	p value
Age at recruitment	18- 35 years	31(59.6%)	25(48.1%)	0.392
	36- 59 years	18(34.6%)	21(40.4%)	
	> 60 years	3(5.8%)	6(11.5%)	
Gender	Male	32(61.5%)	39(75.0%)	0.140
	Female	20(38.5%)	13(25.0%)	
Educational status	Illiterate	7(13.5%)	14(26.9%)	0.101
	Up to 10th std	27(51.9%)	20(38.5%)	
	11th-12th	5(9.6%)	10(19.2%)	
	Graduate	13(25.0%)	8(15.4%)	
Marital status	Unmarried	15(28.8%)	11(21.2%)	0.169
	Married, living together	32(61.5%)	26(50.0%)	
	Married, living separately	3(5.8%)	7(13.5%)	
	Married, divorced	1(1.9%)	4(7.7%)	
	Widow/widower	1(1.9%)	4(7.7%)	
Age of onset	< 35 years	19(36.5%)	9(17.3%)	0.085
	36- 59 years	27(51.9%)	36(69.2%)	
	> 60 years	6(11.5%)	7(13.5%)	
Number of episodes	1episode	0(0.0%)	3(5.8%)	0.145
	2episode	18(34.6%)	13(25.0%)	
	>=3episodes	34(65.4%)	36(69.2%)	
Previous hospitalisations	No hospitalisation	7(13.5%)	6(11.5%)	0.594
	1 hospitalisation	9(17.3%)	5(9.6%)	
	2 hospitalisations	15(28.8%)	19(36.5%)	
	>=3hospitalisations	20(38.5%)	22(42.3%)	
Polarity of previous episodes	1 Depressive episode	1(1.9%)	0(0.0%)	0.373
	1 Manic episode	4(7.7%)	6(11.5%)	
	Depression = Mania	18(34.6%)	14(26.9%)	
	Depression > Mania	11(21.2%)	7(13.5%)	
	Mania > Depression	12(23.1%)	12(23.1%)	
	>=2 mania episodes	6(11.5%)	13(25.0%)	
Psychotropics	No drugs	23(44.5%)	13(25.0%)	0.982
	Typical antipsychotics	7(13.5%)	15(28.8%)	
	Atypical antipsychotics	19(36.5%)	21(40.4%)	
	Antidepressants	2(3.8%)	2(3.8%)	
	Benzodiazepines	1(1.9%)	1(1.9%)	
Duration of Mood Stabilizer	<6months	1(1.9%)	0(.0%)	**0.001**
	6months-1year	7(13.5%)	1(1.9%)	
	1- 2years	5(9.6%)	20(38.5%)	
	>2years	39(75.0%)	31(59.6%)	

There was no significant difference between the two groups in socio-demographic variables (Table 1) such as age (p=0.392), gender (p=0.14), educational qualification (p=0.10) and marital status (p=0.17).There is no statistical significance among the confounding variables such as; age of onset (p=0.085), number of episodes (p=0.145), previous hospitalisations (p=0.594), polarity of episodes (p=0.373), psychotropics (p=0.982). Between the two groups, the duration of illness (p=0.001) was the only confounding variable which was significant between the two groups. The number of mood episodes that occurred was; among Lithium group patients 13 had manic episodes and 8 had depressive episodes. Among *Divalproate sodium group* patients 12 had manic episodes and 6 had depressive episodes. In both the groups' manic episodes were more common than depressive episodes.

For a manic episode relapse; in the *Lithium group*, 39 patients had no episodes of mania, 5 patients developed mania in less than three months, 4 patients between three to six months and 4 patients between six to nine months. In the *Divalproate sodium group*, 40 patients had no episodes of mania, 2 patients developed mania in less than three months, 3 patients between three to six months, 3 patients between six to nine months and 4 patients between nine to twelve months. The time taken for manic episode was not statistically significant between Lithium and *Divalproate sodium group* (p=0.339). For a depressive episode to occur; in the *Lithium group*, 45 patients had no episodes of depression, 2 patients developed depression between three to six months, 2 patients between six to nine months and 3 patients between nine to twelve months. In the *Divalproate sodium group*, 46 patients had no episodes of depression, 1 patient developed depression in less than three months, 3 patients between three to six months and 2 patients between nine to twelve months. The time taken for depressive episode was also not statistically significant between Lithium and *Divalproate sodium group* (p=0.240).

Comparison of severity of manic episode between Lithium and *Divalproate sodium group* using YMRS

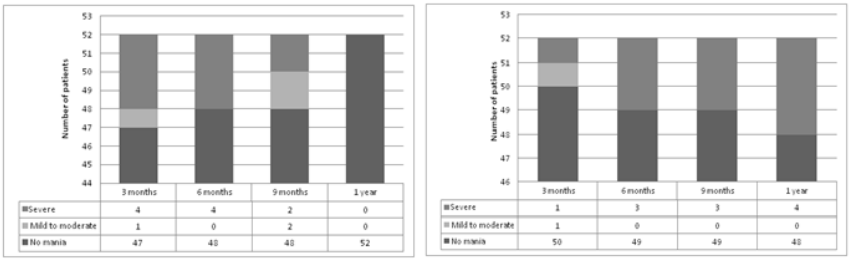

Figure 2A: Figure 2B:

Figure 2 A: Severity of mania in patients taking Lithium; **Figure 2B:** Severity of mania in patients taking Divalproate sodium

The severity of mania was assessed using The Young Mania Rating Scale (YMRS) in Figure2. Patients who are taking Divalproate sodium had more severe manic episode at the end of one year when compared to patients taking Lithium (4 patients v/s none – p=0.041), but the comparison was not significant during initial 3 follow ups at 3, 6 and 9 months (p=0.388, 0.696, 0.331 respectively)

Comparison of severity of depressive episode between Lithium and *Divalproate sodium group* using HDRS:

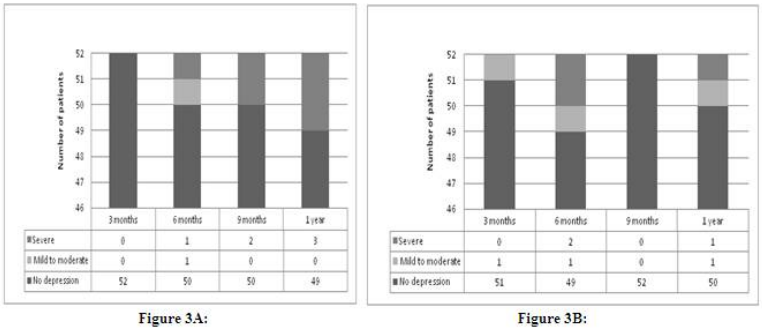

Figure 3A: Figure 3B:

Figure 3A: Severity of depression in patients taking Lithium; **Figure 3B:** Severity of depression in patients taking Divalproate

The severity of depression was assessed using Hamilton Depression Rating Scale (HDRS) in Figure 3. On comparison with patients who are taking Lithium and Divalproate sodium. There was no statistically significant difference in the severity of depressive episode during all four follow ups (3rd, 6th, 9th and 12th month periodic evaluation; p = 0.315, 0.842, 0.153, 0.366 respectively).

Table 2: Suicidal risk assessment between Lithium and *Divalproate sodium group* using Modified SADPERSONS Scale

Groups	No risk	Moderate risk	Severe risk	p Value
		At Baseline		
Lithium	37 (71.2%)	15 (28.8%)	0	
Divalproate sodium	35 (67.3%)	17 (32.7%)	0	0.671
		During *3 months* follow-up		
Lithium	35 (67.3%)	14 (26.9%)	3 (5.8%)	
Divalproate sodium	34 (65.4%)	18 (34.6%)	0	0.173
		During *6 months* follow-up		
Lithium	39(67.3%)	9(26.9%)	4(7.7%)	
Divalproate sodium	34(65.4%)	15(28.8%)	3 (5.8%)	0.371
		During *9 months* follow-up		
Lithium	42(80.8%)	8(15.4%)	2(3.8%)	
Divalproate sodium	40(76.9%)	9(17.3%)	3 (5.8%)	0.857
		During *12 months* follow-up		
Lithium	47(90.4%)	3(5.8%)	2(3.8%)	
Divalproate sodium	38(73.1%)	9(17.3%)	5 (9.6%)	**0.073**

Modified SADPERSONS scale was applied to assess suicidal risk. The severity of suicidal risk scale (Table 2) was not statistically significant during initial and all four follow-ups, but was trending towards significance during the 12th month follow-up (baseline, 3rd, 6th, 9th and 12th month periodic evaluation; p=0.671, 0.173, 0.371, 0.857, 0.0 respectively) In the Lithium group of patients; 4 (7.7%) had no follow-up, 5 (9.6%) have followed-up once, 8 (15.4%) have followed-up twice, 10 (9.2%) have followed-up thrice and 25 (48.1%) have been completely followed-up till the end of one year. In the *Divalproate sodium group* of patients; 5 (9.6%) had no follow-up, 4 (7.7%) have followed-up once, 8 (15.4%) have followed-up twice, 13 (25%) have followed-up thrice and 22 (42.3%) have been completely followed-up till the end of one year. Among 104 recruited patients, 25 patients of Lithium group had completed all four follow-ups as compared to 22 patients of *Divalproate sodium group*. But on comparison between the two groups, they were not statistically significant (p=0.938).

Table 3: Adverse effects of the treatment

Groups	No drug reaction	Minimal reaction	More reaction	p value
		At Baseline		
Lithium	28(53.8%)	24(46.2%)	0	
Divalproate sodium	24(46.2%)	26 (50%)	2(3.8%)	0.303
		During *3rd month*follow-up		
Lithium	23(44.2%)	29(55.8%)	0	
Divalproate sodium	24(46.2%)	23(44.2%)	5(9.6%)	0.057
		During*6th month* follow-up		
Lithium	27(51.9%)	25(48.1%)	0	
Divalproate sodium	26 (50%)	24(46.2%)	2(3.8%)	0.361
		During *9th month* follow-up		
Lithium	30(57.7%)	22(42.3%)	0	
Divalproate sodium	35(67.3%)	16(30.8%)	1(1.9%)	0.312
		During *12th month* follow-up		
Lithium	42(80.8%)	10(19.2%)	0	
Divalproate sodium	39(75.0%)	11(21.2%)	2(3.8%)	0.340

The adverse drug effect (categorised as nausea, diarrhoea, tremors, weight gain, sedation, polydipsia, polyuria, tachycardia, alopecia, any major skin lesions, hypothyroid symptoms, signs of renal dysfunction) profile (Table 3) was the same between Lithium and *Divalproate sodium group* during all four visits except during initial follow up (3months) in which Lithium group was better than *Divalproate sodium group* (five patients on *Divalproate sodium group* had >=3 adverse drug reaction compared to none in the Lithium group), which was statistically significant.

Table 4: Global Assessment Functioning

Groups	Good functioning	Mild impairment	Moderate impairment	Severe impairment	p value
		At *Baseline*			
Lithium	51 (98.1%)	1 (1.9%)	0	0	0.315
Divalproate sodium	52 (100%)	0	0	0	
		During *3rd month* follow-up			
Lithium	46(88.5%)	2(3.8%)	3(5.8%)	1(1.9%)	0.553
Divalproate sodium	49(94.2%)	2(3.8%)	1(1.9%)	0	
		During *6th month* follow-up			
Lithium	46(88.5%)	1(1.9%)	3(5.8%)	2(3.8%)	
Divalproate sodium	46(88.5%)	2(3.8%)	2(3.8%)	2(3.8%)	0.912
		During *9th month* follow-up			
Lithium	46(88.5%)	2(3.8%)	3(5.8%)	1(1.9%)	
Divalproate sodium	49(94.2%)	0	1 (1.9%)	2(3.8%)	0.330
		During *12th month* follow-up			
Lithium	49(94.2%)	0	3(5.8%)	0	
Divalproate sodium	46(88.5%)	0	2(3.8%)	4(7.7%)	0.117

On assessment of social, psychological and occupational functioning by using GAF scale (Table 4). During the initial follow ups Lithium group patients had more functional impairment than *Divalproate sodium group* patients (initial and 3rd follow up). During 6th month follow up two patients in each group had severe impairment. During 9th month and 1year follow up, *Divalproate sodium group* had more severe functional impairment than Lithium group, but was not statistically significant.

□ □□ □□r□□□□□□□□□□ □□ □□d□□□□d□□□ □□□□□r□□□□□r□□ □ □ □□□□□ □□□□□□We also calculated the patients who developed a new manic/depressive episode with varying serum Lithium level. Out of thirteen new episodes manic patients, six had a lower serum Lithium level (<0.8 mEq/L), five patients had serum Lithium level of 0.8-1.2 mEq/L and only two patients had serum Lithium level >1.2mEq/L. Likewise majority of new onset depression episode patient, four out of eight patients had a lower serum Lithium level (<0.8 mEq/L), three patients had serum Lithium level of 0.8-1.2 mEq/L and only one patient had serum Lithium level >1.2mEq/L.□

□ □□ □□r□□□□□□□□□□ □□ □□d□□□□d□□□ □□□□□r□□□□d□□□□□ □□□□ □□□□□r□□□□□□d□□□ □□Among the *Divalproate sodium group* patients, only three out of twelve patients were on adequate dose (more than 1.5gm), had new onset mania. None of the *Divalproate sodium group* patients had new onset depression that is on adequate dose (all six patients who had new onset depression were on sub-therapeutic dose).

□□□□ □ □□□□ □

In our prospective study of one year duration, we compared the mood stabilising effect of Lithium and Divalproate sodium in euthymic bipolar patients. The socio-demographic and confounding variables did not differ between the two groups except that the Lithium group patients had longer duration of treatment than those treated with Divalproate sodium. As a primary outcome of the study, we compared the frequency of manic and depressive episode between two groups. There were similar number of episodes and the predominant mood episode was mania in both the groups. The above finding could also be because the polarity of previous episode in both the groups was predominantly mania. During the period of 9th to12th month follow up, Divalproate sodium had more manic episodes. The above finding emphasises Lithium to be a better long term mood stabiliser than Divalproate sodium. Previous studies have shown that Lithium treatment reduces the risk of relapse in bipolar disorder. The preventive effect is clear for manic episodes, although it is equivocal for depressive episodes.[5] Lithium appears to be the most effective treatment to prevent recurrence or relapse of bipolar disorder and may prolong the time before adjunctive prescribing is necessary.[28] This finding is further supported by the result of recent meta-analysis[29] suggest that Lithium is superior in prevention of manic episodes, in comparison to anticonvulsants. However, there was no significant difference regarding prevention of overall mood episodes, depressive episodes or study completion. Based on the severity of mood episode; patients on Divalproate arm, had more severe manic episodes as the duration of follow up increased. This again emphasises that Lithium is a better anti-manic agent for long-term therapy. But, the frequency and severity of depressive episodes did not differ between both the groups. On comparison of suicidal risk, bipolar patients who were on Lithium had lower suicidal risk than Divalproate patients, especially with prolonged duration of treatment. Both Lithium and *Divalproate sodium group* patients had almost equal follow ups and were equally adherent to

treatment. Two patients on Lithium were switched to Divalproate sodium as they had severe skin reaction which affected the study adherence. Adverse effect profile did not differ during initial and periodic assessment between the two groups. Bipolar patients on Divalproate sodium had more adverse effects during initial follow ups, which were not seen during further follow up. Global assessment of functioning was done considering psychological, social and occupational functioning on a hypothetical continuum of mental-health illness. Patients on *Divalproate sodium group* had more severe impairment in functioning, than patients in Lithium group. The serum Lithium level was less than adequate in majority of new onset manic/depressive episode patients, signifying that majority of the patients who developed new onset manic/depressive episode were on sub therapeutic dose. Further emphasising the relationship between plasma levels of the drug and relapse prevention.

Our sample size was smaller and hence the results cannot be generalised. Telephonic assessments for patients, who missed follow ups, cannot be considered as reliable as face to face interview. Use of other psychotropics (antipsychotics, benzodiazepines) was allowed. We know that medication like Olanzapine, Risperidone and Quetiapine can have a mood stabilising effect, which could have affected the outcome of the study. A follow-up more than 1 year is needed in order to strongly support our finding that, bipolar patients on Lithium were better than Divalproate sodium in preventing the manic episode.

Bipolar patients on Lithium had lesser frequent and less severity of manic episode over one year follow up. The frequency of depressive episode was similar between the Lithium and *Divalproate sodium group*s. Lithium exhibited better anti-suicidal properties. Lithium continues to be a gold standard in spite of certain cutaneous side effects establishing its seven decades of dominance as a mood stabilizer agent. In addition, long-term use of Lithium also ensures better quality of life.

r SU and SA designed this study. SA managed the data collection. SU, SA and KSR analysed the data. KSR wrote the draft of the manuscript under the supervision of SU and SA. All authors contributed to and have approved the the final manuscript.

Background: Lithium is a commonly used drug with a narrow therapeutic index, it has significant adverse effects on kidney and thyroid, and is life threatening during intoxication. Maudsley guidelines on managing bipolar affective disorder patients (BPAD) with lithium recommends checking weight at baseline and every 3rd month, serum lithium after 7th day thereafter 3 months once, renal function test and serum thyroid stimulating hormone (TSH) at baseline and 6 months once. ***Aim:*** To evaluate whether Pre-Lithium workup and monitoring is done in Bipolar affective disorder (BPAD) patients initiated on Lithium as per Maudsley prescribing guidelines in psychiatry. ***Method:*** Retrospective audit conducted in a tertiary care hospital on lithium monitoring in BPAD patients treated with lithium atleast for six months compared against Maudsley prescribing guidelines. ***Results:*** Among medical records of 114 bipolar patients fulfilling study criteria, weight and serum lithium at baseline was checked in 100% of patients; serum creatinine and TSH at baseline along with lithium at 3rd month was done in 83.3%, 78.9% and 68.4% of patients respectively. Maudsley guidelines for serum creatinine, TSH and lithium level at 6th month were met only in 43.8%, 43.8% and 72.8% of patients respectively. ***Conclusion:*** The quality of lithium monitoring in bipolar patients falls well short of accepted standards; Hence addressing the issues in monitoring and following a standard protocol can improve the effectiveness of treatment and quality of life of patients.

Keywords: *Lithium Monitoring, Lithium, Audit, Bipolar Affective Disorder.*

□ipolar affective disorder (BPAD) is a mood disorder characterized by episodes of mania, hypomania and depression and the lifetime prevalence ranges between 0.3% and 4.8%.[1] Bipolar affective disorder is almost always recurrent. Lithium is approved by FDA and commonly used for treating mood disorders. Lithium is a drug with wide therapeutic applications but with a narrow therapeutic index. The accepted serum lithium level for

treating patients is 0.6-1.2 meq/L.[2] Some of the common side effects encountered with lithium are weight gain, sedation, nausea, vomiting, diarrhea, tremors, acne, hair loss, dysphoria, reduced creativity, dysarthria, hypothyroidism, renal disease and during lithium toxicity patients may develop coarse tremor, dysarthria, ataxia, seizures, coma and death. Toxic effects of lithium become more likely as the serum level rises above 1.5 meq/L.[3] But patients can develop lithium toxicity signs at any serum lithium levels depending on their tolerability.[2] Up to 75% of patients treated with lithium experience some side effects.[4] Hypothyroidism occurs in 5% - 35% of patients treated with lithium. It occurs more frequently in women.[5,6] Approximately 10% -20% of patients receiving long term lithium treatment display morphological kidney changes, usually interstitial fibrosis, tubular atrophy and sometimes glomerular sclerosis.[7]

Appropriate baseline assessment prior to lithium treatment will identify patients at significant risk. Also periodic monitoring will help us for early detection of side effects thereby preventing any serious complications. Maudsley prescribing guidelines is one among the various standard guidelines which is accepted widely for monitoring patients on lithium.

The National Institute for Health and Care Excellence (NICE) defines clinical audit as a 'quality improvement process that seeks to improve patient care and outcomes through systematic review of care against explicit criteria and the implementation of change'. By auditing clinical practice against standards derived from evidence-based guidelines, defined aspects of the quality of care delivered to patients can be measured and monitored.[8]For trainees, participation in audit can allow a number of intended learning outcomes to be achieved, these include gaining an understanding of how clinical governance can be applied in practice, and the development of leadership skills related to monitoring performance and effecting change.[9]

Hence we wanted to evaluate whether a standard protocol is being followed in our set up for monitoring patients on lithium treatment.

Aim:

- To evaluate whether Pre-Lithium workup and monitoring is done in Bipolar affective disorder (BPAD) patients initiated on Lithium as per Maudsley prescribing guidelines in psychiatry.

M□□□□□□□□□ M□□□□□□

Study Design & Participants

This was a retrospective study looking at pre lithium workup and lithium monitoring in bipolar affective disorder patients treated with lithium. This study was conducted in a tertiary care medical college hospital in India. We screened medical records of all patients registered in psychiatry department in our hospital between January 2011 and March 2014. We included both out-patients and in-patients aged between 18 years and 65 years, who were

diagnosed to have bipolar affective disorder as per international classification of disease 10th edition (ICD-10).We included only those patients who were started on tablet lithium by the department of psychiatry in our hospital and followed up in our department for at least 6 months duration after initiating lithium.

We excluded patients whose diagnosis is other than bipolar affective disorder and who are not on lithium. We also excluded patients who were already on lithium before visiting our department or patients who were started on lithium by an outside psychiatrist. Among the 451 medical records retrieved with a diagnosis of bipolar affective disorder, 114 patients fulfilled the inclusion and exclusion criteria and were recruited for further analysis. Information were gathered regarding age, gender, primary diagnosis, baseline values of weight, serum creatinine, serum thyroid stimulating hormone level (TSH) and periodic monitoring of serum Lithium, serum creatinine and TSH up to 6 months using a data collection form. In case of any discrepancy regarding the information recorded in the file, it was sorted out after discussion between the authors.

Materials:

Maudsley prescribing guidelines in psychiatry[10] is a standard evidence based and widely accepted guidelines, which provides clinicians with practical and useful advice on prescribing psychotropic agents in commonly encountered clinical situation.

Maudsley guidelines on monitoring patients on lithium recommends checking weight at baseline, 3rd and 6th month, serum lithium to be checked after 7th day of starting lithium or change of dose thereafter every 3 months, estimated glomerular filtration rate (eGFR) and serum thyroid stimulating hormone (TSH) to be done at baseline and 6 months once.

The gathered information was compared with the Maudsley guidelines for identifying whether the baseline work up and periodic monitoring of laboratory values that were carried out during that period was optimal or not. For the purpose of this study we have slightly modified Maudsely guidelines as in instead of eGFR we have chosen serum creatinine levels, as eGFR is not done in our set up.

The study was approved by Institutional human ethics committee.

Statistical analysis*:*

Each of the four outcomes of interest (measures of serum lithium level, serum creatinine, thyroid stimulating hormone and body weight) was measured dichotomously; whether or not the standard had been met. Percentage of people who underwent these assessments was calculated. The data was entered and analyzed using Microsoft Excel worksheet for windows 7.

[illegible]

A total of 114 medical records fulfilling study criteria were identified and reviewed to check whether standard protocol is followed while monitoring patients on lithium.

The mean age of people in our study was 35.3 years (age range: 18 – 62 years) and sample predominantly consisted of male patients (N=41; 65%).

Base line weight was checked in 97.3% of patients, weight at 3rd and 6th month as well as serum lithium at baseline was done in all patients, serum lithium at 3rd month & 6th month was done only in 68.4% & 72.8% of patients respectively, serum creatinine at baseline & at 6th month was checked in 83.3% & 43.8% of patients respectively and serum TSH levels at baseline & at 6th month was done only in 78.9% & 43.8% of patients respectively ([illegible]1).

Table 1: Percentage of people in whom monitoring was carried out as per Maudsley guidelines

[illegible]

Good doctors - Safer patients calls for the reinvigoration of clinical audit to support better patient care and service improvement. The Royal College of Psychiatrists' guidance emphasizes that it is not the direct involvement in data collection that is important, but rather the review of the audit evidence for the quality of care provided, and taking the lead in implementing strategies to improve quality where these are required.[9] Such reflection on the data by clinicians is perhaps the most potent aspect of clinical audit. It is important to note that although audit can generate new knowledge, its primary purpose is to compare practice against pre-determined standards. To our knowledge, this is the first study done in India to audit lithium monitoring practice in BPAD patients receiving lithium. In this study, we selected only those patients who are diagnosed to have bipolar affective disorder, firstly as in these patients lithium is usually started not only for acute management as in 1st episode of mania, but also as a prophylaxis to prevent future episodes wherein lithium is given for long duration. Secondly, recruiting bipolar affective disorder patients alone makes the sample homogenous, where a standard protocol can be followed. For the same reason, patients in extremes of age category were excluded, as these patients may require more frequent assessments and additional investigations.

Though there are various standard guidelines for monitoring patients on lithium, Maudsley practice guideline appears much more simpler, but at the same time evidence based and feasible in our set up, given the fact that health care system especially mental health care in developing countries like India is below compared to developed countries like USA and UK. In our study, we found that weight is checked in 97.3% of patients at baseline and 100% during review which could be explained by the fact that it is easy to check and has been routinely done for all the patients irrespective of the diagnosis, and there is no cost involved. Serum lithium is done for all patients at baseline which is a welcome thing, but subsequently lithium level was not done for more than $1/4^{th}$ of the patients, the reason could be serum lithium at baseline is usually done to adjust the dosage rather than for monitoring side effects. Serum creatinine and TSH at baseline was done in around 80% of patients, but subsequent monitoring of these parameters at 6 month was carried out only in 43.8% of patients. Our study shows quality of lithium monitoring in patients falls well short of accepted standards and targets which could be compared with the similar findings noted in audits done in the west. An audit done in UK on lithium monitoring against recommended standard NICE guidelines in patients recently starting lithium, showed a documented baseline measure of renal or thyroid function in 84% and 82% respectively. For patients prescribed lithium for a year or more, the NICE standards for monitoring lithium serum levels, and renal and thyroid function were met in 30%, 55% and 50% of cases respectively.[11]Despite the existence of explicit standards for monitoring patients who are prescribed lithium, a number of local audits conducted in different areas of the UK over the last 20 years have found this monitoring to be suboptimal.[12,13,14,15]These findings suggest that there is no standard protocol which is being followed in monitoring patients on lithium treatment.

Possible explanation for sub optimal monitoring:

There could be various reasons for this like patient related factors and clinician related factors. Patient related factors:

Previous studies done in western countries have identified certain factors that may influence monitoring rates like willingness of patients to have blood tests and either receiving inadequate information about lithium treatment and the need for regular blood tests or not assimilating the information given,[16,17]Other factors are patient not being compliant to treatment, unaffordability and patient unable to review on time due to personal reasons or simply forgetting to do the test.

Clinician related factors:

Certain clinician related factors that can influence lithium monitoring are clinician unable to spend adequate time with the patient, forgetting to ask for investigation, clinician's perception that patient may not do it; clinicians inadequate knowledge regarding standard protocols for monitoring patients on lithium or despite being aware of standard guidelines clinician may not feel any need to follow the guidelines.

Ours being a tertiary care teaching hospital, where these standard guidelines are often discussed and taught to postgraduate students, the possibility that doctors not being aware of existence of any standard protocol is less likely. But looking at our findings which show a sub optimal standard of monitoring patients on lithium; it appears that theoretical knowledge has not actually translated into clinical practice, which could also be due to various logistic reasons.

Few clinicians may disagree with the recommendations given by Maudsley guidelines, as every patient is different and it is the clinical judgment based on one's own clinical experience that could help in treating these patients, rather than doing serum creatinine and TSH every 6 months. But we should keep in mind, in a country like India where people tend to ignore early symptoms leading to delayed identification of even common medical illness like diabetes; there is always a possibility that one can miss early warning signs of serious adverse effects. Also, given the fact that lithium can cause serious side effects and has a narrow therapeutic index following a standard protocol is worthwhile.

Our findings cannot be generalized to other set up, however one may not be absolutely wrong in assuming that the findings might be similar in other tertiary or non-tertiary care centers in India.

Strengths of the study are the topic itself which needs to be addressed, homogenous sample wherein a standard protocol can be followed, using a simple and feasible guidelines and auditing helps to improve the clinical service provided.

Limitations of the study are the retrospective design of the study itself, relying solely on medical records to collect details (in our study, missing reports and nil documentation were taken as "test not done"), small sample size which is due to strict selection criteria in our study, short term study – however, looking at the findings one can easily assume that the rate of monitoring must be similar or much worse after 1 to 2 years of starting lithium, gathering additional information on patient variables and reasons for asking or not asking an investigation would have given some more insight into issues related to monitoring, and poor documentation in medical records.

Few steps that can be taken to improve the monitoring are discussing with colleagues about the issues in following existing protocols, to formulate own standard protocol which is not only feasible to their setup but also evidence based, attaching such a protocol to the medical records of patients on lithium, insisting on strictly adhering to it and proper documentation.

□

□□□□□□□□□□□□

Lithium is one of the commonly used drugs in psychiatry, which has a wide therapeutic use but can be life threatening at toxic levels and can cause serious side effects if not monitored properly. Despite existence of standard guidelines the monitoring in lithium treated patients is

still at a sub optimal level; hence addressing the issues in monitoring and following a standard protocol can improve the effectiveness of treatment and quality of life of patients.

Managing levels of insomnia in psychiatric patients

Meera Saravanan, Dr. A Jayasudha, Dr. R Sureshkumar, Chinchu S Giju, A Srinidhi, Sri Gayathri and M Tamilselvi

Abstract
Sleep is important in homeostasis, memory, learning and wellbeing. Objectives were to assess the level of insomnia among psychiatric patients, to evaluate the effectiveness of structured teaching programme regarding management of level of insomnia among psychiatric patients and to associate the level of insomnia of psychiatric patients with selected demographic variables. Pre Experimental Design with One group pre-test and post-test design was used. Purposive sampling technique was applied and thirty psychiatric patients were selected. Insomnia severity index tool was used for data collection. Structured teaching programme on management of insomnia for a period of 30 minutes included sleep wave cycle, factors affecting sleep, sleep disturbances and sleep promotion measures. In the pre-test, 46.6% patients have sub threshold, 36.6% have moderate level and 16.7% have severe level of insomnia. In the post-test, 20% patients have no significant insomnia, 60% have sub threshold and 20% have moderate insomnia. Table 4 shows that statistically signified improvement in psychiatric patients after the intervention. The mean and the standard deviation of pre-test level of insomnia is 15.16± 2.78 respectively whereas in the psot-test it was 10.53±2.65 respectively. The t-value was 8.0793 at p>0.001. It shows that structured teaching programme on mangement of level of insomnia was effective to reduce the level of insomnia among psychiatric patients. Thus, there was a statistically significant improvement between pre and post-test level of insomnia among psychiatric patients.

Keywords: sleep, insomnia, structured teaching programme, psychiatric patients.

Introduction
"Sleep is the golden chain that ties health and our bodies together"-Thomas Dekker.
Everyone sleeps! Sleep is familiar to us all, yet still remains a medical mystery. Sleep is a fascinating and the daily experience of every human being. It occupies almost one-third of a person's life and undergoes considerable variation in its pattern as a person grows and matures. Sleep is a state of consciousness, distinct from working, during which we are generally unaware of our bodies and minds.
Sleep is a naturally recurring state of mind, characterized by altered consciousness, relatively inhibiting sensory activity, reduced muscle activity and inhibition of nearly all voluntary muscles during rapid eye movement (REM) sleep and reduced interaction with the surroundings.
Sleep is important in homeostasis, memory, learning and wellbeing. Sleep is essential to survival. It increases in slow wave activity after learning a task have been associated with improved performance of the task. Although the mechanism is not entirely clear, numerous studies support the instrumental role sleep plays in memory consolidation and learning.

Background of the study
Chronic sleep problems affect 50%to 80% of patients in a typical psychiatric practice, compared with 10%to 18% of adults in general US population. (Ford, 2009)
The overall prevalence of symptoms of sleep disorders in the psychiatric outpatients sample was 40.75%.The prevalence of symptoms of narcolepsy, sleep breathing disorder, PLM/RLS, circadian rhythm disorder and parasomnia were 12.5%,14.5%,14.8%,4.5% and 13.8% respectively. (Adhiti Hombali, 2019)
Lack of sleep may lead to a number of problems. Patients who have poor night time sleeps are more likely to have confusion, frustration, depressed mood, attention and memory problems excessive day time sleepiness, more night time falls, and use more over the counter or prescription sleep aids. Disturbed sleep is also associated with a poor quality of life.

Body chronically deprived of sleep is a walking time bomb.17 hours of sustained wakefulness leads to a decreasing performance. Reducing a person's normal sleep time at night by half decreases the activity of T-cells, the cells that destroys bacteria, virus and tumour cells. Better management of sleeping problems in patients can improve these patients health and quality of life.

A study was conducted on promoting rest and sleep with non-pharmacological program was designed to enhance rest and sleep among 250 patients which was implemented in a hospital medical unit. Nursing assistants provided patients with various modalities to improve sleep, including back rubs, warm drinks, blankets warmed in a blanket warmer, aromatherapy, relaxation music, and earplugs. Additional interventions were taken to reduce noise. The outcomes of the study showed 63.45% patients had improved sleep quality and quantity. (Holzinger, Brigitte, 2019).

Effectiveness of sleep management strategies was studied on residents of aged care facilities for the promotion of sleep. Findings suggested that multidisciplinary strategies such as combining a reduction in environmental noise, reduction of night-time nursing care and promotion of daytime activity, were 69% more effective for promoting sleep in the population of interest. Wrist actigraphy was found to be the most accurate objective sleep assessment tool. It was found that lack of sleep, disturbed sleep and the overuse of medications especially sedations reduced the quality of life in older people. Effective safe sleep interventions should be promoted and practiced by nurses. (Matsuda, Risa; Shun, 2019).

A study was conducted on hospitalized patients for the frequency of sleep disruption and daytime function and effectiveness of cognitive behavior therapy and exercise on sleep. There was good evidence supporting the effectiveness of cognitive behavior therapy on sleep. Results of the study showed that exercise improves sleep as effectively as benzodiazepines. (Navarro-Bravo, 2019)

Sleep disturbance is the most common cause of insomnia in psychiatric patients. So, good quality sleep is important to body and mind's ability to renew and refresh. Role of nurse includes preventing the factors that disturbs the sleep and provide environment that is congenial for good sleep. They should provide sufficient information regarding quality of sleep to the patients by sleep promotional measures such as bedtime rituals which help in improving sleep pattern.

Problem Statement: Effectiveness of structured teaching programme on management of level of insomnia among psychiatric patients in a tertiary care Hospital, Coimbatore.

Objectives

- To assess the level of insomnia among psychiatric patients.
- To evaluate the effectiveness of structured teaching programme regarding management of level of insomnia among psychiatric patients.
- To associate the level of insomnia of psychiatric patients with selected demographicvariables.

Methodology

Research design

Pre Experimental Design

One group pre-test and post-test design

⇩

Pre-test (O_1) administration of insomnia severity index to the psychiatric patients

⇩

Intervention (X) administration of structured teaching program on management of level of insomnia

⇩

Post-test (O_2) administration of insomnia severity index to psychiatric patients.

Setting of the study: Psychiatric wards of PSG Hospitals.

Population: Psychiatric patients of both sex with psychiatric disturbance from PSG Hospitals, Coimbatore.

Sampling technique: Purposive sampling technique

Sampling selection criteria

Inclusive criteria

- Those who are cooperative to participate in the study.
- Those have partial/total insight present.
- Those who stay more than a week.
- Both male and females.

Exclusive criteria

- Psychiatric patients who are aggressive.
- Psychiatric patients who are taking sleep medications.

Instrument and tools for data collection

Section-A: Demographic variables : Baseline data information such as name, age, education, religion, occupation and family data like type of family, member of family, income of family of psychiatric patients.

Section-B: Insomnia severity index: Insomnia severity index is a brief self-report instrument measuring the patients perception of both nocturnal and diurnal symptoms of insomnia.

The insomnia severity index has 7 questions. The 7 answers are added up to get a total score. When the patients have total score, should look at the guidelines of scoring/interpretation to check the sleep difficulties.

Scoring

Score	Interpretation
0 – 7	No clinically significant insomnia
8 – 14	Sub threshold insomnia
15 – 21	Moderate insomnia
22 – 28	Severe insomnia

Section-C: Structured teaching programme on management insomnia for a period of 30 minutes. It includes sleep wave cycle, factors affecting sleep, sleep disturbances and sleep promotion measures.

Findings

Tables 1: Frequency and percentage distribution of demographic variables of psychiatric patients n=30

S. No	Demographic variables	Frequency	Percentage (%)
1.	**Age in years**		
	a) Below 40	9	30
	b) Above 40	21	70
2.	**Educational status**		
	a) Illiterate	10	33.33
	b) Higher education	9	30
	c) Graduate	8	26.66
	d) post graduate	3	10
3.	**Occupational status**		
	a) Private	10	33.33
	b) Government	5	16.66
	c) House wife	10	33.33
	d) Business	5	16.66
4.	**Monthly family income**		
	a) 3000	0	0
	b) 4000-6000	11	36.66
	c) 7000-12000	19	63.33
5.	**Type of family**		
	a) Nuclear family	24	80
	b) Joint family	6	20

Table 1 shows the 21 patients (70%) were at the age group of >40 years, 10(33.3%) patients were illiterate 10 patients (33.3%) were working at private sector, 19 patients (63.3%) income were above 10000, 24 patients (80%) belongs to a nuclear family.

Table 2: Assessment of pre-test level of insomnia among psychiatric patients n=30

S. No	Level of sleep disturbance	Pre-test	
		Frequency	Percentage (%)
1.	No significant insomnia	0	0%
2.	Sub threshold insomnia	14	46.6
3.	Moderate insomnia	11	36.7
4.	Severe insomnia	5	16.7

Table 2 revealed with respect that 14 patients (46.6%) have sub threshold insomnia, 11 patients (36.6%) have moderate level of insomnia, 5 patients (16.7%) have severe level of insomnia.

Table 3: Assessment of post level of insomnia among psychiatric patients. n=30

S. No	Level of Insomnia	Post Test	
		Frequency	Percentage (%)
1.	No significant insomnia	6	20
2.	Sub threshold insomnia	18	60
3.	Moderate insomnia	6	20
4.	Severe insomnia	0	0

Table 3 shows that 6 psychiatric patients (20%) have no significant insomnia,18 psychiatric patients(60%) have sub threshold insomnia and 6 psychiatric patients (20%) have moderate insomnia in post-test.

Table 4: Comparison of pre-test and post-test level of insomnia among psychiatric patients n=30

S. No		Mean	S.D	t-value
1.	Pre-test	15.16	2.78	8.0793
2.	Post test	10.53	2.65	

Note: Statistically significant-***p>0.001

Table 4 shows that statistically signified improvement in psychiatric patients after the intervention. The mean and the standard deviation of pre-test level of insomnia is 15.16± 2.78 respectively after providing management of insomnia the level of insomnia is reduced whereas the mean and standard deviation of post-test level of insomnia among psychiatric patients is 10.53±2.65 respectively. The t-value is 8.0793 at p>0.001. It shows that management of insomnia is effective to reduce the level of insomnia among psychiatric patients. Thus, there was a statistically significant improvement between pre and post-test level of insomnia after the management of level of insomnia among psychiatric patients.

Table 5: Association of pre-test level of management of insomnia with selected demographic variables n=30

S. No	Demographic variables	Sub threshold insomnia	Moderate insomnia	Severe insomnia	Calculated value	Tabulated value
1.	**Age in years**					
	a. Below 40	3	4	2	0.2380	3.841 **NS**
	b. Above 40	11	7	3		
2.	**Educational status**					
	a. Illiterate	6	3	1	2.454	7.815 **NS**
	b. Higher education	4	3	2		
	c. Graduate	3	4	1		
	d. post graduate	1	1	1		
3.	**Occupational status**					
	a. Private	3	2	2	4.5359	7.815 **NS**
	b. Government	3	3	1		
	c. House wife	3	3	3		
	d. Business	4	1	2		
4.	**Monthly family income**					
	a. 3000	0	0	0	3.394	5.991 **NS**
	b. 4000-6000	9	2	0		
	c. 7000-12000	5	9	5		
5.	**Type of family**					
	a. Nuclear family	12	8	4	0.035	3.841 **NS**
	b. Joint family	2	3	1		

Note:**p< 0.005, S-significant, NS-Non significant

Table 5 shows that there is no significant association between insomnia and selected demographic variables like age, education, occupation, income and type of family.

Nursing implications

Nursing Education

- Nursing students should explore more on various approaches in management of insomnia.
- Conferences, workshops, seminar and symposium can be held for all health personnel in bringing about behavioural changes among psychiatric patients towards sleep hygiene.
- In-Service education can be given to the staff nurses and faculty members regarding management of level of insomnia in order to improve the good sleeping pattern among psychiatric patients.

Nursing practice

- The nurses working in the health services should be equipped with the knowledge on management of level of insomnia.
- Planned structured teaching programmes on management of level of insomnia to be scheduled for health care workers.
- Pamphlets can be provided with appropriate pictures and explanations to improve sleeping pattern.

Nursing Administration

- Advanced clinical nursing should focus on normal sleeping pattern for patients in any ward setting in hospital
- The administrator shall initiate educating the psychiatric patients and family members about sleep hygiene.
- Promote awareness about management of insomnia to public

Nursing Research

Nurse researchers can do similar study on patients with medical illnesses

Recommendations

- Similar studies can be conducted for large sample of psychiatric patients.
- Similar studies can be conducted among IT professionals and older adults

Conclusion

Structured teaching programme helped to reduce the level of insomnia, from severe level to sub threshold level of insomnia among majority of the psychiatric patients.

ABSTRACT

Background: Insight is awareness of one's symptoms, illness, and need for treatment. In bipolar disorder, insight is better in bipolar depression and nonpsychotic depression when compared with mania and psychotic depression. Insight impacts on medication adherence. In our study, we measured and compared with various clinical parameters of insight. The aim of this study is to assess various dimensions of insight recovery prospectively in bipolar affective disorder patients with treatment and drug compliance. **Materials and Methods:** Patient's insight was assessed using Mood Disorder Insight Scale (MDIS) at baseline, 1st, 3rd, and 6th months. Their insight was then compared with various sociodemographic profiles and correlated with number of mood episodes, family history of mental illness, and 6-month MDIS scores. **Results:** Depression patients scored better in insight components ($P = 0.001$). The good compliance group attributed their symptoms to their illness than the poor compliance group ($P = 0.013$). The MDIS scores were gradually improving from baseline to 6 months ($P \leq 0.001$). There was no relationship between insight and the number of episodes ($P = 0.788$). **Conclusion:** Depressive episode patients had better insight during the baseline, which improved during 6 months follow-up compared with manic patients. Among various components of insight, insight on the attribution of symptoms was a predictor of good compliance. Progression of insight was steady and proportionate to the duration of treatment in depressive episode patients.

Keywords: Bipolar affective disorder, depression, insight, mania

The bipolar affective disorder is common and disabling disorder and is associated with considerable morbidity.[1] It is a mood disorder that is characterized by episodes of depression, mania, hypomania, and mixed episodes, with a period of inter-episodic recovery. The World Health Organization estimated that bipolar disorder was the 46th greatest cause of disability and mortality in the world among 291 diseases and causes of injuries. Insight is defined as the awareness of one's illness, the ability to recognize the symptoms of the illness and the need for treatment. Insight of a patient can be categorized into absent insight, partial insight, and full insight.[2-5]

Insight is being highlighted as state-dependent component in a few studies. In disorder like bipolar affective illness, impairment in insight fully resolves. There are few studies which highlight that insight does not resolve completely even in the euthymic state. The more the number of episodes especially manic episodes, the lesser is the insight recovery. However, psychotic depression is associated with less insight than nonpsychotic depression. Insight continues to be poor in chronic illness like schizophrenia. Nowadays, more attention has been given to insight of the patient toward mental illness. There are many

studies, which were being done which evaluated the relationship between insight and course and outcome of the illness, compliance to medications and the severity of psychopathology. The prevalence of good insight in remitted bipolar affective disorder patients is only 47%.[6] In another study, the prevalence of absent insight was 39.09% in the schizophrenia group, 36.36% in the bipolar disorder with psychotic symptoms and 9.37% in bipolar disorder without psychotic symptoms.[7]

The bipolar affective disorder is usually associated with noncompliance and poor outcome.[8,9] Insight and quality of life, cognitive functions, psychotic symptoms, and the number of episodes in mood disorders are interrelated.[10] Many studies have shown that insight is impaired in the acute phase of illness and insight improves as the patient improves symptomatically. Insight was more impaired during manic episodes when compared with depression.[11] Lack of insight in mania was present for all three components of insight-awareness of illness, social consequences of illness, and therapy benefits.[12] A study has showed that insight of bipolar affective disorder patients and schizophrenia patients were the same during admission. At 6 month follow-up, there was a large difference between both the groups. Bipolar disorder patients had better insight when compared with schizophrenia patients.[13]

Adherence to medications plays a key role in the effectiveness of any treatment. Research on the relationship between insight and adherence to treatment is important because adherence to medication can be modified. Meta-analysis that was done to study the relationship between insight and treatment compliance showed poor insight was associated with poor adherence to medications, which was similar to the literature on schizophrenia patients.[14] Studies on schizophrenia patients showed that patients with more insight have a better long-term outcomes.[15] There are similar researches in bipolar disorder, which showed improvement of insight from baseline and follow-up was related to better outcomes of illness and quality of life.[16]

Various scales are available for the assessment of insight. However, most of the scales were validated to measure insight in psychotic illness. Mood Disorder Insight Scale (MDIS) is a short and self-report instrument, includes all the components of insight and it is specifically modified for affective disorder patients. The MDIS was derived from the insight Scale for psychosis which was developed by Birchwood *et al.*, 1994. This scale measures three aspects of insight-awareness of mental disorder, attribution of symptoms, and need for treatment. Hence, we used this scale, which specifically measures insight in bipolar affective disorder in our study.

Most of the studies on insight were done in schizophrenia patients. Very few studies were done on bipolar disorder patients. There are only very few studies which have studied insight in various phases of illness. In disorder like bipolar affective illness impairment in insight fully resolves. The more the number of episodes especially manic episodes, the lesser is the insight recovery. Insight continues to be poor in chronic illness like schizophrenia.

An earlier study reported a 94% prevalence of impaired insight in symptomatic patients in various psychiatric illness such as depression, manic, and bipolar I patients. The prevalence of insight in remitted patients is 47%.[6]

A prospective study on insight in various phases of bipolar illness, observed that insight was impaired in mania when compared with the euthymic state. Insight was better in patients who had single episode of mania or depression; this insight was similar to preepisode insight. However, patients with multiple episodes of illness in 2 years had poorer insight when compared with insight of patients with less number of episodes.[7,17,18]

Very limited number of studies had compared insight with sociodemographic and clinical variables such as age, educational status, gender, marital status, and family history of mental illness. Most of the studies that have been done in insight are cross-sectional study. There are very few prospective studies on insight in bipolar disorder patients.

Therefore, the aim of this study is to assess insight recovery in bipolar affective disorder patients admitted in the psychiatry ward. We also assessed the correlation of insight about awareness of illness, attribution of symptoms to illness and insight recovery with various phases of bipolar affective illness.

MATERIALS AND METHODS

Participants and procedures

This is a prospective study. Participants of our study were both male and female gender for >12 years. These patients were admitted and were undergoing in-patient treatment in PSG Hospitals, a 2000-bedded tertiary hospital at Coimbatore, for Bipolar affective disorder either in depression or manic phase. These patients were admitted between the period of April 2016 and 2017. The participants were diagnosed with bipolar affective disorder using the International Statistical Classification of Diseases (ICD-10) criteria by the treating consultant. Patients having comorbid mental retardation and other Axis 1 psychiatric disorder except nicotine dependence, patients who did not respond for at least three telephonic calls in

[Downloaded free from http://www.industrialpsychiatry.org on Tuesday, March 16, 2021, IP: 59.92.30.139]

the follow-up and patients <12 years old were excluded from our study.

We recruited 50 consecutive in-patient bipolar affective disorder patients based on the ICD-10 criteria. Nine patients were excluded as per the exclusion criteria. Five of them had follow-up elsewhere, two patients did not give consent and two patients had mental retardation. Informed consent in the local language (Tamil) was obtained from primary caregiver for those patients who were not able to give consent. Once the patient became euthymic informed consent was obtained from the patient as well. The personal identification data such as name, age, gender, educational qualifications, and socioeconomic data of all the participants were recorded. Data related to psychiatry illness such as the number of past episodes and family history of mental illness was also recorded.

Once the patient got admitted, the severity of the present episode was measured using rating scales. The severity of affective symptoms was assessed by the Youngs Mania Rating Scale (YMRS) and Hamilton Depression Rating Scale (HAMD) for mania and depression, respectively. Baseline Insight was assessed using MDIS. Then, the patient was treated according to their clinical diagnosis by the consulting psychiatrist. One month after discharge, the insight was assessed using the MDIS scale and recorded. Then again, at the 3rd and 6th months of follow-up insight was measured using MDIS. The total scores of insight were calculated at baseline, 1st month, 3rd month, and 6th month and compared for improvement in insight.

Drug compliance was assessed clinically from the patient and reliable informant. During follow-up, the course of the illness was assessed, and the escalation of the dose of psychotropics or addition of a new psychotropic medication is also assessed. Patients who missed the follow-up are contacted through telephonic calls, encouraged to attend outpatient department and Insight assessed. Patients who did not respond for at least three telephonic calls were considered as dropouts [Figure 1]. The study was approved by the Institute Human Ethics committee of PSG IMSR and Hospital.

Assessment

Data were collected using the following instruments.

Semi-structured pro forma

The sociodemographic profile of the patient, details of substance use, diagnosis, and clinical details (compliance of medications, the severity of illness using YMRS and HAMD scales, number of past episodes, and family history of psychiatry illness) were assessed.

Mood Disorder Insight Scale

MDIS is a short and self-report instrument. This scale has eight questions which are read by the interviewer and the patient is asked whether their response is agree, disagree, or unsure for each of the eight items in the questionnaire. Depending on the response, the scores are calculated. The total score is 16. The MDIS was derived from the Insight Scale for psychosis, which was developed by Birchwood. This scale has good test–retest reliability and internal consistency. The test–retest reliability (coefficient alpha) of the MDIS was 0.95 ($P < 0.01$). This scale for insight includes all the components of insight and it is specifically modified for affective disorder patients. The administration of this scale does not require any special training as this is a self-report questionnaire. This scale measures three aspects of insight-awareness of mental disorder, attribution of symptoms, and need for treatment.

Data analysis

Data were entered into MS Excel and analyzed using SPSS version 20. Qualitative data were summarized as frequencies and percentages. Quantitative data were checked for normality. Normally distributed data were summarized using mean and standard deviation. Nonnormally distributed data were summarized using Median and inter-quartile range. Association between qualitative variables was tested using Chi-square test. Mann–Whitney U test was used to compare the distribution of MDIS scores by level of compliance and phase of disease; mania or depression. Friedman's test was used to check if the MDIS scores changed significantly with time. Correlation between the YMRS score and MDIS at baseline was tested using the Spearman rank correlation test. Statistical significance was interpreted using an arbitrary cut-off of $P = 0.05$.

RESULTS

Descriptive statistics for the study variables and demographics data are shown in Table 1.

The number of episodes ranged from 2 to 7. Fifteen patients had psychotic symptoms in their mood episodes and twenty-six patients had no psychotic symptoms. Family history of psychiatry illness was present in 26.8% ($n = 11$) and absent in remaining 73.2% ($n = 30$). Twenty-three patients (56.1%) of the participants had good compliance and the remaining 43.9% ($n = 18$) had poor compliance [Table 2].

The insight scores between different age group were compared, the *P* value was not statistically significant ($P = 0.318$). The insight scores, according to educational status, were not

[Downloaded free from http://www.industrialpsychiatry.org on Tuesday, March 16, 2021, IP: 59.92.30.139]

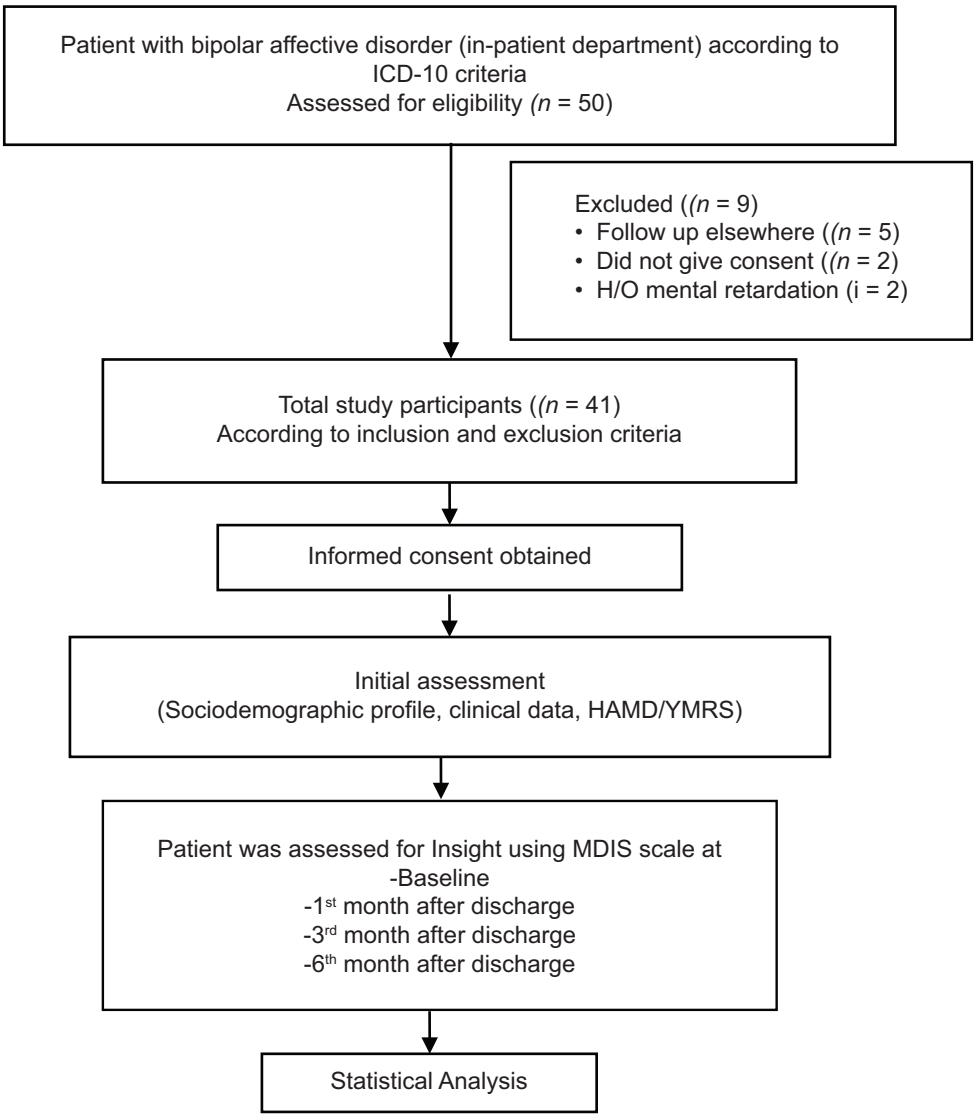

Figure 1: Flow chart

statistically significant ($P = 0.75$). Insight scores did not differ statistically between males and females, P value was 0.552. Insight scores of participants who had family history of mental illness were compared with participants who did not have family history of mental illness also did not have any statistical significance ($P = 0.124$) [Table 2].

The overall scores of the MDIS scale were compared between mania and depression groups, depression patients scored more when compared with manic patients in the insight scale. The more the MDIS score, the better the insight. The P value was also significant $P = 0.001$ [Table 3].

The total scores of MDIS between good compliance and poor compliance group were statistically significant, P value was 0.012. Good compliance group scored better in insight scale than the poor compliance group [Table 4].

In our study, we assessed for the insight score of the participants at baseline, 1st month, 3rd month and 6th month. When these scores were compared from baseline to the end of 6 months, we found that the insight scores were gradually improving. This was statistically significant and P value was < 0.001 [Table 5].

Figure 2 shows the MDIS scores at baseline, 1st month, 3rd month, and 6th month in depressive patients. The MDIS scores of the depressive patient were higher when compared with manic patients. This shows that depressive patients have more insight than manic patients. Figure 3 shows the MDIS scores at baseline, 1st month, 3rd month, and 6th month in manic patients. The MDIS scores of the manic patient were lower when compared with depressive patients indicating manic patients have less insight about illness than depressive patients.

MDIS - Mood disorder insight scale

In Figure 4, MDIS scores were plotted against the period of assessment. The MDIS scores have an increasing trend from baseline to 6 months in the depression group. The progression of insight reached a plateau after 3 months for manic patients.

The number of episodes of illness was compared with MDIS scores. The *P* value was not significant ($P = 0.788$).

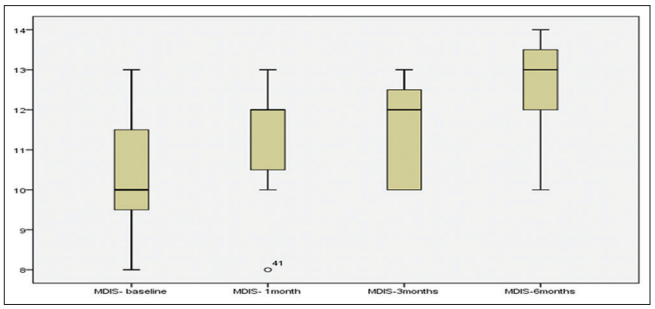

Figure 2: Progression of insight based on Mood Disorder Insight Scale scores at baseline, 1, 3 and 6 months in participants with depression

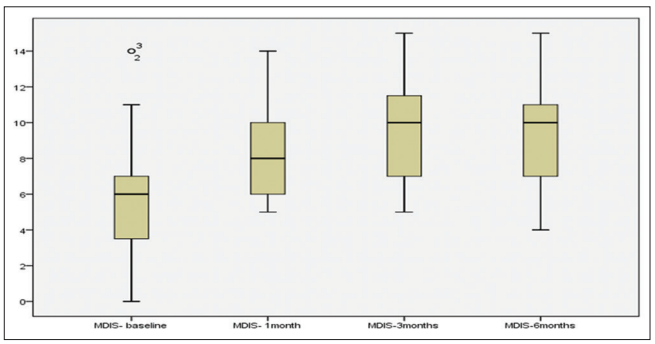

Figure 3: Progression of Mood Disorder Insight Scale from baseline to 6 months in patients with mania

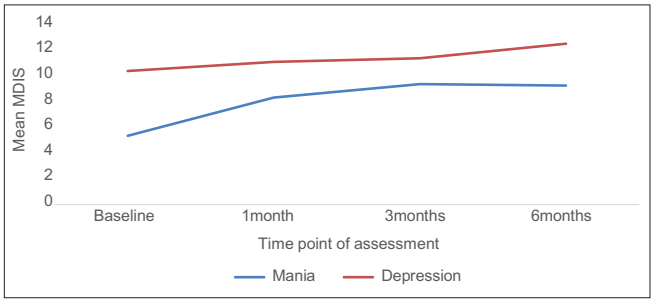

Figure 4: Progression of Mood Disorder Insight Scale from baseline to 6 months in patients with mania and depression

The presence of family history of mental illness was compared with MDIS scores. The *P* value was not significant ($P = 0.701$) [Table 6].

MDIS scores were negatively correlated with both YMRS and HAMD scores, which implies less severe the illness, the better the insight. The correlation with YMRS was statistically significant ($P = 0.003$), whereas with HAMD the correlation was not statistically significant ($P = 0.640$) [Table 7].

DISCUSSION

Insight is a multidimensional and complex phenomenon (Amador *et al.*, 1993). We compared sociodemographic profile (name, age, gender, educational

qualifications, and socioeconomic data) of the participants with MDIS scores. There was no difference in insight between different groups.

In this study, insight scores were lower in females than males ($P = 0.08$), but the P value was not significant. The insight scores were compared with different educational status groups. There was no statistically significant ($P = 0.75$) difference within these groups. On the contrary to our understanding insight did not differ according to the educational status in our study. To our knowledge, no other studies on insight had compared the relationship between educational status and marital status.

Insight scores of participants who had family history of mental illness were compared with participants who did not have family history of mental illness. Though the scores of the participants who had family history of mental illness were higher than the other group, it was not statistically significant.

The overall MDIS scores, when compared between mania and depression groups, showed that depressive patients scored more when compared with manic patients in the insight scale ($P = 0.001$). The individual dimensions of scale were also better among depression than mania, which was statistically significant. Another study which was done to evaluate insight in mania, depression and euthymia in 95 bipolar affective disorder patients showed poor insight among mania patients when compared with depressive patients.[19] The P value was significant 0.001.

Twenty-three patients that is 56.1% of the participants had good compliance and the remaining 43.9% ($n = 18$) had poor compliance. Compliance is a very important part to consider in illness like bipolar affective disorder. Literature on the prevalence of nonadherence also had similar values. The median prevalence of nonadherence is 44.7% in

[Downloaded free from http://www.industrialpsychiatry.org on Tuesday, March 16, 2021, IP: 59.92.30.139]

patients with bipolar affective disorder.[19] In one study that was done to assess the predictors of nonadherence in bipolar affective disorder patients showed treatment nonadherent individuals had more negative attitudes toward medications and reduced insight into illness when compared with treatment adherent individuals.[20] We also compared the MDIS scores between good compliance and poor compliance group. The total scores of MDIS between good compliance and poor compliance group were statistically significant and *P* value was 0.012. Yen *et al.* study[21] showed insight about illness and treatment was positively correlating with adherence to medication in the bipolar affective disorder group and schizophrenia group. So interventions, which concentrated on building insight play a vital role in ensuring good compliance among bipolar patients.

In our study, we assessed for the insight score of the participants at baseline, 1st month, 3rd month, and 6th month. When these scores were compared from baseline to 6 months, we found that the insight scores were gradually improving. This was statistically significant and *P* value was < 0.001. In another prospective study which evaluated the correlation of insight in 65 bipolar disorder patients for 2 years showed insight of the manic patients gradually improved as they returned to the euthymic state.[21]

The average number of episodes in our study among the participants was two. The number of episodes ranged from 2 to 7. In our study, the number of episodes did not make any significant difference in insight of the participants ($P = 0.788$). Similar findings were seen in Cassidy study; on the contrary, showed more the number of episodes, poorer the insight.[22]

Limitations

The sample size is very small in our study, and hence the results cannot be generalized. The initial assessment of insight was not assessed on specifically on the same day after admission for all patients. The treating consultant psychiatrist made a diagnosis of bipolar affective disorder. No separate research diagnostic criteria were used to recruit our patients. With the help of insight scale we have assessed whether the patient is aware of their symptoms in general but have not analyzed about the awareness of individual symptoms. MDIS scale gives only qualitative assessment and not a quantitative assessment.

CONCLUSION

Depressive episode patients had better insight during the baseline, which improved during 6 months follow-up compared with manic episode patients. Among various components of Insight, insight on the attribution of symptoms was a predictor of good compliance during 6 months follow-up than the awareness of mental disorder or need for treatment. Progression of insight was steady and proportionate to the duration of treatment in depressive episode patients. More severe the manic episode poorer was the insight.

Prevalence and Sociodemographic Profile of Lithium-induced Cutaneous Side Effects in Bipolar Affective Disorder Patients: A 1-year Prospective Observational Study in South India

B. S. Suganya Priyadharshini, I. Syed Ummar

ABSTRACT

Objectives: Objective in our study is i) To assess the prevalence and sociodemographic profile of cutaneous side effects in bipolar affective disorder patients (BPAD) on lithium. ii) To assess the course of pre-existing skin reactions, when patient is initiated on lithium therapy. **Methods:** Lithium induced cutaneous side effects were assessed at baseline and monthly for 6 months followed by every 2 months over a year. Dermatologist opinion obtained to diagnose and treat for each patient who developed cutaneous side effects. Data were analyzed in percentage. **Results:** The prevalence of lithium induced cutaneous side effects in our study is 38.46%. On analyzing the individual subtype of cutaneous lesions, acneiform eruption and hairfall were most common. The cutaneous adverse reactions on lithium are more common in early adulthood than in the late adulthood and geriatric age group and among the subtypes of skin lesion acneiform eruptions are more common among males than in females. On analyzing the course of pre-existing lesions, severe alopecia developed with pre-existing systemic lupus erythematosis. **Conclusion:** These novel finding indicate that prevalence of lithium induced cutaneous side effects continues to be high. Hence, clinician should educate the patients before initiating lithium to improve attrition rate.

Key words: *Bipolar disorder, cutaneous sideeffects, Lithium*

INTRODUCTION

Lithium has been used in the treatment of mood disorders for more than five decades[1] and it has been the focus of numerous investigations for its systemic side-effects. Although lithium is notorious to cause cutaneous lesions[2] the literature on skin disorders secondary to lithium therapy is limited.

Lithium is known to cause multiple cutaneous side effects, and the most common side effects are an acneiform and psoriasiform eruption.[3] It is known to cause psoriasis and also exacerbate preexisting psoriasis. Lithium-induced psoriasis are most distressing, and it is associated with the increased risk of suicide and substance use.[4]

It causes specific manifestations such as acneiform eruptions, seborrheic dermatitis, hyperpigmentation, and follicular keratitis. Other cutaneous manifestations includes mucosal and vaginal ulceration, edema, purpura, lupus erythematosus such as syndrome, urticaria, pretibial ulceration, dermatitis herpetiformis, eczema, exfoliative dermatitis, folliculitis, alopecia, allergic vasculitis, hidradenitis suppurativa, lichenoid stomatitis, exacerbation of Darier's disease, palmoplantar hyperkeratosis with ichthyosiform features, increased growth of wart, mycosis fungoides, and hair loss.[5,7-9]

Lithium is also suggested to induce lupus erythematosus. Lithium-induced lupus was more common among females and among adolescence (20–40 years).[6]

In the previous study, females showed increased incidence of cutaneous side effects compared to males. The prevalence of lithium-induced skin reactions is reported to range from 3% to 34%.[7] In another study, the prevalence of lithium-induced skin reactions is reported to be 45%.[8]

Lithium-induced lesions cause disturbances in the self-image and affect their social, occupational, and interpersonal functioning which may contribute to the risk of noncompliance. Even though its cutaneous side effects results in poor compliance, studies in these area are very few hence we have decided to do study with the primary aim is to find the prevalence of lithium-induced skin reactions. Our other objectives are to find the sociodemographic profile and its correlate with lithium-induced skin side effects and the course of preexisting skin reactions with lithium therapy.

MATERIALS AND METHODS

Study design

This is a prospective observational study done in bipolar affective disorder patients who came to our psychiatry department. A total of 52 bipolar affective disorder patients were recruited both from in- and out-patient settings by convenient sampling. The study protocol was explained to the participants, and a written informed consent was obtained from the patient. If patient could not consent, it was obtained from the family member and later from the patient when he/she could consent. The study was approved by Institutional Human Ethics Committee with the reference number 14/147.

Participants

Men and women aged 18–65 years with the primary diagnosis of bipolar affective disorder who were either newly initiated or already on lithium therapy were eligible for the study. Diagnosis of bipolar affective disorder was made by a qualified psychiatrist based on the International Classification of Disease criteria.

Patient on other mood stabilizers and on other medication known to cause cutaneous reactions other than antipsychotics were excluded from the study.

Assessments

Initial assessment

we designed a semi-structured pro forma and dermatological assessment sheet which were used for the initial assessment. It included sociodemographic details of the patient such as age, sex, socioeconomic status and education, details of history of skin lesions, and family history of skin lesion. We arbitrarily divided age group into early adulthood <40 years, late adulthood between 40 and 60 years and more than 60 years. All the patients were asked for the presence of skin lesions currently and in the past through history and by complete physical examination. Semi-structured dermatological assessment sheet includes the details about the type of skin lesions and questionnaire covering the details of skin lesions and its relationship to treatment lithium. These patients were examined by the dermatologist and diagnosis was made. The dermatologist would also determine that the lesion was related to the drug lithium. Necessary treatment for the concerned dermatological diagnosis was given by the dermatologist.

Follow-up assessment

We did follow-up assessments monthly for 6 months and thereafter every 2 months for a year. During each follow-up, patients were examined for the presence of skin lesions. Follow-up assessment was done using semi-structured pro forma which included the course of individual skin lesions and preexisting skin lesions as persisted, remitted or exacerbated, and for the presence of new lesions. If the patient develops any new lesions dermatologist opinion was sought each time and they were given required medications. If the patient missed a follow-up, they were contacted over phone and enquired for the presence of any skin lesions and its course both from the patient and the caregiver. Even if they did not come for follow-up, they were included in the study.

Statistical analyses

The prevalence of cumulative subtype of cutaneous lesions and total prevalence of cutaneous lesions were calculated.

Table 1: Baseline sociodemographic details of the sample study

Variables	Number of patients (%)
Age (years)	
<40	31 (59.6)
40-60	18 (34.6)
>60	3 (5.8)

Lower middle	3 (5.8)
Education	
Illiterate	15 (28.8)
Mid school	30 (57.7)
High school	7 (13.5)
Postgraduate	0

The prevalence of individual lesions is compared with the age and gender.

RESULTS

General characteristics of study sample

In the study sample, the majority were in the age group of <40 years (59.6%), those between 40 and 60 years are 34.6%. Gender distribution was almost equal where females are 48.1% and males are 51.9%. The majority were from upper middle socioeconomic status (94.2%) as per modified Kuppusamy scale and 57.7% had finished their mid school level [Table 1].

Analysis of cumulative prevalence of cutaneous lesion during 1-year follow-ups

The prevalence of lithium-induced skin reactions in our study was 38.46%. On analyzing the cumulative prevalence, acneiform eruption peaked during the 2nd month (n = 11/52), and it abated at the end of 1 year. Hair fall had peaked at the 4th month (n = 6/52) later has gradually came down and again increased at the end of 1 year. Hyperpigmentation occurred from the 3rd month; it peaked in the 5th month and persisted throughout the study. Only one patient had developed seborrheic dermatitis during 1st month, but it abated in between for 4 months with dermatological treatment and reappeared during 8th month and persisted till the end of the study.

Lithium-induced ulcer (n = 1/52) developed during the 1st month, and it persisted throughout. It developed in the right index and middle fingers with multiple ulcers gradually it has increased its size and number. But after the end of the study, lithium was stopped and was changed over to other mood stabilizers.

Combined lesions such as acne with hair fall, acne with hyperpigmentation, and acne with seborrheic dermatitis had occurred. One patient developed acne with hair fall and acne with hyperpigmentation, they cleared up at the end of the study. As shown in Table 2, one patient had acne with seborrheic dermatitis waned off for a month and reappeared.

Prevalence of cutaneous lesions among various age groups

Acneiform eruptions (n = 11/52) and hyperpigmentation (n = 2/52) are common in early adulthood, whereas lithium-induced ulcer (n = 1/52) seen in late adulthood. Hair fall is equal in both early and late adulthood (5.7%). In geriatrics, 1.9% developed acneiform eruptions with hyperpigmentation [Table 3].

Gender difference in the prevalence of cutaneous skin lesions

15.2% (n = 8/52) of males and 11.4% (n = 6/52) females had developed acneiform eruptions, whereas 3.8% males and 7.6% females developed hair fall. Seborrheic dermatitis occurred in males and lithium-induced ulcer in females. Hyperpigmentation has seen in 3.8% males and 1.9% females.

About 3.8% of females had developed acneiform eruption with hair fall whereas acneiform eruption with hyperpigmentation (3.8%) and seborrheic dermatitis (1.9%) occurred in males [Table 4].

Course of preexisting skin reaction

Three patients had preexisting skin lesions, of which one had tinea during initial assessment which gradually subsided with treatment during 3rd month, and one had candidiasis improved and remitted in the 4th month.

One patient had systemic lupus erythematosus, developed severe hair fall at a 2nd month, and they stopped treatment with lithium therapy on their own at the end of 3rd month.

Drop outs

After recruitment of 52 patients, 10 were dropped out at the end of the study. Of which five were dropped out because of poor compliance. One dropped out due to lithium toxicity. One dropped out at the end of the 3rd month due to persistent vomiting, and he was changed over to another mood stabilizer. One dropped out at the end of 5th month due to nonaffordability to do routine serum lithium level. One dropped out due to severe hair fall.

DISCUSSION

In this study, the mean age was 38.6 years and most common age group was early adulthood (18–40 years).

Table 2: Prevalence of cumulative subtype of skin lesions

Type of skin lesion	Initial assessment	Follow ups 1	Follow ups 2	Follow ups 3	Follow ups 4	Follow ups 5	Follow ups 6	Follow ups 7	Follow ups 8	Follow ups 9
	Initial (%)	1st month (%)	2nd month (%)	3rd month (%)	4th month (%)	5th month (%)	6th month (%)	8th month (%)	10th month (%)	12th month (%)

Seborrheic dermatitis	0	1.9	1.9	0	0	0	0	1.9	1.9	1.9
Hyperpigmentation	0	0	0	1.9	1.9	3.8	3.8	3.8	3.8	3.8
Acne and hyperpigmentation	1.9	1.9	1.9	1.9	0	0	0	0	0	0
Lithium-induced ulcer	0	1.9	1.9	1.9	1.9	1.9	1.9	1.9	1.9	1.9
Acne and hair fall	0	1.9	1.9	0	0	0	0	0	0	0
Acne and seborrheic dermatitis	0	0	0	0	1.9	1.9	0	1.9	1.9	1.9

Our sample had an equal gender distribution. Most were in the upper middle socioeconomic status and had completed up to middle school education.

The prevalence of lithium-induced cutaneous side effects in our study was 38.46% which is comparable to the prevalence reported by Sarantidis and Waters and Chan *et al*. Acneiform eruptions and hair fall are most common lesion in our study whereas study by Sarantidis and Waters showed acneiform eruption and psoriasis as the most common secondary cutaneous lesions. The incidence of hyperpigmentation was found significant in our study compared to previous studies.

The course of acneiform eruption showed that the lesions were more during the initial period of follow-ups and gradually improved on treatment with topical retinoids.[10-12] The patient did not have the classical type of distribution but occurred over the extremities (mostly in the back of the shoulders) as reported in previous studies by Jennis and Kerbs *et al*.

Hyperpigmentation, hair fall and seborrheic dermatitis coexist with acneiform eruptions during the course. Seborrheic dermatitis has reduced along the course with treatment but reappears on discontinuation of treatment for the same but when compared with the previous study by Dreno *et al*. where lithium is used as the treatment for seborrheic dermatitis.

In this study, one patient had developed lithium-induced ulcers. She developed multiple small pustular ulcers over the index and middle fingers which was found to be most distressing for the patient. Even with dermatological treatment using topical applications patient continued to have repeated pustular ulcers in hands with fissure.

The cutaneous adverse reactions on lithium are more common in early adulthood than in the late adulthood and geriatric age group and among the subtypes of skin lesion acneiform eruptions are more common among males than in females which is supported by previous study by Chan *et al*. Acneiform eruptions coexists with hair fall and is more common among females. An acneiform eruption with hyperpigmentation is more common among males.

Patient with pre-existing severe skin reactions are prone for new skin reaction and may contribute to poor attrition. Interestingly, patients with milder skin reactions like tinea and candidiasis improved over the course of time. But patient with systemic lupus erythematosis developed severe hairfall, resulting in dropout, which is supported by the previous study.[13,14]

The strength of our study is prospective study, and the recruited patients are studied at multiple intervals for a

Table 3: Percentage of cutaneous skin lesion among various age groups

Table 4: Gender difference in prevalence of cutaneous skin lesions

Age	Acneiform eruption (%)	Hair fall (%)	Seborrheic dermatitis (%)	Hyperpigmentation (%)	Lithium-induced ulcers (%)	Acne, hyperpigmentation (%)	Acne, hair fall (%)	Acne, seborrheic dermatitis (%)
Female	11.4	7.6	0	1.9	1.9	0	3.8	0
Male	15.2	3.8	1.9	3.8	0	3.8	0	1.9

long duration. Dermatologist opinion obtained for each patient who developed lesions during each follow-up.

Our limitations are small sample size to be generalized. Few patients were on lithium with psychotropic medications which would also contribute to the skin lesions. We had taken convenience sampling. A single dermatologist assessing all the cohorts would have made the study better, and it was not possible due to practical reasons. Naranjo scale which is used to assess the association between the drugs-induced reaction and drug is not used in our study. No blinding was done for the primary therapist nor for the dermatologist, and we followed the patients through telephonic calls which may not be correct as direct observation.

CONCLUSION

The prevalence of lithium-induced cutaneous lesions continuous to be high. Clinician should educate the patient before initiating lithium to improve the attrition rate. Physician need not be apprehensive about changing to other mood stabilizers as lithium-induced skin reactions could be managed with dermatological treatment. Physician should also be cautious in starting lithium in selective cohort of sample.

Abstract Bipolar disorder is potentially a lifelong and disabling condition, which requires long-term pharmacological therapy as maintenance treatment. Lithium is considered as first-line mood stabilizer, followed by Divalproate, both are known to reduce the risk of relapse. However, relapses do occur and these medications are also associated with side effects. We aimed to compare the mood stabilizing effect between Lithium and Divalproate in our prospective study. **Methods** 104 bipolar patients who were euthymic (52 patients each on Lithium and Divalproate therapy) were followed up for one year with periodic evaluation done during initial, 3rd, 6th, 9th and 12th month. Time taken to relapse, severity of mood episode, suicidal risk and functioning were assessed using standardized scales. Compliance to medications and adverse effects were also assessed. **Results** The duration of treatment was for a longer period in Lithium group (p=0.001) and this was the only confounding variable which was significant. Patients who are taking Divalproate had more severe manic episode at the end of 1 year when compared to patients taking Lithium (p=0.041). Patients on Lithium also had lesser suicidal risk (trending towards significance). **Conclusion** There was no difference in terms of frequency of depressive episode, adherence, adverse effects and global functioning between the two groups. But Lithium group patients had less frequent and less severe manic episodes and lower suicidal risk, favoring Lithium to be a better mood stabilizer, with less adverse effects and better quality of life.

Key words Bipolar disorder; Mood stabilizer; Maintenance treatment; Quality of life.

Introduction

Bipolar Affective Disorder (BPAD) is one of the most disabling mental illnesses affecting most productive period of life at the age 15-45years.[1] Lithium carbonate has been a gold standard treatment for past five decades. But it has a narrow therapeutic index and significant adverse effects.[2] Anticonvulsants such as Divalproate sodium, Carbamazepine and Oxcarbamazepine, have been proposed as an alternative, also have more adverse effect profile and their comparative efficacy with Lithium is uncertain.[3-8] Lithium Carbonate as a mood stabilizer has been a superior agent to reduce the risk of relapse and to prevent suicidal behaviours.[2-7] In view of its adverse effects, tolerance becomes an issue; which can interfere with adherence.[4-7] Lithium causes multiple skin reactions, the most common are acne and psoriasis. The prevalence of skin reaction with Lithium ranges between 3-34 %. Some studies have shown high chance of discontinuation of Lithium is due to adverse skin reactions.[9] Anticonvulsants approved by FDA, has the next level of

evidence as a mood stabilizer but their long term safety and efficacy in comparison with Lithium remains uncertain[7] Randomised controlled trails have shown superiority of Divalproate sodium to placebo.[10-11] Divalproate sodium has been comparable with Lithium in Manic episode[11] FDA approved mood stabilisers for the treatment of bipolar affective disorder are Lithium, Divalproate sodium, Carbamazepine and Lamotrigine.[17-20] Mood stabilisers can also be used as monotherapy which was approved by FDA.[21-22] Mania with two or more episodes of depression showed a good improvement with Divalproate sodium than Lithium.[23-24] Lithium and Divalproate sodium showed more effect than any other mood stabilisers during acute phase of mania and in maintenance phase.[25-27] Olanzapine, Risperidone and Quetiapine are FDA approved atypical antipsychotics for the acute phase of mania[17,18,20] According to BALANCE study both Lithium monotherapy and combination therapy with Lithium and Divalproate sodium are more likely to prevent relapse than Divalproate sodium monotherapy, irrespective of baseline severity of illness and is maintained for up to 2 years.[12] Bowden *et al*, in his randomized placebo controlled 12 months trial of Lithium v/s Divalproate sodium, has shown no significant difference between the two groups in terms of time to recurrence of mood episode during maintenance therapy. Compared to placebo, Divalproate sodium has lesser discontinuation rate[13.] Even though open labelled trails favours Divalproate sodium in reducing the frequency and intensity of further episodes, there are less comparative study with Lithium in maintenance therapy.[14-16] Long term outcomes are often poor in patients with bipolar disorder despite treatment; therefore more effective treatments are needed to reduce recurrences and morbidity. Hence, we proposed a prospective comparison study of Lithium and Divalproate sodium in euthymic BPAD patients for a period of at least 1year during the maintenance phase. We aimed to compare the mood stabilizing properties of Lithium and Divalproate sodium in BPAD patients. Our other objectives are to evaluate the time taken for relapse of any mood episodes (mania/depression/mixed episodes), assess the severity of the mood episodes, episodes of deliberate self harm, adherence to study treatment, adverse effects of medications and global assessment of functioning.

M

This is a prospective observational study done in patients with bipolar affective disorder who came to the psychiatry department in PSG Institute of Medical Sciences and Research, Coimbatore, India. A total of 104 bipolar affective disorder patients were recruited from out-patient setting. The study protocol was explained to the participants, and a written informed consent was obtained from the patient. If patient could not consent, it was obtained from the family member and later from the patient when he/she could consent. The study was approved by Institutional Human Ethics Committee.

Men and women aged 18 years and above who received a clinical diagnosis of BPAD (as per ICD-10 criteria) in psychiatry out-patient department were eligible for the study. Patients were initiated or continued on a single mood stabilizer either on Lithium or Divalproate sodium. Only patients who achieved remission within 2 months of follow-up were included in the study. Patients who were already on more than one mood stabilizers (Lithium, Valproate, Carbamazepine, Lamotrigine, Gabapentin and Topiramate) during index diagnosis and medically unstable patients with conditions such as renal failure, liver cirrhosis, severe diabetes, arrhythmia etc. were excluded from the study.

After recruiting the patients as per our inclusion and exclusion criteria, 52 patients who were on Lithium therapy and 52 patients who were on Divalproate therapy, were prospectively followed up for 1 year period. Patients were evaluated by the investigator, following 2 months of euthymic period (index evaluation). During follow up patients were evaluated at 3rd, 6th, 9thand 12th month respectively (periodic evaluation). Patients who are missing on follow up are contacted through telephone and requested to come for follow-up and assessed. As it is an observational study, investigators took no role in modifying the dosage of medications, but it was taken care by the primary incharge treating team. During initial evaluation, a semi-structured proforma (socio-demographic details and other confounding variables) is administered. Diagnosis was confirmed by applying a SCID (Structured Clinical Interview for DSM-IV) version for mood disorder. As per earlier literature available, remission is a state that comes close to being symptom free. By which the euthymic status of the patient was ascertained by applying HAM-D and YMRS rating scales. Typically remission should have a score of ≤ 7 on HAM-D and ≤ 2 on YMRS. Severity of suicidal ideas is assessed by Modified SADPERSONS Scale. Global Assessment of Functioning was assessed using a GAF scale. The dosage of the mood stabilizer could be altered by the primary in-charge team based on serum concentration of the drug/adverse effects, during 1 year maintenance period. Participants who remain on the allotted treatment for 1 year of study were periodically evaluated. Use of other psychotropics was allowed during the study trial (antipsychotics, benzodiazepines).Periodic assessment was done as per the figure 1 given below, for confounding variables, SCID-mood disorder sub-scale,

Young Mania Rating Scale (YMRS)/ Hamilton rating scale for Depression (HAM-D) appropriate to the patient (to access the severity of episode if any), Modified SADPERSONS scale-to see suicidal score, adverse drug reaction and Global assessment of functioning (GAF) scale.

Statistical analyses were conducted using software package SPSS version 20. We compared the efficacy of Lithium and Divalproate sodium with the following variables such as age, gender, marital status and education status, which were expressed in percentage and the presence of any statistically significant difference, was analysed using Chi-square test. Also statistically significant difference between the age of onset, number of previous episodes, previous hospitalisation, polarity of previous episodes, psychotropics and duration of mood stabiliser with that of Lithium and Divalproate sodium was done using Chi-square test. Comparison of duration of illness, time taken for any mood episodes, severity of manic episode/depressive episode, suicidal risk, adherence to medications, adverse effects, global assessment functioning between Lithium and Divalproate sodium was done using analysis of variance; p-values <0.05 was considered as significant.

Table 1: Comparison of socio-demographic and confounding variable between Lithium and *Divalproate sodium group*:

Variables		Lithium	Divalproate sodium	p value
Age at recruitment	18- 35 years	31(59.6%)	25(48.1%)	0.392
	36- 59 years	18(34.6%)	21(40.4%)	
	> 60 years	3(5.8%)	6(11.5%)	
Gender	Male	32(61.5%)	39(75.0%)	0.140
	Female	20(38.5%)	13(25.0%)	
Educational status	Illiterate	7(13.5%)	14(26.9%)	0.101
	Up to 10th std	27(51.9%)	20(38.5%)	
	11th-12th	5(9.6%)	10(19.2%)	
	Graduate	13(25.0%)	8(15.4%)	
Marital status	Unmarried	15(28.8%)	11(21.2%)	0.169
	Married, living together	32(61.5%)	26(50.0%)	
	Married, living separately	3(5.8%)	7(13.5%)	
	Married, divorced	1(1.9%)	4(7.7%)	
	Widow/widower	1(1.9%)	4(7.7%)	
Age of onset	< 35 years	19(36.5%)	9(17.3%)	0.085
	36- 59 years	27(51.9%)	36(69.2%)	
	> 60 years	6(11.5%)	7(13.5%)	
Number of episodes	1episode	0(0.0%)	3(5.8%)	0.145
	2episode	18(34.6%)	13(25.0%)	
	>=3episodes	34(65.4%)	36(69.2%)	
Previous hospitalisations	No hospitalisation	7(13.5%)	6(11.5%)	0.594
	1 hospitalisation	9(17.3%)	5(9.6%)	
	2 hospitalisations	15(28.8%)	19(36.5%)	
	>=3hospitalisations	20(38.5%)	22(42.3%)	
Polarity of previous episodes	1 Depressive episode	1(1.9%)	0(0.0%)	0.373
	1 Manic episode	4(7.7%)	6(11.5%)	
	Depression = Mania	18(34.6%)	14(26.9%)	
	Depression > Mania	11(21.2%)	7(13.5%)	
	Mania > Depression	12(23.1%)	12(23.1%)	
	>=2 mania episodes	6(11.5%)	13(25.0%)	
Psychotropics	No drugs	23(44.5%)	13(25.0%)	0.982
	Typical antipsychotics	7(13.5%)	15(28.8%)	
	Atypical antipsychotics	19(36.5%)	21(40.4%)	
	Antidepressants	2(3.8%)	2(3.8%)	
	Benzodiazepines	1(1.9%)	1(1.9%)	
Duration of Mood Stabilizer	<6months	1(1.9%)	0(.0%)	**0.001**
	6months-1year	7(13.5%)	1(1.9%)	
	1- 2years	5(9.6%)	20(38.5%)	
	>2years	39(75.0%)	31(59.6%)	

There was no significant difference between the two groups in socio-demographic variables (Table 1) such as age (p=0.392), gender (p=0.14), educational qualification (p=0.10) and marital status (p=0.17).There is no statistical significance among the confounding variables such as; age of onset (p=0.085), number of episodes (p=0.145), previous hospitalisations (p=0.594), polarity of episodes (p=0.373), psychotropics (p=0.982). Between the two groups, the duration of illness (p=0.001) was the only confounding variable which was significant between the two groups. The number of mood episodes that occurred was; among Lithium group patients 13 had manic episodes and 8 had depressive episodes. Among *Divalproate sodium group* patients 12 had manic episodes and 6 had depressive episodes. In both the groups' manic episodes were more common than depressive episodes.

For a manic episode relapse; in the *Lithium group*, 39 patients had no episodes of mania, 5 patients developed mania in less than three months, 4 patients between three to six months and 4 patients between six to nine months. In the *Divalproate sodium group*, 40 patients had no episodes of mania, 2 patients developed mania in less than three months, 3 patients between three to six months, 3 patients between six to nine months and 4 patients between nine to twelve months. The time taken for manic episode was not statistically significant between Lithium and *Divalproate sodium group* (p=0.339). For a depressive episode to occur; in the *Lithium group*, 45 patients had no episodes of depression, 2 patients developed depression between three to six months, 2 patients between six to nine months and 3 patients between nine to twelve months. In the *Divalproate sodium group*, 46 patients had no episodes of depression, 1 patient developed depression in less than three months, 3 patients between three to six months and 2 patients between nine to twelve months. The time taken for depressive episode was also not statistically significant between Lithium and *Divalproate sodium group* (p=0.240).

Comparison of severity of manic episode between Lithium and *Divalproate sodium group* using YMRS

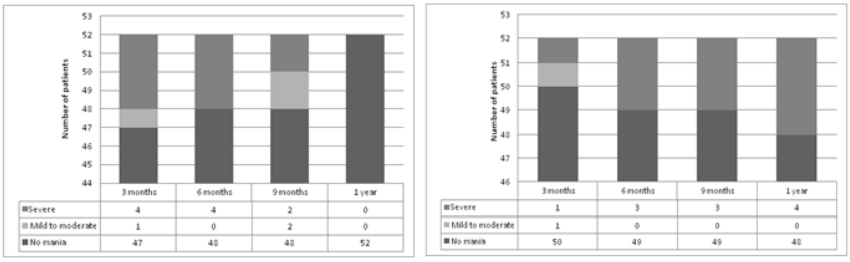

Figure 2A: Figure 2B:

Figure 2 A: Severity of mania in patients taking Lithium; **Figure 2B:** Severity of mania in patients taking Divalproate sodium

The severity of mania was assessed using The Young Mania Rating Scale (YMRS) in Figure2. Patients who are taking Divalproate sodium had more severe manic episode at the end of one year when compared to patients taking Lithium (4 patients v/s none – p=0.041), but the comparison was not significant during initial 3 follow ups at 3, 6 and 9 months (p=0.388, 0.696, 0.331 respectively)

Comparison of severity of depressive episode between Lithium and *Divalproate sodium group* using HDRS:

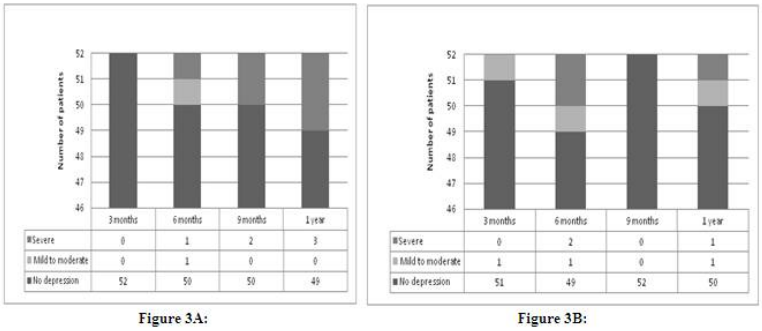

Figure 3A: Figure 3B:

Figure 3A: Severity of depression in patients taking Lithium; **Figure 3B:** Severity of depression in patients taking Divalproate

The severity of depression was assessed using Hamilton Depression Rating Scale (HDRS) in Figure 3. On comparison with patients who are taking Lithium and Divalproate sodium. There was no statistically significant difference in the severity of depressive episode during all four follow ups (3rd, 6th, 9th and 12th month periodic evaluation; p = 0.315, 0.842, 0.153, 0.366 respectively).

Table 2: Suicidal risk assessment between Lithium and *Divalproate sodium group* using Modified SADPERSONS Scale

Groups	No risk	Moderate risk	Severe risk	p Value
		At Baseline		
Lithium	37 (71.2%)	15 (28.8%)	0	
Divalproate sodium	35 (67.3%)	17 (32.7%)	0	0.671
		During *3 months* follow-up		
Lithium	35 (67.3%)	14 (26.9%)	3 (5.8%)	
Divalproate sodium	34 (65.4%)	18 (34.6%)	0	0.173
		During *6 months* follow-up		
Lithium	39(67.3%)	9(26.9%)	4(7.7%)	
Divalproate sodium	34(65.4%)	15(28.8%)	3 (5.8%)	0.371
		During *9 months* follow-up		
Lithium	42(80.8%)	8(15.4%)	2(3.8%)	
Divalproate sodium	40(76.9%)	9(17.3%)	3 (5.8%)	0.857
		During *12 months* follow-up		
Lithium	47(90.4%)	3(5.8%)	2(3.8%)	
Divalproate sodium	38(73.1%)	9(17.3%)	5 (9.6%)	**0.073**

Modified SADPERSONS scale was applied to assess suicidal risk. The severity of suicidal risk scale (Table 2) was not statistically significant during initial and all four follow-ups, but was trending towards significance during the 12th month follow-up (baseline, 3rd, 6th, 9th and 12th month periodic evaluation; p=0.671, 0.173, 0.371, 0.857, 0.0 respectively) In the Lithium group of patients; 4 (7.7%) had no follow-up, 5 (9.6%) have followed-up once, 8 (15.4%) have followed-up twice, 10 (9.2%) have followed-up thrice and 25 (48.1%) have been completely followed-up till the end of one year. In the *Divalproate sodium group* of patients; 5 (9.6%) had no follow-up, 4 (7.7%) have followed-up once, 8 (15.4%) have followed-up twice, 13 (25%) have followed-up thrice and 22 (42.3%) have been completely followed-up till the end of one year. Among 104 recruited patients, 25 patients of Lithium group had completed all four follow-ups as compared to 22 patients of *Divalproate sodium group*. But on comparison between the two groups, they were not statistically significant (p=0.938).

Table 3: Adverse effects of the treatment

Groups	No drug reaction	Minimal reaction	More reaction	p value
		At Baseline		
Lithium	28(53.8%)	24(46.2%)	0	
Divalproate sodium	24(46.2%)	26 (50%)	2(3.8%)	0.303
		During *3rd month*follow-up		
Lithium	23(44.2%)	29(55.8%)	0	
Divalproate sodium	24(46.2%)	23(44.2%)	5(9.6%)	0.057
		During*6th month* follow-up		
Lithium	27(51.9%)	25(48.1%)	0	
Divalproate sodium	26 (50%)	24(46.2%)	2(3.8%)	0.361
		During *9th month* follow-up		
Lithium	30(57.7%)	22(42.3%)	0	
Divalproate sodium	35(67.3%)	16(30.8%)	1(1.9%)	0.312
		During *12th month* follow-up		
Lithium	42(80.8%)	10(19.2%)	0	
Divalproate sodium	39(75.0%)	11(21.2%)	2(3.8%)	0.340

The adverse drug effect (categorised as nausea, diarrhoea, tremors, weight gain, sedation, polydipsia, polyuria, tachycardia, alopecia, any major skin lesions, hypothyroid symptoms, signs of renal dysfunction) profile (Table 3) was the same between Lithium and *Divalproate sodium group* during all four visits except during initial follow up (3months) in which Lithium group was better than *Divalproate sodium group* (five patients on *Divalproate sodium group* had >=3 adverse drug reaction compared to none in the Lithium group), which was statistically significant.

Table 4: Global Assessment Functioning

Groups	Good functioning	Mild impairment	Moderate impairment	Severe impairment	p value
		At *Baseline*			
Lithium	51 (98.1%)	1 (1.9%)	0	0	0.315
Divalproate sodium	52 (100%)	0	0	0	
		During *3rd month* follow-up			
Lithium	46(88.5%)	2(3.8%)	3(5.8%)	1(1.9%)	0.553
Divalproate sodium	49(94.2%)	2(3.8%)	1(1.9%)	0	
		During *6th month* follow-up			
Lithium	46(88.5%)	1(1.9%)	3(5.8%)	2(3.8%)	
Divalproate sodium	46(88.5%)	2(3.8%)	2(3.8%)	2(3.8%)	0.912
		During *9th month* follow-up			
Lithium	46(88.5%)	2(3.8%)	3(5.8%)	1(1.9%)	
Divalproate sodium	49(94.2%)	0	1 (1.9%)	2(3.8%)	0.330
		During *12th month* follow-up			
Lithium	49(94.2%)	0	3(5.8%)	0	
Divalproate sodium	46(88.5%)	0	2(3.8%)	4(7.7%)	0.117

On assessment of social, psychological and occupational functioning by using GAF scale (Table 4). During the initial follow ups Lithium group patients had more functional impairment than *Divalproate sodium group* patients (initial and 3rd follow up). During 6th month follow up two patients in each group had severe impairment. During 9th month and 1year follow up, *Divalproate sodium group* had more severe functional impairment than Lithium group, but was not statistically significant.

□ □□ □□r□□□□□□□□□□ □□ □□d□□□□d□□□ □□□□□r□□□□□r□□ □ □ □□□□□ □□□□□□We also calculated the patients who developed a new manic/depressive episode with varying serum Lithium level. Out of thirteen new episodes manic patients, six had a lower serum Lithium level (<0.8 mEq/L), five patients had serum Lithium level of 0.8-1.2 mEq/L and only two patients had serum Lithium level >1.2mEq/L. Likewise majority of new onset depression episode patient, four out of eight patients had a lower serum Lithium level (<0.8 mEq/L), three patients had serum Lithium level of 0.8-1.2 mEq/L and only one patient had serum Lithium level >1.2mEq/L.□

□ □□ □□r□□□□□□□□□□ □□ □□d□□□□d□□□ □□□□□r□□□□d□□□□□ □□□□ □□□□□r□□□□□□d□□□ □□Among the *Divalproate sodium group* patients, only three out of twelve patients were on adequate dose (more than 1.5gm), had new onset mania. None of the *Divalproate sodium group* patients had new onset depression that is on adequate dose (all six patients who had new onset depression were on sub-therapeutic dose).

□□□□ □ □□□□ □

In our prospective study of one year duration, we compared the mood stabilising effect of Lithium and Divalproate sodium in euthymic bipolar patients. The socio-demographic and confounding variables did not differ between the two groups except that the Lithium group patients had longer duration of treatment than those treated with Divalproate sodium. As a primary outcome of the study, we compared the frequency of manic and depressive episode between two groups. There were similar number of episodes and the predominant mood episode was mania in both the groups. The above finding could also be because the polarity of previous episode in both the groups was predominantly mania. During the period of 9th to12th month follow up, Divalproate sodium had more manic episodes. The above finding emphasises Lithium to be a better long term mood stabiliser than Divalproate sodium. Previous studies have shown that Lithium treatment reduces the risk of relapse in bipolar disorder. The preventive effect is clear for manic episodes, although it is equivocal for depressive episodes.[5] Lithium appears to be the most effective treatment to prevent recurrence or relapse of bipolar disorder and may prolong the time before adjunctive prescribing is necessary.[28] This finding is further supported by the result of recent meta-analysis[29] suggest that Lithium is superior in prevention of manic episodes, in comparison to anticonvulsants. However, there was no significant difference regarding prevention of overall mood episodes, depressive episodes or study completion. Based on the severity of mood episode; patients on Divalproate arm, had more severe manic episodes as the duration of follow up increased. This again emphasises that Lithium is a better anti-manic agent for long-term therapy. But, the frequency and severity of depressive episodes did not differ between both the groups. On comparison of suicidal risk, bipolar patients who were on Lithium had lower suicidal risk than Divalproate patients, especially with prolonged duration of treatment. Both Lithium and *Divalproate sodium group* patients had almost equal follow ups and were equally adherent to

Copyright © 2019, Medpulse Publishing Corporation, MedPulse – International Journal of Psychology, Volume 10, Issue 2 May 2019

treatment. Two patients on Lithium were switched to Divalproate sodium as they had severe skin reaction which affected the study adherence. Adverse effect profile did not differ during initial and periodic assessment between the two groups. Bipolar patients on Divalproate sodium had more adverse effects during initial follow ups, which were not seen during further follow up. Global assessment of functioning was done considering psychological, social and occupational functioning on a hypothetical continuum of mental-health illness. Patients on *Divalproate sodium group* had more severe impairment in functioning, than patients in Lithium group. The serum Lithium level was less than adequate in majority of new onset manic/depressive episode patients, signifying that majority of the patients who developed new onset manic/depressive episode were on sub therapeutic dose. Further emphasising the relationship between plasma levels of the drug and relapse prevention.

Our sample size was smaller and hence the results cannot be generalised. Telephonic assessments for patients, who missed follow ups, cannot be considered as reliable as face to face interview. Use of other psychotropics (antipsychotics, benzodiazepines) was allowed. We know that medication like Olanzapine, Risperidone and Quetiapine can have a mood stabilising effect, which could have affected the outcome of the study. A follow-up more than 1 year is needed in order to strongly support our finding that, bipolar patients on Lithium were better than Divalproate sodium in preventing the manic episode.

Bipolar patients on Lithium had lesser frequent and less severity of manic episode over one year follow up. The frequency of depressive episode was similar between the Lithium and *Divalproate sodium group*s. Lithium exhibited better anti-suicidal properties. Lithium continues to be a gold standard in spite of certain cutaneous side effects establishing its seven decades of dominance as a mood stabilizer agent. In addition, long-term use of Lithium also ensures better quality of life.

r SU and SA designed this study. SA managed the data collection. SU, SA and KSR analysed the data. KSR wrote the draft of the manuscript under the supervision of SU and SA. All authors contributed to and have approved the the final manuscript.

Lithium has been used in the treatment of mood disorders but its use is limited for its narrow therapeutic window and renal dys function. We aimed to correlate severity of renal dysfunction with duration of lithium therapy and serum lithium levels. We also analysed patients with Lithium induced renal dysfunction with normal creatinine values, but with abnormal eGFR. **M** **d** We included Bipolar patients who are on atleast 2 years of Lithium therapy & with minimum of 2 serum Creatinine values during treatment, baseline & 6months post-baseline. We recruited 906 patients, only 55 patients qualified for our inclusion criteria. We had 110 creatinine values & we calculated eGFR based on Modification of Diet in Renal Disease study group formula. We correlated duration of lithium therapy, serum lithium levels with average S.Creatinine levels and average eGFR. There was no correlation between duration of lithium treatment with average serum creatinine values (r = -0.17) or average eGFR (r = +0.24).There was no correlation between serum lithium levels with average serum creatinine values (r = -0.04) and average eGFR (r = -0.06).Among 19 patients with high serum creatinine values , almost all except one had Grade 2 renal dysfunction eGFR value Neither the duration of lithium therapy (upto 17 years) , nor serum lithium levels correlated with renal dysfunction. Fifteen percent of patients with normal creatinine levels had early renal dysfunction on eGFR, indicating probably eGFR as an early indicator than creatinine.

Introduction

Lithium has been used in the treatment of mood disorders for several decades. But its use is limited for its narrow therapeutic window and multiple systemic side effects. Various studies were done to find the relationship between the serum lithium levels, duration of therapy, and dosage of lithium carbonate with its clinical responses. Among the available psychotrophics, Lithium remains a key drug especially in maintenance therapy. Lithium needs regular monitoring of serum lithium levels and renal dysfunction because of its narrow therapeutic window, as it is excreted nearly exclusively through the kidneys. The effect on Lithium induced renal dysfunction remains a controversy for more than four decades. Histopathological changes have been demonstrated way back in 1977, concluding chronic renal disease may develop only in patients with renal concentration of lithium reaches toxic level- either periodically or continuously.[1]

The duration of lithium treatment and cumulative dose has been suggested as major determinants of nephrotoxicity, but were only from small case series with

A comparative study of effects on working and logical memory in psychiatry patients receiving combined electroconvulsive therapy with pharmacotherapy and pharmacotherapy only. *MedPulse – International Journal of Psychology*. June 2019; 10(3): 19-23. http://www.medpulse.in

multiple methodological issues.[2,3] Previous meta- analysis have shown poor quality, emphasizing the need for large scale studies. [4,5] In the study by Stephen Clos *et al*, no effect was found on rate of eGFR change over time in euthymic BPAD patients on Lithuim maintenance therapy.[6] Lithium causes a modest decline in renal function. However, the available research suggests that ESRD is a very rare complication of long-term lithium treatment, affecting ~1% of patients who have taken lithium for over 15 years.[7] With this above background, we planned for a study aiming for correlation of severity of renal dysfunction with duration of lithium therapy and serum lithium levels. We also did a correlation between socio-demographic variable and severity of renal dysfunction. We also analysed patients with Lithium induced renal dysfunction with normal creatinine values, but with abnormal eGFR.

M□□□□□□□

We included patients with bipolar affective disorder who are on atleast 2 years of Lithium therapy & with minimum of 2 serum Creatinine values during the treatment, one at baseline & atleast one after>= 6 months post-baseline. We excluded patients who were on short duration of lithuim treatment (< 2 years) or who had only one/no serum creatinine value. We also excluded patients who were on not on follow-up at PSG. We retrieved 1296 Serum lithium values of Bipolar affective disorder patients from PSG Hospitals MRD records (2013 – 2017). 522 values were repeat serum lithium values of same patient. Hence 774 patients with all the available lithium values were included. 295 patients excluded , as they were all inpatients and they had another out-patient file. Among the remaining 499 patients, 339 patients were excluded (160 patients were left), as they had one or no serum creatinine value.105 patients were excluded as they did not have serum creatinine values both at baseline and 6months post-baseline. Finally, 55 Patients were analysed for the study. We had 121□creatinine values & we calculated corresponding eGFR based on Modification of Diet in Renal Disease (MDRD) study group formula,[8] eGFR (mL × min^{-1}× [1.73 m^2] $^{-1}$)= 175 × (S_{Cr} standardized [mg × dL^{-1}]) $^{-1.154}$× (age [years])$^{-0.203}$Correction factor: for women × 0.742 for blacks × 1.18 186 x [Plasma Creatinine (µmol/L) x 0.0011312] $^{-1.154}$ x [age (years)] $^{-0.203}$ x [0.742 if female] x [1.212 if black] The following categories of eGFR were considered, as per KDOQI criteria. [9] Grade 1 -> 90 ml/min/1.73 m^2: Grade 2 – 60 to 89 ml/min/1.73 m^2: Grade 3a – 45 to 59 ml/min/1.73 m^2: Grade 3b–30 to 44 ml/min/1.73 m^2: Grade 4– 15 to 29 ml/min/1.73 m^2 : Grade 5–<15 ml/min/1.73 m^2.We analyzed baseline socio-demographic variables , namely, age & sex .We categorized age into adolescence, adults & geriatric population. We also analysed the co-morbidities, duration of follow-up after initiation of study, serum Lithium Level, total serum Creatinine values & total eGFR values. We correlated duration of lithium therapy with patients average S.Creatinine levels and average eGFR. We also correlated serum lithium levels with patients average S.Creatinine levels and average eGFR. We compared patient's serum creatinine level and the corresponding eGFR. We analysed patients having normal serum creatinine (<=1 mg/dl) values with patients having abnormal eGFR.

□□□□□□□□□□□□□□□□□□□□□□□□We analysed duration of lithium therapy, serum lithium levels, average serum creatinine levels , eGFR as a continuous measures. We used Pearsons correlation co-efficient to correlate duration of lithium therapy, serum lithium levels with serum creatinine and eGFR. If the r value is +1, it means a positive correlation and if it is1, it means a negative correlation. We also tabulated normal serum creatinine (<=1 mg/dl) values with abnormal eGFR in varying ranges.

□□□□□□□□

Majority of the patients were men & in adult age group. Majority of patients followed upto 5 years & more than two-fifth followed up more than 5 years. Diabetes was the commonest co-morbidity. Six percentage of patients had serum lithium level in toxic range. Seventeen percentage of patients had serum creatinine value more than one. Thirty percentage of patients had eGFR less than 90.

Table 1: Socio-demographic variables at baseline and Lithium parameters

Socio-demographic parameters & Lithium variables			Mean
Age(yrs)	<18	1 (1.8%)	44.93
	18-65	50 (90.9)	
	>65	4 (7.3)	
Sex	Male	32 (58.2)	-
	Female	23 (41.8)	
Duration of Lithium(yrs)	<2	0(0%)	
	2-5	32 (58.1%)	5

Co-morbidity	>5	23 (41.9%)	-
	DM	11 (20%)	
	HT	1 (1.8%)	
	DM & HT	4 (7.3%)	
	CVA	1 (1.8%)	
	Nil	38 (69.1%)	
Duration of Follow-up after initiation of study(yrs)	<2	2(3.6%)	3.2
	2-5	53 (96.4%)	
Average serum Lithium Level(mg/dl)	<0.8	27 (49.1%)	0.75
	0.8 – 1.2	24.5 (44.1%)	
	>1.2	3.5 (6.4%)	
Total Serum Creatinine values	≤ 1	91 (82.8%)	0.78
	>1	19(17.2%)	
Total eGFR values	≥90	77 (70%)	102
	60-89	32 (29%)	
	45-59	1 (1%)	

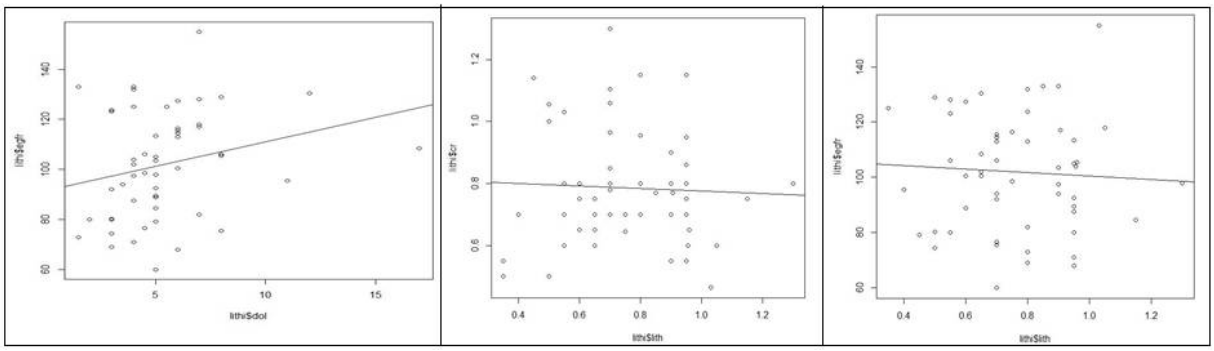

Figure 1 **Figure 2** **Figure 3**

Figure 1: Pearsons Correlation curve comparing duration of Lithium therapy with average serum creatinine values: **Figure 2:** Pearsons Correlation curve comparing serum lithium levels with average serum creatinine values; **Figure 3:** Pearsons Correlation curve comparing serum lithium levels with average estimated Glomerular filtration rate

Figure 1, The above curve denotes no correlation between duration of lithium treatment with average eGFR (r =+0.24).
Figure 2, The above curve denotes no correlation between serum lithium levels with average serum creatinine level (r = -0.04).
Figure 3, The above curve denotes no correlation between serum lithium levels with average eGFR (r = -0.06).

Table 2: Comparison of patients with normal creatinine levels with low eGFR

Sr. No	Sr. Creat. Values (mg/dl)	eGFR Values (ml / min / 1.73 m²)
1	0.8	76
2	0.8	77
3	0.8	80
4	0.8	74
5	0.8	74
6	0.8	80
7	0.9	77
8	1.0	87
9	0.9	85
10	0.7	86
11	1.0	85
12	0.8	68
13	0.9	89
14	0.8	72
15	0.98	87

Among 102 (102 / 121) normal serum creatinine values, 15 serum creatinine values (14.7 %) had low corresponding eGFR values.

Table 3: Comparison of patients with high creatinine levels with eGFR values.

Sr .No	Sr. Creat. Values (mg/dl)	eGFR Values (ml / min / 1.73 m²)
1	1.01	79
2	1.09	72
3	1.24	63
4	1.02	66
5	1.10	75.9
6	1.20	64
7	1.03	79
8	1.09	72
9	1.01	82
10	1.21	64
11	1.38	60
12	1.36	**57**
13	1.20	66
14	1.11	75
15	1.10	74
16	1.09	74
17	1.02	77
18	1.05	78

All the patients, except one had Grade 1 renal dysfunction, eGFR between 60 to 98.

□

□□□□□□□□□□

We did a retrospective study on effect of lithium levels and duration of lithium therapy on renal dysfunction. Majority of the recruited were adult men with diabetes as the common co-morbidity. The duration of lithium therapy, did not correlate with renal dysfunction in-terms of serum creatinine values. Three patients were on treatment for more than ten years, one for even seventeen years. The corresponding eGFR values also did not correlate with duration of lithium therapy. Previous studies and meta-analysis also concluded the same result. In the study by Stefan Clos *et al*, both, duration of exposure to lithium and mean serum lithium level were not significant predictors for eGFR decline. Our study also reveals serum lithium level (which is a marker of adequacy of lithium dose), did not correlate with renal dysfunction, either by creatinine levels or eGFR levels. Previous studies have shown that exposure to lithium (in the absence of episodes of toxicity) is a causal factor and the length of lithium exposure as a predictor of renal dysfunction.[10,11] In contrary, our study did not show correlation. A large UK community sample study by Miney *et al*[12] had a short observation period of 2 years and did not analyse longitudinal changes. In our study patients were on lithium, even for 17 years and the mean duration of lithium was five years. In a UK cohort study, Close and colleagues 13 used diagnostic codes for adverse renal outcomes rather than eGFR. We preferred eGFR as an indicator of renal dysfunction as it is a better predictor than serum creatinine. In an observational study by, Aprahamian and colleagues,[14] a single-blind follow-up study , no significant change in renal function of elderly patients after 4 years of chronic low-dose lithium use , as evidenced by our study. About fifteen patients (15 %), with normal creatinine levels had low eGFR values, indicating eGFR could pick-up renal dysfunction early. Among 19 patients with high serum creatinine values, almost all except one had Grade 2 renal dysfunction eGFR value .A single patient had grade 3 renal dysfunction 9 (eGFR –57).Our study limitations are , retrospective study design which has its own critics. The sample size was small and hence results can't be generalized. Mean duration on lithium was five years; a longer study would be of more credit. We could have had a control population, with which we would have analyzed in a better way. Our study was an observational study , hence only the available creatinine & lithium level were used for analysis.Almost one-third of patients had a co-morbid physical illness , disorders like diabetes and hypertension is known to cause renal dysfunction. Cockcroft-Gault equation is well suited for estimation of GFR changes during pharmacotherapy, instead we used MDRD equation, which is applied in adults with chronic renal disease. The National Kidney Foundation grades chronic kidney disease based on kidney damage (for ≥ 3 months, as defined by structural of functional abnormalities of the kidney, with or without decreased GFR, manifest by either : Pathological abnormalities; or markers of kidney damage, including abnormalities in the composition of the blood or urine, or abnormalities in imaging tests) and eGFR. In our study, we used only eGFR as an indicator of renal dysfunction. The strengths of our study are, we had a strict inclusion criteria, thereby excluded patients an acute phase of lithium treatment

(less than two years of treatment). We included patients only with post-baseline creatinine levels, atleast after 6 months, hence had a minimum renal exposure to lithium.

□□□□□□□□□□

In our study, neither the dosage (analysed with serum lithium level), nor the duration of lithium treatment, caused renal dysfunction. Hence, clinicians prescribing lithium need not be anxious on renal parameters, but need to monitor as per guidelines. We would also recommend clinicians to monitor eGFR than creatinine, to identify renal dysfunction early.

ABSTRACT

Background: Specific learning disorder in general called as dyslexia is a neuro developmental disorder, which occurs more commonly in males (Male:Female ratio is 4:1), there are evidence to suggest role of prenatal gonadal hormone exposure in neurodevelopment. However, studies on association between 2nd to 4th digit ratio and dyslexia are mixed. Objective: To compare the 2nd and 4th digit ratio (2D:4D) of both hands between children with dyslexia and children without dyslexia.
Methodology: A case control study, recruited 30 children with dyslexia and 30 age and education matched normal controls, after getting informed consent from their parents. Collected socio demographic details, applied CARS, Schonell's reading and spelling test, followed by detailed evaluation by psychiatrist and clinical psychologist, including psychological testing to confirm the diagnosis of dyslexia. The digit length of index and ring finger on both hands of all children were measured using Vernier Calliper by direct method.
Results: In both the hands 2D:4D ratio was more in children with dyslexia than normal children, but the difference was not significant (p – 0.146). Analysis of only male samples showed digit ratio is higher in dyslexic children than normal children; which were significant (p – 0.03).
Conclusion: Our study does not support an association between digit ratios and dyslexia; however, trend towards higher ratio in dyslexia especially in male children are interesting and needs further exploration. Need more studies in this area to form a definite conclusion.

Keywords: Dyslexia, Specific learning disorder, Digit ratio, 2D:4D, Biomarker.

INTRODUCTION

Dyslexia is a neuro - developmental disorder, Prevalence of dyslexia ranges from 4 % to 17%. The prevalence is higher in males (Male: Female ratio is 4:1),[1]. This suggests there could be some factors that is different in either sex which plays a role in the development of this disorder. The neurobiology of dyslexia remains largely unknown but evidence suggests that neuronal migration and axon guidance pathways may be disrupted in dyslexia [2].

Normal brain is sexually dimorphic, due to the influence of gonadal hormones on neurodevelopment during antenatal period. Aberrations in neurodevelopment due to gonadal hormonal imbalance are one of the mechanisms for developing dyslexia. The relation between imbalance in gonadal hormones and dyslexia is very complex.

The absence of testosterone leads the central nervous system to develop passively, in a primarily female fashion, while the presence of testosterone induces the masculinization of the brain, indicating that the sexual dimorphism of the brain is mediated by the epigenetic action of gonadal steroids [3]. Geschwind and Galaburda suggested that testosterone inhibited the growth of certain areas of the left hemisphere and

facilitated the growth of the same areas in the right hemisphere. As a result, language skills would be negatively affected and hand preference would tend to shift toward the left. In extreme forms, this abnormal cortical development would render an individual incapable of handling effectively the linguistic tasks required for reading and writing [4]. Ramus, based on animal studies demonstrated that rodents with induced ectopias and microgyri exhibit learning deficits. Focal cortical abnormalities in specific areas of left perisylvian cortex are the primary cause of dyslexia. When foetal testosterone exposure is high, cortical disruption propagates to the thalamus, provoking additional sensory impairments as a consequence of the conjunction of high fetal testosterone exposure and ectopias or microgyri [5]. A study showed high prenatal testosterone may impair developing auditory perceptual processes and phonological processing in the left hemisphere. These impairments in phonology in turn can adversely affect development in reading [6].

But it's not possible to measure the prenatal gonadal hormone exposure directly. Hence, we need to evaluate it indirectly using an indicator which could predict gonadal hormones concentration in utero. The digit ratio is the ratio of the lengths of different digits, typically as measured from the basal / proximal crease of the finger to the tip of the finger. Androgen and Estrogen differentially regulate the network of genes that controls condrocyte proliferation, leading to differential growth of digits in males and females [7].

The ratio between the length of the 2nd and 4th digits is: (a) fixed in utero; (b) lower in men than in women; (c) negatively related to testosterone and sperm counts; and (d) positively related to estrogen concentrations [8]. 2D:4D ratio may be used as an indicator and predictive factor in a variety of disorders associated with a disturbed testosterone/estrogen hormone balance like Gender identity disorder, Autism, Dyslexia, Migraine, Stammering, Immune dysfunction, Infertility [8].

The existing literature shows mixed results regarding the relation between digit ratio and dyslexia; there is also ongoing debate whether 2nd digit to 4th digit ratio is a reliable indicator of prenatal gonadal hormones exposure. Few researchers even question the proposed role of gonadal hormones in the development of dyslexia. This is an interesting area and has a wide scope for research. There are many studies on digit ratio in autism, but only very few studies in dyslexia. Hence this study is planned to examine the relationship between 2nd digit to 4th digit ratio and dyslexia. A reliable finding in this area of research would have a very significant clinical implication; this has prompted us to carry out this study.

The objective of the study was to compare the 2^{nd} to 4^{th} digit ratio (2D:4D) of both hands between children with dyslexia and children without dyslexia.

METHODOLOGY

Hypothesis

Children with specific learning disability (Dyslexia) will have smaller 2^{nd} digit to 4^{th} digit ratio compared to children without dyslexia.

Subjects and Procedure

We screened all children aged between 5 and 18 years old, who attended psychiatric outpatient department in PSG institute of medical sciences and research, between May 1st 2014 and July 31st 2014. PSG institute of medical sciences and research is a tertiary care general hospital. A final year MBBS student who got trained in applying Schonell reading test, Schonell spelling test and Childhood Autism Rating Scale administered these tests on all children. All children were evaluated in detail by a psychiatrist; the diagnosis of dyslexia and the type of dyslexia was confirmed only after further psychological testing by the child psychologist. We consecutively recruited 30 children with dyslexia who fulfilled the inclusion and exclusion criteria.

Control group had 30 age and education matched children who visited hospital for non psychiatric problems or were recruited from the community. Control group didn't had any academic difficulties or psychiatric problem according to parents, Schonell reading test, Schonell spelling test and childhood autism rating scale was administered to all children in control group as well, child suspected to have dyslexia or autism were referred to psychiatry for further evaluation.

Children were included in the study after getting informed consent from their parents and only if the child was willing to participate in the study. Children with autism, Asperger's syndrome, mental retardation,

attention deficit hyperactivity disorder, schizophrenia, medical or surgical condition which would interfere with measurement of digit length e.g., contractures, trauma, amputation etc, were excluded from the study. Children who were recruited for the study, the length of their index finger and ring finger (from the basal crease to the tip of the finger) of both the hands is measured using Vernier Calliper by direct method, which is an accurate as well as easy method to measure the digit length [9].
The study was approved by Institutional human ethics committee, PSG institute of medical sciences and research.

Materials

1. **Semi structured proforma:** This Proforma is used to get basic details of the cases and controls. It includes the name, age, sex, education medium, syllabus, socio economic status, height, weight, IQ, co morbidity.
2. **Childhood Autism Rating Scale (CARS):** It is a tool for assessing autism. This is scored based on the interview with the primary care giver and observation of the child. The child is diagnosed as having autism if they score above 30 [10].
3. **Schonell reading test:** A reading test that determines the reading age, however it does not test reading comprehension. The reading age is calculated from the number of words read correctly and compared to the student's chronological age to see if the student is reading at the level for their age, or are reading either below or above level for their age [11].
4. **Schonell spelling test:** A spelling test that determines the spelling age. It comprises of 100 words, and the child is asked to write 30 words (applicable for their class).The spelling age is calculated from the number of words wrote correctly and compared to the student's chronological age to see if the student is writing at the level for their age, or are writing either below or above level for their age [12].

STATISTICAL ANALYSIS

Statistical analysis was done using the Statistical package for social sciences (SPSS) version-18. Continuous variables were assessed using the unpaired t-test and categorical variables were assessed using the chi-square test. P value of less than 0.05 is considered as statistically significant.

RESULTS

Table 1 – Socio-demographic variables

		CASE (N=30)	CONTROL (N=30)	p Value
Age (Mean, SD) in years		11.60 ± 3.328	13.40 ± 2.568	0.092
Education (Mean, SD) in years		6.90 ± 2.998	8.50 ± 2.610	0.470
Sex	**Female**	3	18	0.001
	Male	27	12	
Medium	**English**	28	27	0.640
	Tamil	2	3	
Syllabus	**CBSE**	1	29	0.313
	Samachir	0	30	
SES	**Lower middle**	0	6	0.010
	Upper middle	27	24	
	Upper	3	0	

The mean age of cases and controls were 11.6 years and 13.4 years respectively, the difference in age between the 2 groups was not statistically significant. There is no statistical difference between the 2 groups on other socio demographic profiles like education, medium, syllabus and socioeconomic status. Most of the children

on either group were from upper middle socioeconomic class, studied in English medium and their syllabus was samachir, which is the most popular syllabus in the state of Tamil Nadu, India.
The children with dyslexia were predominantly males (90% of the cases) were as in control group only 40 % were males; this was statistically significant (p = 0.001).

Table 2: 2D:4D ratio between male and female children

Male Vs Female (n-39) (n-21)		t	df	Sig. (2-tailed)	Mean Difference	95% CI of Difference	
						Lower	Upper
Rt hand 2D:4D	Equal variances assumed	-0.761	58	0.450	-0.01239	-0.04498	0.02020
	Equal variances not assumed	-0.674	29.596	0.506	-0.01239	-0.04994	0.02517
Lt hand 2D:4D	Equal variances assumed	-0.761	58	0.450	-0.01239	-0.04498	0.02020
	Equal variances not assumed	-0.674	29.596	0.506	-0.01239	-0.04994	0.02517

Taken all 60 children together and divided them into 2 groups based on sex, male children had lower 2nd to 4th digit ratio on either hand when compared to controls, shown in (table 2), but the difference is not significant (p = 0.506).

Table 3: 2D:4D ratio between SLD and control groups

SLD Vs Control (n-30) (n-30)		t	Df	Sig. (2-tailed)	Mean Difference	95% CI of Difference	
						Lower	Upper
Rt hand 2D:4D	Equal variances assumed	1.490	58	0.142	0.02283	-0.00784	0.05349
	Equal variances not assumed	1.490	33.222	0.146	0.02283	-0.00833	0.05398
Lt hand 2D:4D	Equal variances assumed	1.490	58	0.142	0.02283	-0.00784	0.05349
	Equal variances not assumed	1.490	33.222	0.146	0.02283	-0.00833	0.05398

The comparison of 2nd to 4th digit ratio using independent t test between children with dyslexia and normal children showed that the mean digit ratio on both hands is more in children with dyslexia than normal children, which is in contrary to our hypothesis, however this was not statistically significant (p = 0.146). Our sample predominantly contained children with writing disorder (23/30 children). So, we decided to compare the 2D: 4D ratios between children with writing disorder only and controls.
As shown above in (table 4) the 2nd digit to 4th digit ratio in both right and left hand was higher in children with writing disorder than control group, but this again was not significant (p = 0.134). The sub-analysis comparing children with writing disorder and controls yielded a result similar to dyslexia group in general. Since the number of children with reading and mathematics disorder were very few, it was not possible to do a separate analysis on them. As dyslexia is more common in males and testosterone is expected to play a major role, a separate analysis was done comparing the digit ratio between male children with and without dyslexia.
The 2nd to 4th digit ratio on either hand was higher in male children with dyslexia compared to male children without dyslexia; the difference was statistically significant with a p value of 0.03. This is shown in (table 5).

Table 4: 2D:4D Ratio between dysgraphia children and controls

Dysgraphia Vs Control (n-23) (n-30)		T	Df	Sig. (2-tailed)	Mean Difference	95% CI of Difference	
						Lower	Upper

	Equal variances not assumed	2.456	12.001	0.030	0.05263	0.00594	0.09932

DISCUSSION

There are very few studies in this area, to best of our knowledge this is the first study in India looking into the relation between 2nd digit to 4th digit ratio and dyslexia. We have taken 30 children with dyslexia (cases) and 30 normal age and education matched controls. There was a significant difference between the two groups with respect to gender distribution, predominance of male children in dyslexia group could be explained by the general prevalence of dyslexia, which is more common in males (Male: Female ratio is 4:1) and ours being a consecutive sampling.

The current study did not show any difference in the 2nd to 4th digit ratio between children with dyslexia and normal children, neither the right hand comparison nor the left hand comparison between groups showed significant difference, which is in contrast to the observation made by Manning et al 2002 who reported 2nd digit to 4th digit ratio is low in dyslexia compared to Non dyslexic individuals. But our finding is in concurrence with the findings of two other studies, which also reported no association between 2D:4D ratio and dyslexia. A study done in Netherland on children with dyslexia with a phonological deficit showed no evidence for an association between reading disabilities and the 2nd digit to 4th digit ratio, also showed no support for the assumed relation between the 2nd digit to 4th digit ratio and prenatal testosterone[10]. Another study showed digit ratios were sexually dimorphic 'male lower than female' pattern, no difference in digit ratio between dyslexic and normal reading children. Digit ratios were not related to any sensory measure.[11]

The present study showed that 2nd to 4th digit was lower in children without dyslexia than in children with dyslexia, which is contrary to our own hypothesis that 2nd to 4th digit ratio will be low in dyslexic children compared to normal children, and contradicts those studies which shows an association between digit ratio and dyslexia. This finding is difficult to explain by any existing literature on dyslexia and digit ratio. However similar finding was reported in a study on 2nd to 4th digit ratio among 107 individual across all departments and all academic grades, who completed an Internet-based questionnaire on autism or dyslexia in self and family members, the study showed an association between autism and lower 2nd digit to 4th digit ratio, whereas interestingly dyslexia was associated with a higher 2nd to 4th digit ratio in that study [12].

Males had a lower digit ratio compared to females irrespective of being dyslexic or not, points in favour of the concept of sexual dimorphism in digit ratio as suggested by a study [13], however could not agree fully because the difference was not significant.

Some of the theories put forward to explain dyslexia and digit ratio are testosterone theory in the context of cerebral lateralization with testosterone suppressing certain areas in left hemisphere, Extreme male brain theory which suggests excess masculinization of brain leading to dyslexia.

In this study there is no difference in the digit ratio between left hand and right hand nor there do any association of digit ratio in either of this hand and dyslexia. Comparison of only male samples between groups also revealed a higher ratio in children with dyslexia than normal children; this was significant ($p = 0.03$). These findings are in contrast to theories explaining dyslexia and digit ratio.

Our finding does not support an association between digit ratio and dyslexia; neither has it supported the cerebral lateralization theory or extreme male brain theory. The reasons could be digit ratio depends on the production of testosterone and sensitivity of digits to foetal testosterone, which can vary across different ethnic groups, this can explain why there is no difference in digit ratio between groups but this can't explain the reason for lower ratio in controls.

May be there is no real association between dyslexia and digit ratio as supported by studies, 2nd to 4th digit length may not be an indicator of prenatal gonadal hormone exposure 14 and most of the studies supporting the association has not directly compared dyslexia with normal children, it was either done on children with family history of dyslexia or comparing individuals in different academic fields [12]. So, findings in these studies could be influenced by some confounding factors.

Strength of the study

The sample in our study is homogenous and it's a direct comparison between children with dyslexia and without dyslexia. We recruited the children consecutively so any bias in sampling is avoided. Exclusion of comorbid condition like autism, Asperger's syndrome etc which could have confounded the findings if present, as studies also show an association between these disorders and digit ratio.15 All children in dyslexia group were evaluated in detail by a psychiatrist and clinical child psychologist. Using direct method to measure digit ratio by Vernier Calliper, which is an accurate as well as easy method to measure digit length.

Limitations of the study

The findings of this study should be interpreted with caution because of small sample size, possibility of type II error could not be ruled out. The investigator was not blind to the diagnosis, however any bias in measurement was unlikely as the results contradicts our own hypothesis. Measurement was done by a single investigator; having 2 or 3 persons to measure the digit could have added more reliability and validity to the findings. Controls were recruited based on the parents report on their children's academic performance, physical and mental status, not evaluated by psychiatrist or clinical psychologist, it's possible that children with subtle psychological disturbance are missed and mistakenly recruited as normal controls. Despite all these limitations, the finding of this study is unique and cannot be dismissed.

CONCLUSION

This study does not support the association of 2nd digit to 4th digit ratio and dyslexia; neither do the theories put forward to support such an association. However, this study has certain limitations, we need more studies in this area with a larger sample size to overcome above limitations and form a definite conclusion.

The finding children with dyslexia having a higher digit ratio than controls especially in male samples are interesting and needs further exploration.

ABSTRACT

Introduction: In India, the family is the main support system for people with mental illnesses. It has been observed that >90% of patients with chronic mental illness live with their families and continue to take care of basic necessities [1-3]. Most often, the patients who have mental illness are brought for psychiatric help by the family. The family members take care of their medications, earn a living for them, stay with them, and most importantly, offer them emotional and psychological support. This also has a significant role in the rehabilitation of the patient and in bringing him or her to the mainstream. This family support system, which is unique to India, is supposed to be one of the good prognostic indicators for mental illness [4]. Family means to feel secure and to be loved and cared for. Conventionally, joint family setups in India have taken care of the older adults and sick people with utmost attention. Thus, the family has always taken the major share in responsibilities of mental health care compared to the government.

Aim: The aim of this study is to evaluate the effectiveness of structured teaching program on management of violent behaviour among primary care givers of mentally ill.

Methodology: The pre experimental study was undertaken on management of violent behaviour among primary caregivers of mentally ill clients. Convenient sampling technique was used. The data was collected through structured questionnaire. Descriptive and inferential statistics were used to analyze the data.

Results: Majority of the 17 primary care givers (85%) had adequate knowledge and 3 primary care givers (15%) had moderately adequate knowledge regarding the management of mentally ill.

Conclusion: The results showed high significant level with mean difference score of 23.55 and the 't' value was 2.81 ($p<0.05$). Hence, null hypothesis is rejected and H_1 research hypothesis is accepted. The study found that structured teaching program helped the primary care givers in caring with the mental ill.

INTRODUCTION

The family in India is the primary support mechanism for mentally ill individuals. It was noted that > 90% of chronic mental ill patients live with their families and continue to take care of fundamental necessities. A global program of deinstitutionalization and gradual transfer of inpatient care to community settings has meant that caregivers are taking on increasing levels of care giving duties and are

widely recognized for their input to patient care and recovery [4]. The intrinsic factors are a combination of personality characteristics, current intense mental distress and problems in dealing with anger. The extrinsic factors are more varied including the physical and social settings where violence and aggressive characteristics of the victims the experience and training of health and social professionals and the perceived risk of danger to others. Understanding how such variable contextual factors interacts with historical behaviour in the aetiology of violence and aggression is important in informing evidence based approaches to the prevention of violence and aggression that would otherwise emerge and aggression that has already occurred or is still in progress [5]. This approach is anomalous because the impact of violence and aggression in mental health, health and community setting is significant and diverse, adversely affecting the health and safety of service users, care givers and staff [6]. Critically, the management of violence and aggression may itself be hazardous to those exhibiting violent or aggressive behaviour and accentuate risks to their health and safety [7].

Statement of the Problem

Pre experimental study to assess the effectiveness of structured teaching program on knowledge regarding management of violent behaviour among primary care givers of mentally ill in tertiary care hospital in Coimbatore India.

OBJECTIVES

1. To assess the management of violent behaviour among primary caregivers of mentally ill.
2. To evaluate the effectiveness of structured teaching program on management of violent behaviour among primary caregivers of mentally ill.
3. To associate the management of violent behaviour among primary caregivers of mentally ill with selected demographic variables.

Assumptions

1. Primary caregivers may not have adequate knowledge on management of violent behaviour of mentally ill.
2. Administration of structured teaching program may enhance management of violent behaviour among primary caregivers of mentally ill.

Research Hypotheses

H_1: There will be a significant difference in the pre and post test of management of violent behaviour among primary caregivers of mentally ill**.**

H_2: There will be a significant association of the post test of management of violent behaviour with selected demographic variables among primary caregivers of mentally ill.

Research Variables

Independent Variable: Structured teaching program on management of violent behaviour.
Dependant Variable: Knowledge on management of violent behaviour among primary caregivers of mentally ill.

Research approach and design: Pre experimental research design.

Setting of the study

The study was conducted in PSG Hospital. PSG Hospital is a tertiary care hospital which has bed strength of 1400 and 19 specialty OPDs. This study was conducted among am 20 participants who were admitted in psychiatric ward at selected PSG Hospital at Coimbatore.

Population and Sampling

The population of the study consists of primary caregivers of patients on mentally ill. The sample consists of primary caregivers of patient who stay with the patient during hospitalization. The total number of patients with mentally ill from January 2018 to December 2018 was used as the baseline data to determine the sample size**.** Total of 1274 patients were with the diagnosis of affective disorders.

Sample size: Sample size has been calculated by using allowable error method and 20 samples of patient's primary caregiver were selected.

$$n = \frac{4pq}{L^2}$$

P =mean/total population in a year×100
Mean = 1274/12= 106
P = (106/1274×100) =8.32
q =100-p
q= 100-8.32=91.66
L =allowable error=13

$$n = \frac{4x8.32x91.66}{13^2}$$

=18.05
Estimated sample size is 20

Sampling technique: Convenient sampling technique was used in this study. Sample size of the study was 20 primary caregivers of mentally ill [8,9].

Sample Selection Criteria

Inclusive Criteria:

- Primary care givers who could read and understand English/Tamil.
- Primary care givers who were willing to participate.

Exclusive Criteria:

- Primary caregivers such as health professionals and home nurses.
- Primary care givers who are below the age of 15 years.

Technique of data collection if interval, give detailed description of intervention performed

The tool constructed in this study consists of 3 parts.

Section A: Demographic profile of the primary caregivers:
Includes age, relationship with the patient, educational status, occupational status, family income and previous information regarding violent behaviour.

Section B: Demographic profile of mentally ill:
Age, diagnosis, duration of illness, duration of violent behaviour and previous information regarding violent behaviour.

Section C: The Management of Aggression Violence Attitude Scale (MAVAS) was modified as knowledge questionnaire with the expert content validity. It is self administered and consists of 27 questions. Thirteen were related to the causes of aggression, violence and reflected the internal, external, and situational/interactional models of violent behaviour. And 14 items represented different approaches to the management of aggression.

Reliability of Scale for the Management of Aggressive and Violent Behaviour (C_MAVAS): Psychometric properties testing in mental health nurses were assessed in China among mental health nurses. A convenient sample of 262 qualified mental health nurses working in a local psychiatric hospital was recruited. The result showed that the content validity of the C_MAVAS was very satisfactory with validity indices of 97.4% for the overall scale and 90% to 100% for individual items. Exploratory factor analysis yielded a four-factor solution: 'interactional perspectives on patient violence', 'best ways perceived for violence management', 'internal or biomedical perspectives on patient violence', and 'external perspectives on patient aggression and violence', were important in shaping their attitudes towards managing violence and patient disruptiveness. Internal consistency of the Chinese version was barely satisfactory (Cronbach's alpha=0.51-0.67) for the four factors/subscales and its test-retest reliability was good (Pearson's coefficient=0.84). The findings suggests the C_MAVAS is a valid and reliable tool to measure mental health nurses' attitudes towards patient violence/aggression in a mental hospital setting [8,9].

Scoring	
Level of Knowledge	**Percentage**
Inadequate knowledge	< 50%
Moderately adequate knowledge	51-75%
Adequate knowledge	>75%

INTERVENTION

Structured teaching program on management of violent behaviour in the aspect of definition, causes, symptoms and management of violent behaviour. It includes communication strategies, environmental strategies, behavioural strategies, therapeutic strategies, and ways to protect you and stress management.

Ethical issues: The project was approved by the Intuitional human ethics committee (IHEC), PSG Institute of Medical Science and Research. Detailed information on the research project was communicated to caregivers, including procedures for protecting interviewees' and patients' privacy; arrangements for secure access to and storage of data; confidentiality arrangements for the one-on-one interviews in a private room; and the non-recording of patients' names.

Plans for data analysis: The data analysis plan includes descriptive and inferential statistics.

Descriptive Statistics

- Percentage and frequency to analyze demographic variables.
- Mean and standard deviation to analyze the pre and post test scores of management of violent behaviour among primary caregivers.

Inferential Statistics

Paired "t" test was used to compare the pre and post test scores of management of violent behaviour among primary caregivers of mentally ill.

- Chi-Square test was used to find out the association between demographic data and management of violent behaviour among primary caregivers.

Table 1: Assessment of post test level of management of violent behaviour among primary care givers (n=20).

S. No	Knowledge level	Category	Frequency	Percentage
1.	Inadequate knowledge	< 50%	3	15
2.	Moderately adequate knowledge	51-75	16	80
3.	Adequate knowledge	>75%	1	5

Table 2: Frequency and percentage distribution of post test of violent behaviour among primary care givers (n=20).

S. No	Knowledge level	Category	Frequency	Percentage
1.	Inadequate knowledge	<50%	-	-
2.	Moderately adequate knowledge	51-75%	3	15
3.	Adequate knowledge	>75%	17	85

Table 3: Comparison of pre test and post test violent behaviour among primary care givers (n=20).

S. No	Characteristic	Pre test		Post test		Mean Difference	t-value
		Mean	S.D	Mean	S.D		
1.	Primary care givers knowledge assessment	57.25	7.785	80.8	19.3	23.55	t=2.81 S*

DISCUSSION

In the present study the demographic variables of patient shows the 7 samples (35%) were at the age group 21-30 years, 12 samples (60%) were male, and 18 samples (90%) were Hindu, 14 samples (70%) were 1-3 years of duration of illness, 15 samples (75%) were married patients.12 samples (60%) were nuclear family, 14 samples (70%) were urban people.

A similar study was conducted in violence behaviour in adolescents and the results shows that the mean frequency 60.2% and fighting injury and (non injured: 84.5%) and the bullying frequency varied widely cross sectional from 57.0% for fighting was most highly associated with smoking, drinking, feeling irritable or bad tempered and having been bullied [10].

In the present study the effectiveness of structured teaching program on violent behaviour among primary care givers were showed the mean value of pre test was 57.25 and was increased in post test to 80.8. The difference between the pre test and post test mean was 23.6. The 't' value was 3.84, which had

high statistical significance at p<0.05 level and which confirms that there was a statistically significant difference between pre test and post test knowledge of primary care givers in the management of mentally ill patients.

The present study results were consistent with the findings of the following studies carried out on caregiver reports of patient-initiated violence in psychosis. Patient violence was unrelated to carergiver burden or carergiver distress ($P > 0.05$). Self-esteem was significantly lower in carergivers reporting patient violence ($t = 2.199$, $df = 60$, $P = 0.03$, mean difference = −3.10 [95% CI −5.92 to −0.281]), while levels of functional coping through emotional support were significantly higher ($t = 2.902$, $df = 61$, $P = 0.005$, mean difference = −0.56 [95% CI = −0.956 to −0.176]) [11].

In the present study the association between selected demographic variables and effectiveness of structured teaching program on violent behaviour among primary care givers showed that the there is significant association with the effectiveness of structured teaching program and religion $\chi^2 = 3.95$, marital status $\chi^2 = 3.95$ and the occupational status $\chi^2 = 3.95$. It was inferred that religion, marital status and occupational status had association with the effectiveness of structured teaching program on violent behaviour among primary care givers mentally ill.

A similar study was conducted on caregiver reports of patient-initiated violence in psychosis. The association of the study showed that regarding gender ($\chi^2 = 8.23$, $df = 1$, $P = 0.004$), with a history of voluntary admissions ($\chi^2 = 17.2$, $df = 1$, $P < 0.01$). Fewer had a history of violence ($\chi^2 = 11.3$, $df = 1$, $P = 0.001$) or sexual offences ($\chi2 = 7.43$, $df = 1$, $P = 0.006$) [12-14].

CONCLUSION

The study was conducted to assess the effectiveness of structured teaching program on management of violent behaviour among primary care givers of individual with mental health problem. A questionnaire based on violent behaviour among primary care givers. In the overall majority of pre test of 16 primary care givers (80%) had moderately adequate knowledge, 3 primary care givers (15%) had inadequate knowledge and 1 primary care giver (5%) had adequate knowledge. In the with respect to majority of post test of 3 primary care givers (15%) had moderately adequate knowledge and 17 primary care givers (85%) had adequate knowledge. The mean difference score was 23.55 and the ‘t’ value was 2.81 which had high statistical significance at p<0.05 level. Hence the null hypothesis is rejected and H_1 the research hypothesis is accepted. The study found that education had helped to develop knowledge and increase ability of the primary care givers in caring for patient who are on mentally ill.

Background: Suicide has a strong association with mental disorder and contributes to the excess mortality of the mentally ill. Suicidal ideation is prevalent and appears to be a precondition for suicide attempts among psychiatric patients with Major Depressive disorder. Though ideas and attempts may overlap there are studies that show the two are separate clinical entities with unique psycho-socio demographic profile. ***Aim:*** To study the correlation of psychotic symptoms with suicidal ideation and with suicidal attempt. ***Methodology:*** Cross sectional study of patients consecutively admitted with major depressive disorder. Severity of suicidal ideations and attempts were rated on validated scales and the sociodemographic and clinical correlates were analyzed. ***Results:*** There were more suicide attempts in patients without psychotic symptoms than those with psychotic symptoms with various levels of severity. ***Conclusion:*** There was no correlation between severity of psychotic symptoms and suicidal attempt in the sample.

Keywords: *Psychotic symptoms, Severe depression, Suicide*

□sychological autopsy studies show that considerable number of patients with mental illness committed suicide. These studies show that 90% of people who committed suicide fulfilled criteria for mental illness. Therefore it is important to identify people at risk for suicide, especially those with mental illness(1)(2)(3).

Patients with affective disorders and alcoholism carry the highest risk of suicide. Unipolar depression can present as either with or without psychotic symptoms. Severe depression may or may not be associated with psychotic symptoms, whereas the mild and moderate forms of depression is never associated with psychotic symptoms(4). Studies predict a prevalence of 0.4% for psychotic symptoms in patients with major depressive disorder.

There have been studies looking at differences between psychotic and non psychotic depression, even beyond the presence of psychotic symptoms(5)(6)(7)(8) (9)(10). That is they have

studied differences in heritability, environmental and genetic risk factors, treatment response and mortality.Some studies also say that risk of suicide is higher in patients with psychotic depression than those in non-psychotic depression but there are other studies that refute these findings too(11)(12).

Rationale for study

In a register based prospective cohort study on 34,671 patients with severe depression in Danish psychiatry hospitals out of which 12,101were psychotic depression patients, 755 completed suicide during follow up. But psychotic depression was not found to be an independent risk factor for suicide in severe depression (AOR=0.97 [0.83-1.15]) though other risk factors like older age, male gender, and a previous incident of self-harm were significant risk factors for both groups (psychotic and non-psychotic depression)(1).

But in yet another study which was a prospective case study of records of 61psychotic depression and 59 non psychotic depression cases analysed for mortality outcomes at 15 years after initial assessment, they found that patients with psychotic depression had a two-fold higher risk of mortality than those with severe depression without psychotic symptoms. Butthere was no statistically significant difference in the number of patients who had died by suicide between the two groups(13).

On reviewing literature on Indian studies on the topic, we were not able to come across similar studies looking into risk of suicide in patients with psychotic depression, as compared to non-psychotic depression. Thus we wanted to carry out this study in an Indian population in south India to see if we are able to replicate the findings in the western studies and we wanted to analyse further the correlation between psychotic symptoms and various aspects of suicide such as suicidal idea or attempt and method of suicide.

Aim

Primary aim was to study the correlation of psychotic symptoms with suicidal ideation and with suicidal attempt. Secondary objectives were to study the correlation between the severity of psychotic symptoms and method of suicide and to study the correlation between the content of psychotic symptoms and method of suicide.

M□□□□□□□□□□

This study employed a cross sectional consecutive sampling methodology. Study was conducted in the psychiatry in-patient ward at a private medical college hospital in Coimbatore, Tamil Nadu. Study duration was 1 year (from January 2016 to December 2016) and all the consecutive patients, between the ages of 18 and 65 years, admitted in the psychiatry ward with the diagnosis of major depressive disorder were screened for study inclusion after getting informed consent.

Inclusion criteria consisted of patients whose age was between 18 and 65 yrs and with a diagnosis of major depressive disorder diagnosed by their respective consulting psychiatrist in the department who was blind to the study protocol. The study researcher administered the SCID for DSM IV interview schedule and if the diagnosis was confirmed for Major depressive disorder then the patient was included in the study.

Exclusion criteria consist of patients who refused to give consent and patients who had co morbid mental retardation or neuro-psychiatric co morbidity like dementia. Patients with

Bipolar depression were excluded from the study as we wanted to study specifically unipolar depressive disorder group of patients. Patients with co morbid physical illness, substance abuse and other psychiatric co morbidities were also excluded from the study. Total sample size for the study was 53.

Instruments:

Once the patient was recruited into the study, the researcher had collected details about the socio demographic and clinical variables by using a semi structured profoma and then administered the Hamilton depression rating scale(HAMD-17) to assess the severity of depression. The researcher then administered the following scales for assessment of severity of suicidal behaviour:

- a scale that was developed in order to assess the severity of suicide attempts. The scale consists of 15 questions which are scaled from 0-2, which take into account both the logistics of suicide attempt as well as the intent. The scale has high reliability and validity[16].
- this scale was developed for assessing severity of suicide ideas. Principal component analysis revealed a bi dimensional structure, with factors corresponding to (1) Desire and Ideation and (2) Plans and Preparations. Each factor displayed acceptable internal consistency and expected patterns of convergent validity via associations with hopelessness, depressive symptoms, impulsivity, and a self-report measure of suicidal behaviors[19].

Statistical analysis

We performed statistical analysis with PASW (SPSS) version 19.0 for Windows. The correlation of socio-demographic variables with suicide ideation and depressive patients who attempted suicide, patient history with suicidal attempts, severity of depression with suicidal ideation and suicide attempt were determined using The correlation of suicidal ideation and suicide attempt were determined using P-value less than 0.05 was considered as statistically significant.

1

Majority of the patients belonged to early adulthood age group of 18 to 40 years (47.2%). Both genders were equally represented among the sample. Majority of the patients belonged to middle and low socio economic status (90.6%), were married (75.5%), residing in rural community (69.8%) and were graduates (35.8%) and were living in a nuclear family (71.7%). Majority of the patients did not have family history of suicide (84.9%).

Three-fourth of the patients did not have any past suicide attempts. One patient had attempted suicide three times (1.9%). 12 patients had attempted once (22.6%). 80% of the patients had very severe depressive episode (42/53) as per HAM-D rating scale.

Among 53 recruited depression patients, 35 patients (66%) had suicidal ideas and 13 patients attempted suicide (24.5%). Among the patients who had suicidal ideas (35/53), majority of the patients (41.5%) had severe suicidal ideas as per MSIS scale (total score >20) - table 4.

Poisoning was the commonest method of suicide (11.3%) followed by hanging (5.7%). Electric shock, burns, wrist slash were other methods of suicidal attempts.(Table 1).

Depressive patients who had attempted suicide before had severe suicidal ideas than patients without previous suicidal attempt which was statistically significant (table 2; p-value- **0.01**) Patients who had past history of suicide attempt had higher intent for current suicide attempt which was statistically highly significant (table 3; p-value-**0.000**)

rr

There were more suicide attempts in patients without psychotic symptoms than those with psychotic symptoms with various levels of severity (Table 5). There was no correlation between severity of psychotic symptoms and suicidal attempt in the sample. Considering the content of psychotic symptoms, we found that one patient who had auditory hallucination, had multiple suicide attempts. Poisoning was the common method of suicide, both in patients with delusions and hallucination (Table 6).

From our study we found that majority of the depressive patients had suicidal ideas (66.0%) and one-fourth of the depressive patients had attempted suicide. The above results emphasises the need to address and how common the prevalence of suicide idea and suicide attempts among depressive patients.

In our study, the suicidal idea was more common in early adulthood age group, which was not found in previous studies(14). In our study, the over-represented groups in the sample with attempted suicide were men of the older age groups, especially men between 45 and 64, and women over 65, who also had more severe suicide attempt in the sample. The severity of suicide ideas was high among low socio-economic status and married group. This is in contrary to previous studies in which suicidal ideas were common among the un-married patients (15). Further in our sample we found that unemployed and rural inhabitants had more severe suicide ideas. In previous studies, unemployment remained a risk factor, but urban background was also a risk factor. Living in nuclear family was a high risk factor in our sample which is in accordance with previous studies. Also a history of past suicide attempt, remains a risk factor for more severe suicide ideas for current episode.

Presence of psychotic symptoms in depressive patients did not correlate with suicide idea or attempt. All the patients with suicidal attempt in the sample were patients who had very severe depression on HAMD rating scale. Suicidal attempt has been found to be positively correlated with severity of depression in other Indian studies also(16). Also the severity of suicidal ideation was positively correlated with the severity of depression on HAMD rating scale. ($p = 0.020$).

The type of positive symptoms (delusions and hallucinations) did not correlate with method of suicide. Poisoning was the commonest method of suicide in both men and women. Men had attempted more lethal methods for committing suicide such as hanging or electric shock. Almost all women show poisoning as method who attempted suicide. Benzodiazepine poisoning was the most common method used for poisoning by women.

We used validated scales and we stuck to a homogenous sample analyzing subjects with diagnosis of major depressive disorder alone and excluded subjects with substance abuse and other psychiatric co morbidities that could influence suicidal behavior such as personality disorders or adjustment disorder etc. In our sample the patients with severe depression was represented adequately and there were no dropouts, thus were able to assess suicidal behavior true to our study objective.

Some of the limitations of our study are that the researcher may have been biased when assessing the suicidal behavior as the severity rating was also done by the same interviewer. Since it was a cross sectional study we have not analyzed the course of the suicidal behavior in these group of patients and their response to treatment. We have not studied the correlation of the presence of any recent life events with severity of suicidal behavior. Further studies are needed to compare whether the correlations with severity of suicidal behaviour differ in other psychiatric illnesses like schizophrenia, bipolar disorder, personality disorder etc.

□□□□□□□□□□

There was no correlation between severity of psychotic symptoms and suicidal attempt in the sample. The sample was too small to analyse for the correlation of content of psychotic symptoms with suicidal attempt.□

It was a Cross sectional study design. Patients consecutively admitted with major depressive disorder (DSM IV TR) were recruited. Severity of suicidal ideations and attempts were rated on validated scales and the socio demographic and clinical correlates were analyzed. ***Results:*** Clinical correlates like severity of depression, severity of suicidal ideation and history of past suicidal attempt were positively correlated with severity of suicidal ideation as well as severity of current suicidal attempts in the cohort of depressive disorder patients. ***Conclusion:*** Assessment of current episode severity of both suicidal ideation as well as suicidal attempt is important in identifying high risk patients with major depressive disorder.

Keywords: *Clinical, Socio-Demographic, Correlates, Depressive Patients, Suicidal Ideas, Suicidal Attempts*

□ccording to World health organization (WHO), over 800,000 people die due to suicide every year. Also for every suicide there are many more people who attempt suicide every year. WHO defines suicidal act as the injury with varying degree of lethal intent and suicide as, such acts with fatal outcome? Suicidal acts with no fatal outcome are defined as suicide attempts, attempted suicide, Para suicide, or act of deliberate self-harm.

A prior suicide attempt is the single most important risk factor for suicide in the general population. In 2004, suicide was the 16th leading cause of death worldwide. Also suicide is the second leading cause of death among 15–29 year olds and this is an alarming finding. It is not only in the developed countries that suicide has been studied, but 75% of global suicides occur in low and the middle income countries.

There are several studies that have been done on incidence of suicide in India. Over the years studies have reported incidence rates that range from 2.36 to 42 per 100,000 populations. Majority of these studies have been done in hospital based setting and few in community based samples. In one of the earliest article on attempted suicide by Venkoba Rao, an incidence rate of 43/100,000 in Madurai was reported. Also in the same study, 1 in 12 cases of the suicide attempts were fatal (4). According to the NCRB report in 2010 the rate of suicide was 11.4 per 100,000 populations; an increase of 5.9% when taking into accounts the rate from the year 2008 onwards.

Suicide has a strong association with mental disorder and contributes to the excess mortality of the mentally ill. A systematic review and meta-analysis, by Harris and Barraclough et al, which included 249 reports on the mortality of mental disorders, comparing the relative risk of suicide for a given psychiatric disorder with the expected suicide rate in the general population, all psychiatric diagnoses (except mental retardation), had an increased mortality rate underscoring the importance of making a correct psychiatric diagnosis in suicide risk assessment.

Suicidal ideation is prevalent and appears to be a precondition for suicide attempts among psychiatric patients with Major Depressive disorder. The overall level of psychopathology of suicide attempters is higher compared with that in patients with ideation. Another important aspect to look at is whether suicide and attempted suicide along with other suicidal behavior form a single entity. Previous studies on suicide and attempted suicide reveals that these two phenomena tended to be regarded as one, directed at death, which succeeded in some cases and failed in others. Whereas there are recent investigators who have suggested that suicide and attempted suicide are two separate clinical entities with unique psycho-socio demographic profile, though there may be some overlap.

In the Weissman et al study they had conducted nine cross-national epidemiological surveys using similar diagnostic assessment and criteria (DSM 3) and reported lifetime prevalence rates per 100 for □□□□d□□d□□□□□ that ranged from 2.09 (Beirut) to 18.51 (Christchurch, New Zealand). Lifetime prevalence rates per 100 for □□□□d□□□□□□ □□□ranged from 0.72 (Beirut) to 5.93 (Puerto Rico).

Other studies have analyzed suicidal behavior and its correlates in specific psychiatric disorder as well. In a study by Srivastava et al they had found a positive correlation between suicide attempt and factors like the severity of depression, male gender, and age less than 35 years, being married, and being employed.

In another study done at Varanasi, on a sample of 60 out-patient psychiatry patients with diagnosis of Major depressive disorder (DSM IV-TR), they reported that all the patients who express suicidal ideation did not attempt suicide. Suicidal attempts were reported in only 16.6% of patients with major depressive episode with suicidal ideation. Also young patients with depression, unmarried men, married women and students, having severe suicidal ideation with agitation or paranoid symptoms were more likely to attempt suicide.

Rationale for study

There are no Indian studies comparing the clinical and socio demographic variables with the severity of suicidal ideation and suicide attempt as distinct entities in major depressive disorder. Most of the studies had considered both these groups as a continuum, whereas we want to study these two groups as distinct factors influencing suicidal behavior in depression. Also though many studies had studied correlation of suicidal behavior with severity of depression, they had not analyzed the socio demographic and clinical correlations with the severity of suicidal ideation or severity of attempt.

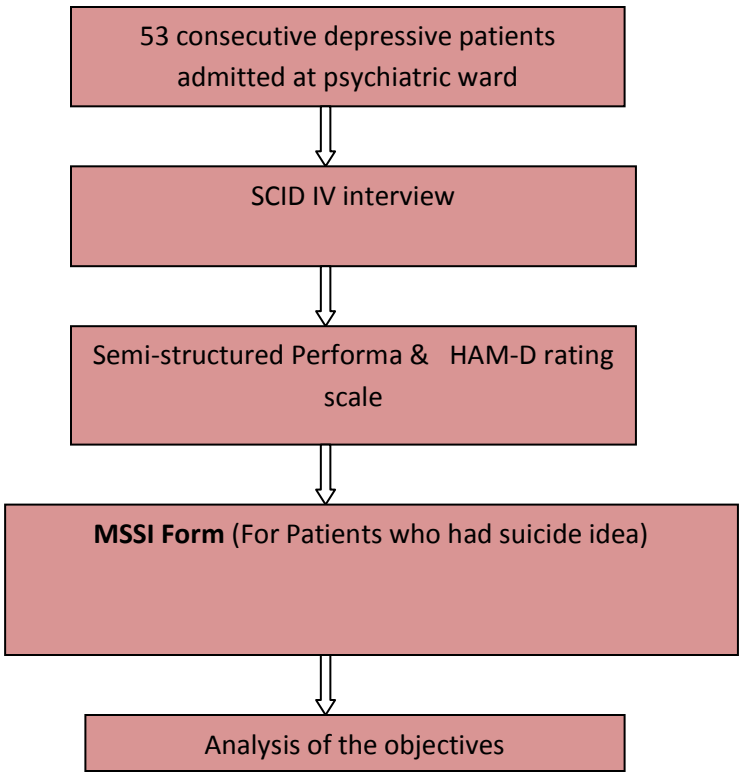
Aim

To compare the socio demographic and clinical variables between the patients with suicidal ideation and those with suicide attempt in a cohort of major depressive disorder patients.

Objectives

1. To compare the correlation of socio demographic and clinical variables with the severity of suicidal ideation.
2. To compare the correlation of socio demographic and clinical variables with the severity of suicidal attempt.

M□□□□□□□□□



This study was a cross sectional consecutive sampling study that was conducted in the psychiatry In-patient ward at a private medical college and hospital in Coimbatore, Tamil Nadu. Study duration was 1 year (from January 2016 to December 2016) and all the consecutive patients, between the ages of 18 and 65 years, admitted in the psychiatry ward with the diagnosis of major depressive disorder were screened for study inclusion (Fig. 1).

After explaining the study protocol, we got written informed consent from the patient and the family member who had accompanied the patient. Consenting patients were interviewed by the researcher.

Inclusion criteria consisted of patients whose age was between 18 and 65 yrs and should have been admitted in the psychiatry ward with diagnosis of Major depressive disorder by their respective consulting psychiatrist in the department who was blind to the study protocol. The study researcher administers the SCID for DSM IV interview schedule and if the diagnosis is confirmed for Major depressive disorder the patient is included in the study.

Exclusion criteria consists of patients who refused to give consent and patients who with mental retardation or neuro-psychiatric co morbidity like dementia were also excluded as they would not be able to accurately respond to the severity assessment scales being administered. Patients with Bipolar depression were excluded from the study as we wanted to study specifically unipolar depressive disorder group of patients. Patients with co morbid physical illness, substance abuse and other psychiatric co morbidities were also excluded from the study. Total sample size for the study was 53.

Fig 1. Flow chart for study recruitment and methodology

Measurements

Once the patient was recruited into the study, the researcher had collected details about the socio demographic and clinical variables by using a semi structured profoma. The researcher then administered the Hamilton depression rating scale (HAMD-17) to assess the severity of depression. The researcher then administered the following scales for assessment of severity of suicidal behaviour:

1. **□ □□□□d □□□ □□□□□ □□□□□□ □□□□□r □ □□□□ □ □□□□** a scale that was developed in order to assess the severity of suicide attempts. The scale consists of 15 questions which are scaled from 0-2, which take into account both the logistics of suicide attempt as well as the intent. The scale has high reliability and validity[16].
2. **M □d□□d □□□□□□□□r □□□□□d □□□d □□□□□□M □□□□□** this scale was developed for assessing severity of suicide ideas. Principal component analysis revealed a bi dimensional structure, with factors corresponding to (1) Desire and Ideation and (2) Plans and Preparations. Each factor displayed acceptable internal consistency and expected patterns of convergent validity via associations with hopelessness, depressive symptoms, impulsivity, and a self-report measure of suicidal behaviors.

□

Statistical analysis

We performed statistical analysis with PASW (SPSS) version 19.0 for Windows. The correlation of socio-demographic variables with suicide ideation and depressive patients who attempted suicide, patient history with suicidal attempts, severity of depression with suicidal ideation and suicide attempt were determined using □□□□□□□r □□□□□□□ The correlation of suicidal ideation and suicide attempt were determined using □□r□□□□□rr□□□□□□□ P-value less than 0.05 were considered as statistically significant.

□□□□□□□□

Socio-demographic and clinical variables in the whole sample

Most of the patients belong to early adulthood age group (47.2%). Out of the total sample of 53 patients, 24 were males and 29 were females. Majority of the patients belong to middle and low socio economic status (90.6%), were married (75.5%) residing in rural community (69.8%) and were graduates (35.8%) and were living in a nuclear family (71.7%). Most of the patients did not have family history of suicide (84.9%).

The mean severity of depression on HAMD-17 rating scale in the sample was 28.72 (+/- 6.3), thus indicating severe depression. 79.2% of the patients had very severe depressive episode (42/53) as per HAM-D rating scale.

Three-fourth (75%) of the patients did not have any past suicide attempts. Out of the total patients who had attempted suicide (N=13), one patient had attempted suicide three times in the

past (1.9%) and 12 patients had attempted once (22.6%). Among 53 recruited depression patients 35 patients (66%) had suicidal ideas and 13 patients had attempted suicide (24.5%). Among the patients who had suicidal ideas, majority (62%) of the patients had severe suicidal ideas as per MSIS scale (i.e, total score >20). Among patients who did attempt suicide (13/53), majority of them (53.8%) had high suicide attempt severity (SRAF total score>20), 30.8 % had medium severity and 15.4 % had low severity of suicide attempt.

Correlation of Socio demographic variables with severity of suicidal ideas

Suicidal ideas were common and were more severe, in age group 18-40 years than middle and late adulthood age group. The severity of suicidal ideas was high among lower socioeconomic status patients and who were married. Unemployment and patients residing in rural background and patients in nuclear families had more severe suicidal ideas. But none the above socio demographic variables were statistically significant when compared across the grades of severity of suicidal ideation (Table 1)

Correlation of socio-demographic variables with severity of suicidal attempt

Depressive patients who are in early adulthood age group (18-40 years) had a more severe suicide attempt than other age group which was statistically significant (p-value-**0.026**). None of the other variables were statistically significant in their correlation with severity of suicidal attempt (Table 2).

Poisoning was the commonest method of suicide in both men and women. Men had attempted more lethal methods (hanging/electric shock). Almost all women show poisoning as method who attempted suicide. Benzodiazepine poisoning was the most common method used for poisoning by women (Table 2a).

TABLE 2: Correlation of socio-demographic variables with severity of suicidal attempt

	MORE THAN ONCE	0 (0.0%)	0 (0.0%)	1 (100.0%)	

| | | □□□□

In the other studies they have looked into only the incidence of suicidal thoughts and attempts, whereas in our study the correlation of socio demographic and clinical variables with the severity of suicidal ideation and attempts were analyzed.

Gender

Though there were higher no. of males with severe suicidal ideation (50%) compared to females (34.5%), but this difference was not statistically significant. In the cross-national study by Weissman et al, also there was no statistical significant difference in the suicidal ideation between the genders. In other Indian studies also no significant difference has been identified.

When taking the suicidal attempters group, more number of males (33.3%) had attempted suicide than females (17.2%). Even when considering severity of suicidal attempt across from low to high it were the males who were consistently higher represented across the severity of the attempt but not statistically significant. This is comparable to findings by Narang et al (sample size 208), that found that the prevalence of suicidal attempt was high among males with psychiatric illness (ICD 10 criteria), when compared to females. In contrast the western studies have shown that there is significantly higher risk in women than in men for suicidal attempt. Our study is unique in that other Indian or western studies have not compared the correlations with the severity of suicidal attempts and ideation in patients with major depressive disorder without co morbidities.

Socio economic status and place of living

In our sample the lower socioeconomic status patients were represented the most (52.8%), followed by the middle class (37.7%) and higher socioeconomic status were only 9.4%. When considering severe suicidal ideation, all the 3 groups were comparable. Whereas compared to the high and middle income groups, the low income group had most persons with suicidal ideation but these differences were not statistically significant. But when considering rural versus urban, though rural population had the most representation (69.8%), the no. of patients who had the most severe suicidal ideation were seen in the urban group (56.3%) versus the rural group (35.1%), but again this was not statistically significant. But when looking at patients with suicidal attempts the proportion were almost equal in the rural versus urban and in the various socioeconomic strata. This finding is comparable to findings from Narang et al

Marital, Literacy and employment

In our sample the proportion of patients representing unmarried population was very less (24.5%) compared to married (75.5%), thus not allowing for meaningful comparison. When considering the employment status, there was no statistically significant difference in the severity of suicidal ideation with both employed and unemployed having proportions of 36.4% and 46.2% respectively showing severe levels of suicidal ideation. But when we compared the

severity of suicidal attempt, the proportion of employed patients (18.2%) had more severe suicidal attempt than unemployed (7.7%), but the difference did not reach statistical significance. Also when comparing illiterate versus literate patients, the severity of suicidal ideation was comparable across the levels of literacy studied. But in severity of suicidal attempt, the proportion of literate patients had more severe attempt than the illiterate group (in which only 1 patient had a low severe suicidal attempt). These findings are comparable to the Srivastava et al study[7] that found that more educated patients in the group were more likely to attempt suicide. However, Kessler et al had found that poorly educated subjects were more vulnerable to suicidal attempts, but here we also have to note that this study included various psychiatry diagnoses whereas the srivastava et al study included only major depressive disorder patients similar to our current study.

Correlation of Type of family and family h/o suicide with severity of suicidal idea and attempt

Though the proportion of patients who had severe suicidal ideation was slightly higher in joint family (46.7%) group compared with nuclear family (39.5%), it was not statistically significant. Concordantly the proportion of patients with suicidal attempt were also higher in joint family group (33.3%), compared to the nuclear family group. But these differences were not statistically significant same as even reported in study by Narang et al, in which they had a larger sample size (100).

Only 8 patients out of the whole sample had reported family history of suicide. But the proportion of these patients with severe suicidal ideation was 50%, which was slightly higher than the patients without family history of suicide who had severe suicidal ideation (40%). Similarly even though the sample size was very less in the patients with family history of suicide, 25% of them had severe suicidal attempt which was greater than when compared with the patients without family history in whom the proportion of patients with severe suicidal attempt was only 11 %. But again these differences were not statistically significant. Indian studies have shown that family history of attempted suicide or completed suicide was common among patients suffering from depression.

Correlation of history of previous suicide attempts with severity of suicide ideation & attempt

12 patients (22.6%) in the sample had at least one history of previous suicidal attempt and one patient had previous history of more than once. The proportion of patients who had severe suicidal ideation was higher in the group of patients with previous suicidal attempt (92.3%) than those without (25%). This difference was statistically significant ($p = 0.01$)

All the patients who attempted suicide during the current episode (13) had a previous history of suicide attempt, compared to those without suicide attempt during current episode that had none. This difference was also statistically significant ($p = 0.000$). Thus from this study we further confirm to the understanding that the history of previous suicide attempt in major depressive

disorder appears to be a major risk factor for suicidal attempt or severe suicidal ideation during the subsequent episodes also. This finding has been replicated in previous studies that have found attempted suicide to be one of the predictors of future suicide. Studies in India shows that about 18% of suicide victims had a previous suicide attempt.

Correlation between Severity of depression and suicide ideation and attempt in the sample

All the patients with suicidal attempt in the sample were patients who had very severe depression on HAMD rating scale. Suicidal attempt has been found to be positively correlated with severity of depression in other Indian studies also[15]. Also the severity of suicidal ideation was positively correlated with the severity of depression on HAMD rating scale. (*p = 0.020*)

Correlation of severity of suicide idea and severity of suicide attempt

Depressive patients who had higher suicidal ideas in our sample had attempted suicide with higher intentionality which was statistically significant (*R value= 0.364, p-value-**0.007***). Study by Kessler et al had shown that cumulative probabilities for transition from suicidal idea to plan were 34 % and for transition from plan to attempt was 72% [21]. But they had included various co morbidities and whereas our study is specifically on major depressive disorder and also we have not differentiated between suicidal ideators and suicidal plan in our study. We have not analyzed the individual factors in the rating scales for suicidal ideation and attempts across the various variables studied.

Strengths and limitations

This was a cross sectional study in the inpatient ward during the patient's current depressive episode thus we were able to assess in cross sectionally, the suicidal behavior without any recall bias. In our sample the patients with severe depression was represented adequately and there were no dropouts, thus were able to assess suicidal behavior true to our study objective. We used validated scales and we stuck to a homogenous sample analyzing subjects with diagnosis of major depressive disorder alone and excluded subjects with substance abuse and other psychiatric co morbidities that could influence suicidal behavior such as personality disorders or adjustment disorder etc.

Some of the limitations of our study are that the researcher may have been biased when assessing the suicidal behavior as the severity rating was also done by the same interviewer. Since it was a cross sectional study we have not analyzed the course of the suicidal behavior in these group of patients and their response to treatment. We have not studied the correlation of the presence of any recent life events with severity of suicidal behavior. Further studies are needed to compare whether the correlations with severity of suicidal behavior differ in other psychiatric illnesses like schizophrenia, bipolar disorder, personality disorder etc.

Severity of depression was correlated with severity of suicidal ideations as well as severity of suicidal attempts. In addition to identifying suicidal behavior, the assessment of severity of suicidal ideations and past suicidal attempts is of great importance in identifying high risk patients presenting with major depressive disorder.

Acknowledgments

We thank our institution, PSG Institute of Medical Science & Research, Coimbatore and our department of Psychiatry, for allowing us to conduct this research and our colleagues for the great insights that helped in improving the manuscript.

Circadian rhythm
Sleep functioning
Social rhythm

ABSTRACT

Background: Recent treatment guidelines support treatment of biological rhythm abnormalities as a part of treatment of bipolar disorder, but still, literature examining various domains (Sleep, Activity, Social, and Eating) of biological rhythm and its clinical predictors are less.

Objectives: The main aim of our study is to compare various domains of biological rhythm among remitted bipolar I subjects and healthy controls. We also explored for any association between clinical variables and biological rhythm among bipolar subjects.

Methods: 40 subjects with Bipolar I disorder and 40 healthy controls who met inclusion and exclusion criteria were recruited for the study. Diagnoses were ascertained by a qualified psychiatrist using MINI 5.0. Sociodemographic details, biological rhythm (BRIAN—Biological Rhythm Interview of assessment in Neuropsychiatry) and Sleep functioning (PSQI- Pittsburgh Sleep Quality Index) were assessed in all subjects.

Results: Mean age of the Bipolar subjects and controls were 41.25 ± 11.84 years and 38.25 ± 11.25 years respectively. Bipolar subjects experienced more biological rhythm disturbance when compared to healthy controls (total BRIAN score being 34.25 ± 9.36 vs 28.2 ± 6.53) ($p = 0.002$). Subsyndromal depressive symptoms (HDRS) had significant positive correlation with BRIAN global scores($r = 0.368$, $p = 0.02$). Linear regression analysis showed that number of episodes which required hospitalization ($\beta = 0.601$, $t = 3.106$, $P = 0.004$), PSQI ($\beta = 0.394$, $t = 2.609$, $p = 0.014$), HDRS ($\beta = 0.376$, $t = 2.34$, $t = 0.036$) explained 31% of variance in BRIAN scores in remitted bipolar subjects.

Conclusion: Biological rhythm disturbances seem to persist even after clinical remission of bipolar illness. More studies to look into the impact of subsyndromal depressive symptoms on biological rhythm are needed.

1. Introduction

In humans, periodic fluctuations in levels of melatonin, growth hormone, prolactin, cortisol and thyrotropin show a circadian pattern. This circadian rhythm is governed by the master clock Suprachiasmatic Nucleus which synchronizes environmental cues with endogenous timing system (Roenneberg et al., 2003), the major environmental cue (zeitgeber) being the timing of sunlight. Synchronization of these circadian rhythms was found to be disturbed in subjects with bipolar disorder (Chung et al., 2012). Social *zeitgebers* like timing of meals, work schedules and schedules of other family members can influence social rhythm and thereby, circadian rhythm (Carney et al., 2006). Social zeitgeber theory states that in vulnerable individuals, circadian rhythm abnormalities can lead to mood episodes (Grandin et al., 2006). Moreover, in the expert guidelines, interventions stabilizing circadian rhythms, especially Interpersonal social rhythm therapy, have been recommended for a long time, as a treatment during maintenance phase of major depression and bipolar disorder (Yatham et al., 2013).

Biological rhythm disturbance especially sleep, has been well studied in bipolar disorder. These studies had established persistent sleep disturbance during remitted phase especially delayed sleep onset, more sleep awakenings after sleep onset, poor sleep efficiency and high sleep wake variability (Ng et al., 2015). These disturbances not only impair the functioning in remitted phase of the bipolar illness (Giglio et al., 2010), but also increase the risk of relapse of mood disorder (Gruber et al., 2011). Growing evidence also points to baseline social rhythm irregularity in mood disorders (Yatham et al., 2013). Subjects with Bipolar spectrum disorders were found to have less social rhythm regularity, which had been shown to be predictive of shorter time to relapse with manic or depressive episode (Shen et al., 2008). Though studies focusing on biological rhythm abnormalities during interepisode period had targeted sleep and activity rhythm using actigraphy (McKenna et al., 2014), social rhythm had not been always studied. Moreover, social rhythm in bipolar disorder had been extensively

studied in isolation in the context of Interpersonal social rhythm therapy (Van Tienoven et al., 2014).

Growing literature especially in the last 4 years, had looked into the association between Bipolar disorder and Biological rhythm using a validated scale, Biological Rhythms Interview of Assessment in Neuropsychiatry (BRIAN) to look into sleep, activity, social and eating rhythms (Mondin et al., 2017; Cudney et al., 2016; Cardosa Tde et al., 2015; Duarte Faria et al., 2015; Rosa et al., 2013). Cross sectional assessment of Biological rhythm using BRIAN in 1023 young adults (18–24 years) showed that subjects with euthymic bipolar disorder had more biological rhythm disturbance when compared to healthy controls. Interestingly, bipolar subjects had more biological rhythm disturbance during depressive phase, followed by hypomanic/Manic/mixed phase and euthymic phase of illness (Mondin et al., 2017). Similar finding was also observed in drug naïve Bipolar subjects (18–24 years), where it was observed that biological rhythm continued to be disturbed even during the euthymic phase of illness when compared to healthy community controls (Duarte Faria et al., 2015, Rosa et al., 2013). In another prospective study in young adults with bipolar disorder, biological rhythm disturbance tend to reduce significantly, at 6th and 12th month follow-ups when compared to its baseline (Cardoso Tde et al., 2015).

Though the existing studies had found that biological rhythm was more disrupted in euthymic Bipolar disorder than healthy controls, the recruited subjects in those studies also had another axis I comorbidity along with bipolar disorder (Mondin et al., 2017; Duarte Faria et al., 2015; Rosa et al., 2013). In light of finding that disorders like Substance use disorders (Logan et al., 2014), Post traumatic stress disorder (Agorastos et al., 2014) and Attention deficit hyperactivity disorder (Kooij and Bijlenga, 2013) have been found to be independently associated with persistent chrono-disruption, the findings of the above study could not be entirely attributed to bipolar disorder itself. Moreover, the above studies ((Mondin et al., 2017; Cardosa Tde et al., 2015; Duarte Faria et al., 2015; Rosa et al., 2013) were mostly focused on young adults (18–29 years) who were predominantly from urban background and thus we need studies with different population characteristics to evaluate the generalizability of these findings. Also, by examining biological rhythm in bipolar subjects (without any psychiatric comorbidities), any observed biological rhythm disturbances can be more likely due to bipolar disorder.

So, the primary aim of the study is to compare the biological rhythm (sleep, social, activity and eating domains) between remitted bipolar I subjects (without any psychiatric comorbidities) and healthy controls. Our secondary aim is to explore for any association between clinical variables (sociodemographic details, illness variables, quality of sleep) and biological rhythm in subjects with bipolar disorder.

2. Methodology

2.1. Recruitment of participants

With prior informed consent, subjects attending outpatient services of department of Psychiatry in a tertiary medical college hospital, Coimbatore, India were screened for inclusion and exclusion criteria for a period of 4 months in 2014. None of the subjects attending outpatient services received any structured program focusing on regulation of circadian rhythm. 40 subjects who met the below mentioned inclusion and exclusion criteria were recruited by consecutive sampling. [3-didn't consent for the study, 6- illiterate in Tamil(local language), 4-medically very sick for evaluation].

Subjects of 18 to 60 years of age, of either gender, diagnosed to have Bipolar affective disorder type 1 (as per DSM IV TR criteria by a qualified psychiatrist) who were euthymic (with a score of ≤ 8 as per Young Mania Rating Scale and a score of ≤ 8 as per 17 item Hamilton Depression Rating Scale) for the last 6 months (as corroborated by medical records) were included into the study. Additionally, these subjects should have consented for the study and should be able to read and write Tamil, the predominant language prevalent in this part of the country. Each subject was independently assessed by the psychiatrist to rule out associated comorbidities and if needed, the details were cross-checked with the medical records as well.

We had excluded subjects who had brief period of euthymia (less than 6 months), current mood episode [hypomania, Mania (YMRS score > 8) or depression (17 item HDRS > 8)], Mental retardation, comorbid axis I disorders (using MINI 5.0) like substance use disorders (except nicotine dependence), Post traumatic stress disorder and Attention deficit hyperactivity disorder (independently evaluated by the psychiatrist), Bipolar disorder secondary to general medical condition, medical conditions which induce sleep disturbance like Obstructive sleep apnoea and neurodegenerative conditions.

Age, gender & occupation matched healthy controls (n = 40) who were 18–60 years old, of either gender and literate in Tamil were recruited for the study with prior informed consent. Controls were meticulously screened for psychiatric illness like Bipolar disorder, Depression, Schizophrenia, Anxiety disorder, Mental retardation and Substance use disorder using structured assessment tool (MINI 5.0). Similarly, controls who had medical disorders like Obstructive Sleep apnea and who were illiterate in Tamil were also excluded. The entire protocol adhered to Indian Council of Medical Research (ICMR) Ethical guidelines for biomedical research on human participants (2006) which was reviewed and approved by the Institutional hospital ethics committee.

2.2. Administration of tools

Evaluation was done by two Investigators, one being psychiatrist and other being a medical graduate who was trained in psychiatric evaluation. The following tools were administered: (1) MINI 5.0 (Mini neuropsychiatric interview) to evaluate for BPAD and other axis I comorbidities (2) 17 item Hamilton depression rating scale (HDRS) (3) Young Mania rating scale (YMRS) (4) Biological Rhythm Interview of Assessment in Neuropsychiatry (BRIAN) (Giglio et al., 2009) (5) Pittsburgh Sleep Quality Index (PSQI) (Buysse et al., 1989) (7) Semi structured assessment tool to collect details about sociodemographic variables and clinical variables like age of onset of illness, number of episodes, rapid cycling, number of episodes, duration of the episodes and others. To reduce the risk of recall bias, these details were cross checked with the clinical data in the file and other informants if necessary.

BRIAN scale, developed by Bipolar Disorder Program in Brazil (Giglio et al., 2009), contains 18 items focusing on three important areas related to biological rhythm disturbance in psychiatric patients, namely sleep/activity, social rhythms and eating pattern. It measures the frequency of problems related to the maintenance of circadian rhythm regularity in the last 14 days. For example, in social rhythm, "Do you have difficulties in synchronizing daily routines and sleep patterns with significant others (family, friends, spouse)? How frequently?". Items are rated using a 4-point scale: (1) = not at all, (2) = seldom, (3) = sometimes, and (4) = often or in some items 1 = never, 2 = seldom, 3 = often, 4 = always. The total BRIAN scores ranges from 1 to 72, where the higher scores suggest severe biological/circadian rhythm disturbance. The scores were regrouped and scored as 5 domains namely, sleep, activity, social, eating and chronotype. Validity and reliability of BRIAN had been established not only in English but also in Portuguese version (Giglio et al., 2009).

PSQI (Pittsburgh Sleep Quality Index) (Buysse et al., 1989) is a self-administered instrument for measuring sleep quality in the last 30 days. The instrument has 19 questions which are grouped in to 7 sub-components, generating a score range 0–21. PSQI global score > 5 indicates poor sleep quality implying clinically significant sleep disturbance. As the scales like BRIAN and PSQI were self-administered, these were translated to the local language (Tamil) and back translated

to English. In the pilot study, these translated (Tamil) scales were administered to a group of bipolar subjects to assess the feasibility of the scales and necessary changes were made based on their feedback. The Tamil version of the BRIAN has been validated as part of this study, which is discussed in further sections of the study. Any doubts raised by subjects during assessment, were clarified by the investigators now and then.

2.3. Statistical analysis

Statistical analysis was conducted using SPSS for Windows – Version 19.0. Analysis of the socio demographic and clinical data using Shapiro-Wilk test of normality showed non–normal distribution and thus non parametric tests were used. Comparison of Socio demographic data, BRIAN scores and PSQI scores among cases and controls was performed using Mann – Whitney *U* test for continuous variables and $\chi 2$ test for discrete variables. Correlation among variables like, BRIAN, PSQI and clinical variables in bipolar subjects was done using Spearman's test of correlation. In order to find the predictors of biological rhythm disturbance, linear regression was performed with BRIAN scores as the dependent variable. Internal consistency reliability of the translated scale was measured using cronbach's α.

3. Results

3.1. Demographics and illness description

The mean age of the Bipolar subjects and controls were 41.25 ± 11.84 years and 38.25 ± 11.25 years respectively. Comparison of socio demographic details between bipolar subjects and controls didn't show any statistically significant difference in age, gender, socio economic status and occupational status (Table 1). The mean age of onset of Bipolar disorder was 27.38 ± 10.55 years (Table 2), with a median of 25 years. Mean HDRS and YMRS score in our subjects were 3.05 ± 1.12 and 3.75 ± 0.72, respectively, indicating that these subjects were euthymic at the time of evaluation.

3.2. Comparison of biological rhythm among the groups

Bipolar subjects (34.25 ± 9.36) experienced more biological rhythm disturbance when compared to controls (28.2 ± 6.53), which was statistically significant ($p = 0.002$) as measured by Mann- Whitney *U* test (Table 3). Activity ($p = 0.001$), eating ($p = 0.001$) and social ($p = 0.012$) domains of biological rhythm were more impaired in bipolar subjects when compared to controls. No statistically significant difference was found in sleep and chronotype domains of biological rhythm between bipolar subjects and controls. Analysis of PSQI scores revealed delayed sleep latency ($p < 0.001$) in bipolar subjects when compared to healthy controls, but they didn't differ on sleep efficiency, sleep quality, sleep duration and days disturbed due to sleepiness.

3.3. Clinical correlates of biological rhythm

As the parameters studied were not normally distributed in bipolar subjects, Spearman's test of correlation was used. Based on the correlation analysis, it was found that higher the number of mixed episodes, more worse were the biological rhythm disturbances (total BRIAN score $r = 0.291$, $p = 0.06$, trend towards of significance) (Table 4). Age(in years), duration of illness(in months), age of onset of bipolar disorder(in years), time elapsed since last episode(in months) number of manic episodes, number of depressive episodes, number of episodes requiring hospitalization and number of episodes with suicidal attempts did not correlate significantly with BRIAN total score and its domain scores(sleep, activity, eating and social). As depicted in Fig. 1, there was a near significant positive correlation between total BRIAN score and persisting sleep disturbances (PSQI score) ($r = 0.298$, $p = 0.06$, trend towards significance) in bipolar subjects (Table 5).

3.4. Subsyndromal mood symptoms and biological rhythm

There was significant positive correlation between BRIAN Global score ($r = 0.368$, $p = 0.02$), activity domain ($r = 0.359$, $p = 0.023$), sleep domain ($r = 0.344$, $p = 0.03$) and depressive symptoms (HDRS

Time elapsed after the last episode(months)	25.4 ± 11.06	
Medications		
Lithium 800–1200 mg (1012.5 ± 245.05)		28 (70%)
Divalproex sodium 1000 − 1500 mg (1456.45 ± 122.4)		12(30%)
Antipsychotics (Olanzapine 2.5 mg, Quetiapine 25 mg)		9 (22%)
Benzodiazepines (Clonazepam 0.25 mg)		0 (0%)

Table 3
Comparison of BRIAN scores between remitted bipolar subjects(n = 40) and Healthy controls(n = 40).

Domains	Remitted Bipolar subjects (Mean ± S.D)	Healthy Controls (Mean ± S.D)	P value (Mann-Whitney *U* test)
Sleep Domain	8.70 ± 3.413	7.93 ± 2.674	0.309
Activity domain*	8.60 ± 3.433	6.28 ± 2.320	**0.001**
Social Domain*	5.70 ± 2.233	4.75 ± 1.706	**0.012**
Eating domain*	6.78 ± 2.904	4.80 ± 1.800	**0.001**
Chronotype	4.47 ± 0.877	4.58 ± 0.781	0.440
Total BRAIN score*	34.25 ± 9.364	28.20 ± 6.533	**0.002**

score). But, there was no significant correlation between eating domain (r = 0.009, p = 0.95) or social domain(r = 282, p = 0.07) of the BRIAN and depressive symptoms (HDRS). But subsyndromal manic symptoms (YMRS) didn't have any statistically significant correlation with global BRIAN scores (r = − 0.178, p = 0.272).

3.5. Predictors of biological rhythm disturbance

In order to find the predictors of biological rhythm in remitted bipolar subjects, we performed linear regression with age, number of Manic episodes, number of Depressive episodes, number of Mixed episodes, number of episodes which required hospitalization, number of episodes with suicidal attempt, mean duration of episode, HDRS, YMRS, PSQI scores as independent variables and BRIAN global score as the dependent variable. Results of linear regression shows that number of episodes which required hospitalization (β = 0.601, t = 3.106, P = 0.004), HDRS(β = 0.376, t = 2.34, t = 0.036) and PSQI (β = 0.394, t = 2.609, p = 0.014) predicted 31% of variance in BRIAN sores(R^2 = 0.310, F = 2.594, P = 0.02).

3.6. Psychometric properties of BRIAN

Cronbach α for all five items of the translated BRIAN was 0.83 which showed good internal consistency reliability among the items of the scale. Concurrent validity of translated BRIAN was measured using Spearman's correlation, which showed statistically significant correlation between total BRIAN scores and PSQI items, especially total PSQI scores (r = 0.459, p = 0.001), PSQI daytime dysfunction(r = 0.324, P < 0.001), PSQI sleep disturbance (r = 0.498, P < 0.001), and PSQI sleep quality (r = 0.311, p = 0.003), which suggests good concurrent validity.

4. Discussion

4.1. Comparison of biological rhythm among the groups

Our study finding showed that bipolar subjects experienced greater biological rhythm disturbances than healthy controls especially in respect to activity, eating and social domains. This finding holds more significance as none of the recruited bipolar subjects had any axis I comorbidity and thus impaired biological rhythm disturbance can be attributed more likely to bipolar disorder in this study. Though previous studies have (Mondin et al., 2017; Duarte Faria et al., 2015; Rosa et al., 2013) showed more disturbances in social, sleep and activity rhythms in bipolar subjects, our study didn't find any difference in sleep rhythm

Table 4
Correlation between Clinical variables and Biological rhythm in bipolar subjects(n = 40).

Clinical variables	BRIAN Sleep	BRIAN Activity	BRIAN Social	BRAIN Eating	BRIAN Total
Age	0.086	−0.025	0.028	0.113	0.262

*Statistically significant trend towards significance(P = 0.06).

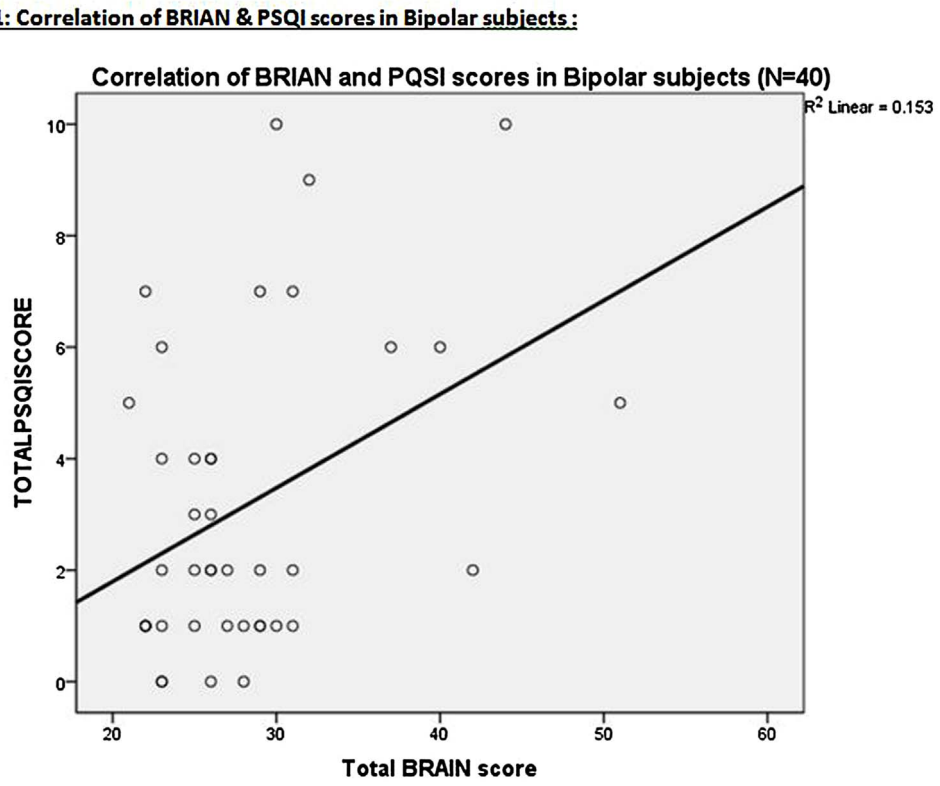

Fig. 1. Correlation of BRIAN & PSQI scores in Bipolar subjects.

between bipolar subjects and healthy controls.

4.2. Subsyndromal depressive symptoms and biological rhythm

Interestingly, mean HDRS score in remitted bipolar subjects was low (3.05 ± 1.12), yet these subsyndromal depressive symptoms had a significant association with biological rhythm even during the euthymic phase of the illness. This finding is in line with the results of study by Cardoso Tde et al. (2015), in which serial prospective assessments of biological rhythm, depressive and anxiety symptoms were done at baseline, 6th month & 12th month. This study emphasized that significant positive correlation existed between lesser Biological rhythm disturbances and lesser depressive and anxiety symptoms at 6th month & 12th month follow up. Recent meta-analysis comprising 12 studies involving 5837 patients showed that subsyndromal depressive symptoms during the euthymic phase of bipolar disorder, doubled the risk of having a subsequent mood episode (Radua et al., 2017). But, it is not yet clear whether the association between subsyndromal depressive symptoms and increased risk for subsequent mood episode is mediated by persisting biological rhythm disturbances in bipolar disorder (Levenson et al., 2015).

4.3. Sleep rhythm and bipolar disorder

In our study, bipolar subjects had increased sleep onset latency as measured by PSQI when compared to healthy controls. Sleep rhythm abnormalities such as increased sleep latency measured by actigraphy during euthymic phase of illness in bipolar I disorder have been shown to have high negative impact on the course of illness (Saunders et al., 2013; Gershon et al., 2012). Based on the observation that seasonal depression occurs when circadian rhythms are phase delayed relative to external light and/or sleep/wake cycle, Lewy et al. proposed a phase shift hypothesis of Seasonal affective disorder (Lewy et al., 1988). This hypothesis emphasized the use of light therapy for the treatment of seasonal affective disorder, which synchronizes internal circadian rhythm with external light and/or sleep/wake cycle rhythm.

In the present study, there was no statistically significant difference in sleep rhythm between bipolar subjects and controls which could be secondary to medications especially lithium (70%). Lithium had been shown to increase behavioral circadian length across many species (Abe

* Statistically significant = $p < 0.05$

et al., 2000). In mice, Lithium was shown to increase amplitude of oscillations in the central and peripheral oscillators, by enhancing PER 2 protein expression through GSK −3β signaling pathway (Li et al., 2012). In skin fibroblasts of bipolar patients, presence of PER3 and RORA clock gene variants predicted period lengthening effect of lithium and GSK3β clock gene variants predicted rhythm effects of lithium (McCarthy et al., 2013). In view of possible role of psychotropics on biological rhythm, future studies focusing on medication-free bipolar subjects are required.

4.4. Clinical predictors of biological dysrhythms

In our study, the regression analysis showed that number of episodes which required hospitalization, subsyndromal depressive symptoms and poor sleep quality (PSQI) predicted biological rhythm disturbances during the euthymic phase of illness. Prospective studies will be able to explain whether these clinical variables predicted more severe persisting biological rhythm abnormalities (Pinho et al., 2015) or whether the persistent rhythm abnormalities predicted depressive and mixed symptoms (Alloy et al., 2015).This in light of growing evidence for social/circadian rhythm dysregulation model of development of bipolar spectrum disorders (Alloy et al., 2015), assumes more importance.

4.5. Regulation of social rhythm as a treatment strategy

Circadian rhythm dysregulation model hypothesizes that disruptions in social rhythm have a pivotal role in course of bipolar spectrum disorders (Alloy et al., 2015). Social rhythm irregularity had been consistently found in bipolar subjects (Ashman et al., 1999) even during euthymic phase (Shen et al., 2008). Recently, Interpersonal social rhythm therapy had been shown to have good adjunctive effect in reducing depressive symptoms or hypomanic symptoms by increasing social rhythm regularity and reducing potential life event triggers (Nusslock and Frank, 2012). But interventions purely focusing on improving social rhythm, increased the regularity of daily routines only, but didn't predict changes in depressive or hypomanic symptoms (Faria et al., 2014). In view of inconsistencies in efficacy, interventions focusing on regularizing social rhythm, also need more research in remitted bipolar disorder.

4.6. Limitations

However, following limitations need to be considered 1) As the scales used were self-administered questionnaires, there could have been some amount of recall bias. This has been ameliorated to some extent by cross verification with file reports and multiple informants. 2) Our sample size was small. Thus these results need to be replicated in a larger sample in future studies. 3) We had not used objective assessment tools like actigraphy for measurement of sleep and activity rhythm. 4) Since the study purely focused on subjects with Bipolar I disorder, the results may not be generalizable to other forms of bipolar disorder. 5) Since all patients were on maintenance medications, their sleep parameters could have been influenced by those drugs. Thus, prospective naturalistic follow up studies could help us in understanding the persistent chronobiological disturbance in these patients, more conclusively.

5. Conclusion

Our study has shown that Biological rhythm disturbance seems to persist even after clinical remission of bipolar illness. Though our study has found higher biological rhythm disturbances in remitted bipolar subjects, the findings are preliminary in view of small sample size. Further studies on impact of biological rhythm on onset and course of bipolar illness may help us in understanding pathophysiology of bipolar disorder and thereby, may pave the way for new therapeutic targets for treating bipolar disorder.

ABSTRACT:

The role of social cue recognition and attributional bias on social functioning has been sparsely studied in remitted bipolar disorder (BD). In view of this, we evaluated thirty subjects with BD (without a history of psychotic symptoms) who were in remission and thirty age and, gender-matched healthy controls for social cue recognition [using SoCueReTI (Social Cue Recognition Test- Indian Setting)], and attributional bias (using an Attributional style questionnaire). Social functioning was assessed in subjects with BD using the Functional assessment short test (FAST) - Interpersonal relationships. Subjects with BD had significant deficits in recognizing social cues in low-intensity and high-intensity vignettes when compared to healthy controls. Deficits in recognizing social cues in low-intensity vignettes were significantly correlated with the FAST scores, even after controlling for the number of episodes and duration of illness. Further replication studies are needed to ascertain the association between social cue recognition deficits and social functioning in BD.

1. Introduction

Social cognition refers to the ability to perceive, understand, and respond to the intentions, behaviors, and dispositions of others (Green et al., 2008). It is a multifaceted construct involving multiple domains like social cue recognition, attributional bias, Theory of mind (ToM), and emotional perception (Green et al., 2008). Pooled estimates from various studies showed that ToM and emotional perception were significantly impaired in remitted bipolar disorder (BD) when compared to healthy controls (Samamé et al., 2015). Various studies that investigated the association between social cognition and functional outcome in BD have consistently found an association between emotional perception deficits and poor social functioning. Most of these studies had examined ToM and emotional perception. Only a few studies looked into other domains of social cognition, namely, social cue recognition and attributional bias (Vlad et al. 2018).

Social cue recognition (or social perception) helps to understand and appraise social roles, rules, and context. It involves using verbal and nonverbal cues to make inferences about a social situation. It thereby helps in establishing relationships and facilitating social interaction (Corrigan and Green, 1993; Savla et al. 2013). In subjects with BD, social cue recognition deficits were found, not only during the symptomatic phase of BD (Bazin et al. 2009) but also during the euthymic phase of the illness (Cusi et al. 2012). In the study by Cusi and colleagues, it was found that social cue recognition deficits negatively correlated with work/ school and marital role functioning (Cusi et al. 2012). Interestingly, BD subjects with a history of psychotic symptoms had intermediate deficits in auditory, visual, and visual-auditory decoding (emotional perception) tasks when compared to subjects with schizophrenia and to subjects with BD without a history of psychotic symptoms (Zenisek et al. 2015). Similarly, in another study, BD subjects with a history of psychotic symptoms had severe emotion recognition deficits, when compared to BD subjects without a history of psychotic symptoms. However, higher-order social cognitive domains like ToM and interpersonal problem-solving skills were not significantly different between BD subjects with or without psychotic symptoms (Thaler et al. 2013). In this context, we wished to examine inherent social cue recognition deficits of BD in those without a history of psychotic symptoms.

Attributional style/ bias, a social cognitive ability, typically helps to make inferences about the causes of positive and negative social events, linking them to internal (personal), external (other person), or situational factors (Savla et al. 2013). Externalizing bias is the tendency to over attribute positive rather than negative events to oneself, and personalizing bias is the tendency to attribute negative events to others

rather than to situational factors (Kinderman and Bentall, 1996). Earlier studies that compared subjects with or without psychiatric illness had found attenuated externalizing bias in subjects with psychiatric illness (Bhojak et al. 1989; Mezulis et al. 2004). These studies included subjects with various psychiatric illnesses, like depression, anxiety disorder, bipolar disorder, and psychosis. Subsequently, a few studies examined attributional bias exclusively in BD (Lahera et al. 2012, 2015; Lyon et al. 1999; Stange et al. 2013a, 2013b). It is noteworthy that higher anger and intentionality biases were significantly associated with sub-threshold depressive symptoms and poor psychosocial functioning in subjects with BD (Lahera et al. 2012, 2015).

As the bulk of the research was in the western population, there were major concerns about the universality of externalizing bias in the non-western populations (Mezulis et al., 2004). Interestingly, a cross-cultural study had found a large externalizing bias among students studying in the USA (all ethnicities), but the bias was small or attenuated or even absent in students studying in the Asian countries like India and Japan (Chandler et al. 1981, Mezulis et al. 2004). Similarly, many cross-cultural studies reported that emotional recognition was better among members of the same national, ethnic, or regional groups (Elfenbein and Ambady, 2002). These cross-cultural differences could be explained by diverse individual and interpersonal cultural schemata, which influences the self-other constructs and thereby, the way one person may interpret another's actions (Green et al. 2008; Vogeley and Roepstorff, 2009). These findings highlight a strong influence of culture on the understanding and processing of attributional bias. Thus, it is clear that the tools that are used to assess social cognition in one culture may not be useful in another culture. The tools which are adapted to the Indian culture might be able to assess social cognition in the Indian population in a better way. In this context, Social Cognition Rating Tools in the Indian Setting (SOCRATIS), a tool that is adapted to the Indian context, had shown good content validity and known-groups validity to assess social cognition (Mehta et al. 2011).

We conducted this study with the following aims: 1. to compare the social cue recognition ability and attributional bias between subjects with BD (in remission) without a history of psychotic symptoms and age and gender-matched healthy controls 2. to determine whether any association exists between social cognition measures (social cue recognition and attributional bias) and social functioning in subjects with BD. We hypothesized that subjects with BD (in remission) will have social cue recognition deficits and attenuated externalizing bias when compared to healthy controls. We also hypothesized that in subjects with BD, social cue recognition deficits and attenuated externalizing bias will be directly associated with social functioning.

2. Methods

2.1. Subjects

Subjects were recruited from the outpatient services of the Department of Psychiatry in a tertiary care medical college and hospital (PSG Institute of Medical Sciences and Research, Coimbatore, India) from May 2017 to September 2018, by consecutive sampling. We included subjects with bipolar disorder ($n = 30$) and healthy controls ($n = 30$), who satisfied the following inclusion and exclusion criteria.

We included subjects with BD between the ages of 18 and 60 years, of either gender, fulfilling the DSM 5 criteria for bipolar affective disorder Type 1 using MINI plus 7.0.2 (Sheehan et al. 1998). Only those subjects with BD who were in remission as defined by scores on the 17-item Hamilton Rating Scale for Depression (HDRS) ≤ 8 Hamilton (1960) and Young Mania Rating Scale (YMRS) ≤ 6 (Young et al. 1978) for at least 8 weeks (Masand et al. 2008) were included. The symptomatic remission for the previous 8 weeks was confirmed based on clinical health records and corroboration from reliable informants. This stringent definition of euthymia was entertained because of the known influence of subsyndromal depressive symptoms over attributional bias (Lahera et al., 2012) and social functioning (Ospino et al. 2018). We only included those subjects with BD who could read and understand Tamil (the local vernacular language). Subjects with BD were excluded if they had a lifetime history of psychotic symptoms during the episodes, substance use disorders (except nicotine), and other DSM V disorder classes (assessed using MINI plus 7.0.2). The lifetime history of psychotic symptoms was carefully ascertained from the subjects with BD (using MINI plus 7.0.2) and from their caregivers whose information was assessed to be reliable. Additionally, clinical health records of all recruited subjects with BD were carefully scrutinized for a lifetime history of psychotic symptoms. Those who had severe cognitive impairment, intellectual disability, neurodegenerative disorders, general medical illness that could impair cognitive performance, hearing or visual impairment which could interfere with test performance, and those who had received electroconvulsive therapy in the previous 6 months were also excluded from the study. Age and gender-matched healthy controls were included after ascertaining the absence of a lifetime diagnosis of any DSM V disorder classes (assessed using MINI plus 7.0.2) and of neurological illness or severe cognitive impairment which could impair the test performance.

Ethics clearance was obtained from the Institutional Human Ethics Committee as per the Indian Council of Medical Research (ICMR)'s national ethical guidelines for biomedical and health research involving human participants (2017). The investigator (E.K) underwent a supervised 3-day training focusing on administration and scoring of the SOCRATIS tool.

2.2. Procedures

After obtaining informed written consent, socio-demographic data and relevant illness variables were collected from the participants and cross-checked with health records. In the case of any discrepancy, the author (E.K) cross-checked with the treating psychiatrist and the query was resolved. Socio-demographic details were assessed using the modified Kuppuswamy scale, updated for the year 2018 (Saleem, 2018). Among subjects with BD and healthy controls, the current severity of depressive symptoms was assessed using the 17-item Hamilton Depression Rating Scale (HDRS) and the current severity of mania was assessed using the Young's Mania Rating Scale (YMRS).

2.2.1. Assessment of social cue recognition

In subjects with BD and healthy controls, social cue recognition was assessed using SoCueReTI (Social Cue Recognition Test- Indian setting), a part of the SOCRATIS tool. SoCueReTI was modified and culturally adapted from the original Social cue recognition test (Corrigan and Green, 1993). SoCueReTI had shown good content and known groups validity. As shown by Mehta et al. 2011, SoCueReTI could also classify 82.5% of the subjects (patient vs controls) correctly ($p < 0.05$) with 95% confidence intervals of 0.78–0.92. A cut-off value of 0.87 had 84.2% sensitivity and 81% specificity in precisely classifying subjects. The mean Cronbach's alpha coefficient of SoCueReTI was found to be 0.78, indicating good internal consistency. The intraclass correlation coefficient for the total scores in original and Indian versions was > 0.7 for social cues in low-intensity and high-intensity vignettes/ videos, indicating good concurrent validity with the original social cue recognition test (Mehta et al. 2011). The SoCueReTI videos were enacted by Indian actors, with attire and physical setting appropriate to the Indian context. The scripts for each of the videos were translated into Tamil by a bilingual translator, followed by a back translation by another bilingual translator to ensure the quality and accuracy of the translation. In this assessment tool, four high–intensity, and four low-intensity vignettes were played for the participants depicting various social situations. An example of a low-intensity vignette - a friend who becomes socially embarrassed and leaves, when his repeated attempts to join a casual chat are not acknowledged by his friends. An example of a high-intensity vignette - a father scolding his adolescent son for having caused an

accident while speeding on his new motorbike. The low-intensity vignettes/ videos will have a lesser degree of emotional arousal. Hence it will be difficult to perceive and recognize the social cues in the low-intensity vignettes when compared to the high-intensity vignettes. During each video, the participants were presented with 18 cues - 9 abstract or social cues and 9 concrete or non-social cues. At the end of each video, the participants were asked to respond to a series of 'true or false' questions related to the enacted social situation in the video. Every correct response to the 'true or false' questions pertaining to recognition of a social cue earned a score of 1 and every incorrect response received no score. If a participant correctly recognized all the 9 social cues in each of the eight videos, he/she could receive a maximum score of 72. The total score thus received by each participant was divided by the maximum possible score (i.e. 72) to obtain a social perception index . Thus, lower social perception index scores indicate higher social cue recognition deficits.

2.2.2. Assessment of attributional style

Attributional bias was assessed in subjects with BD, and healthy controls, using the Attributional style questionnaire, a part of SOCRATIS. This questionnaire was modified from the Internal, Personal, and Situational Attributions Questionnaire (IPSAQ) (Kinderman and Bentall, 1996) and was culturally adapted to the Indian context (Mehta et al. 2011). The Attribution style questionnaire has shown good content validity and known-groups validity. The mean attribution scores were much lower in subjects with schizophrenia when compared to the healthy controls. Among subjects with schizophrenia, the mean Cronbach's alpha coefficient was found to be 0.71 for all the items, 0.75 for the positive items, and 0.57 for the negative items (Mehta et al. 2011). In our study, a total of 32 hypothetical social situations were read to the participants (e.g., a friend refused to talk to you). The participants were asked to make causal attributions that were classified as internal (related to self) and external (personal or situational). Two bias scores, namely externalizing bias and personalizing bias were calculated from the responses.

Externalizing bias (EB) scores were calculated as follows:

$EB = P_i\text{-}N_i$, where P_i represents the number of positive events, for which the subject made internal attributes (i.e., attributed them to something within himself/ herself) and N_i represents the number of negative events, for which the participant made internal attributes. A positive EB score indicates that the participant attributes more positive events preferentially to himself/ herself in contrast to negative events, indicating a strong self-serving/ externalizing bias.

Personalizing bias (PB) scores were calculated as follows:

$PB = N_{ep} / N_{ep} + N_{es}$, where N_{ep} represents the number of negative events which the participants attribute to people (external personal attributes), and N_{es} represents the number of negative events which the participants attribute to situations (external situational attributes). A PB score over 0.5 indicated a tendency to use personal rather than situational external attributions for negative events.

2.2.3. Assessment of social functioning

Social functioning was assessed in subjects with BD using the Interpersonal relationships sub-item of the Functional Assessment Short Test (FAST). This sub-item assesses 6 areas, namely, maintaining a friendship, participating in social activities, having a good relationship with people close to them, living together in family, having satisfactory sexual relationships and being able to defend their interests, on a four point Likert scale. A score of 0 indicates no difficulty and a score of 3 indicates severe difficulty. Higher scores indicate higher impairment in social functioning (Rosa et al. 2007).

2.3. Statistical analysis

The normality of data was checked using the Shapiro-Wilk test, which showed that data was non-normally distributed. Between-group differences (BD vs healthy controls) among socio-demographic variables were tested with the Mann-Whitney *U* test for continuous variables and Fisher's exact test for discrete variables. Among the two groups, scores of social cue recognition and attributional bias were tested for any statistically significant difference, using the nonparametric Mann-Whitney *U* test with the significance level set at $p<0.05$. Effect size (for the nonparametric tests) was calculated using Cohen $r = z / \sqrt{N}$ (Fritz et al. 2012).The effect size was considered large, medium and small if Cohen's r was 0.5, 0.3, and 0.1, respectively Coolican (2009). Spearman's correlation was used to find out the correlation among illness variables, social cue recognition, attributional bias, and social functioning (FAST–interpersonal relationships) in subjects with BD. All statistical analyses were performed using IBM SPSS statistics version 20.0 (SPSS Inc., Chicago, IL, USA).

3. Results

3.1. Socio-demographic and illness details

The median age of subjects with BD and healthy controls was 36 years (IQR = 32–40.5) and 34.5 years (IQR = 29.5–38), respectively, with no significant difference between the groups ($U = 375$, $p = 0.27$). A higher percentage of subjects with BD were unmarried and belonged to low and middle socioeconomic status when compared to healthy controls. There was no statistically significant difference in gender, education, and occupation between subjects with BD and healthy controls (Table 1). The average number of episodes was 3.63 ± 1.67 and the average duration of illness was approximately 6.5 years. While the mean

HDRS and YMRS scores in subjects with BD were 3.67 ± 1.24 and 4.10 ± 1.19 respectively, the mean HDRS and YMRS scores in healthy controls were 0.78 ± 0.34 and 1.2 ±0.42, respectively. Twenty-four (80%) subjects with bipolar disorder were on mood stabilizers (lithium or divalproex sodium or a combination of the two), while six (20%) were on antipsychotic monotherapy (Table 2).

3.2. Comparison of social cue recognition between subjects with BD and healthy controls

Subjects with BD had statistically significant deficits in recognizing social cues (abstract) in both high-intensity ($p < 0.001$, ES = 0.29) and low-intensity ($p < 0.001$, ES = 0.31) vignettes when compared to healthy controls, with a medium effect size (ES). With respect to recognition of non-social (concrete) cues, subjects with BD had statistically significant deficits only in low-intensity vignettes ($p = 0.005$, ES = 0.31), but not in high-intensity vignettes (Table 3). None of the illness variables like age, the total number of episodes, age of onset of illness, duration of illness, HDRS scores, and YMRS scores had any statistically significant correlation with social cue recognition (Table 7).

3.3. Comparison of attributional bias between subjects with BD and healthy controls

Subjects with BD attributed less positive events (P_i) ($U = 197.5$, $p < 0.01$) and more negative events (N_i) ($U = 158$, $p < 0.01$) to something within oneself, when compared to healthy controls, which suggested attenuated externalizing bias or self-serving bias in subjects with BD ($U = 150.8$, $p < 0.01$) (Table 4). Subjects with BD were found to attribute negative events more to situational external factors than to personal external factors (personalizing bias), though the difference was not statistically significant as compared to healthy controls ($p = 0.119$). In subjects with BD, gender (males being 50%) did not have any significant influence on the scores of P_i ($p = 0.74$), N_i ($p = 0.74$), externalizing bias ($p = 0.266$) or personalizing bias ($p = 0.706$) (Table 6). Neither the illness variables like duration of illness, the total number of episodes, age of onset nor the social cue recognition scores had a significant correlation with attributional bias scores (Table 7). In subjects with BD, age was positively correlated only with P_i ($r = 0.37$, $p = 0.04$), which suggested that higher age was associated with attributing positive events to something within oneself.

Table 2
Illness characteristics in subjects with bipolar disorder (n=30):

S No.	Characteristics	Mean ± S.D	n(%)
1.	Age (years)	35 ± 8.477	
2.	Total number of episodes	3.63 ± 1.671	
3.	Number of manic episodes	2.13 ± 1.074	
4.	Number of depressive episodes	1.87 ± 1.359	
5.	Duration of illness (months)	77.13 ± 57.52	
6.	Number of episodes requiring hospitalization	2.25 ± 0.989

* = As some subjects were on combination of lithium and divalproex sodium, the percentage will not match with mood stabilizers

3.4. Correlation among illness variables, social cue recognition, attributional biases, and social functioning in subjects with bipolar disorder

In subjects with BD, the median value of their social functioning score was 6 (IQR = 6-12). Social functioning impairment was found to be significantly associated with longer duration of illness ($r = 0.434$, $p = 0.017$), higher number of episodes ($r = 0.41$; $p = 0.048$) (Table 7) and deficits in social cue recognition in low-intensity vignettes ($r = -0.47$, $p = 0.02$) (Table 5). The other illness variables (total number of manic episodes, total number of depressive episodes, and total number of episodes that required hospitalization) and attributional biases (externalizing and personalizing biases) did not correlate significantly with social functioning (Table 7). There was a small but significant negative partial correlation between social functioning and social cue recognition deficits in low-intensity vignettes ($r = -0.27$, df = 25, $p = 0.04$), after controlling for illness variables, namely duration of illness and the total number of episodes.

4. Discussion

This study found statistically significant deficits in social cue recognition and attenuated externalizing bias among remitted BD type 1 subjects (without a history of psychotic symptoms) when compared to age and gender-matched healthy controls. Social cue recognition deficits, but not externalizing bias, were significantly associated with social functioning impairment among subjects with BD.

4.1. Social cue recognition deficits in bipolar disorder

The finding of significant deficits in social cue recognition in euthymic BD is in line with previous studies (Bazin et al. 2009; Cusi et al. 2012). Bazin and colleagues had previously evaluated social cue recognition in symptomatic subjects with BD. They had found that subjects with mania had more deficits in attributing intention to implicit cues (Bazin et al. 2009). Cusi and colleagues in their study found that asymptomatic subjects with BD also had significant impairment in making judgments about social situations (Cusi et al. 2012). In line with the previous studies, there was no significant relationship among affective disorder burden indicators (earlier age of onset, longer duration of illness, a greater number of affective episodes), YMRS, HDRS, and social cue recognition (Bora et al. 2005; Cusi et al. 2012). Since the present study included only the subjects with BD without a history of psychotic symptoms, it may not be able to clarify whether these deficits were in anyway different from the subjects with BD who have a history of psychotic symptoms.

In this study, subjects with BD without a history of psychotic symptoms had significant deficits in decoding and reasoning of social and non-social cues when compared to healthy controls. The deficits in decoding social cues were significant in both low & high-intensity vignettes, while deficits in decoding non-social cues were evident only in low-intensity vignettes. The relationship between social cue recognition and the level of situational arousal can be explained based on the limited capacity model of information processing (Nuechterlein and Dawson, 1984) The recognition of social cues requires a greater degree of processing capacity when compared to the recognition of non-social cues. Similarly, processing capacity is more efficient during the middle levels of arousal, when compared to extreme levels of arousal. Overall, the deficits could be more evident in high attention-demanding tasks, namely, social cue recognition in low-intensity situations. Thus, the social cue recognition deficits seen in subjects with BD might imply that they were less conservative in considering rules, goals, and affect when asked to recognize cues on the more difficult cognitive tasks. This could represent a deficit in over-inclusive thinking (Corrigan and Nelson, 1998).

The presence of social cue recognition deficits in the remitted phase of BD, raises a question: whether the observed deficits in social cue

recognition existed even before the onset of BD (as an endophenotype) or whether it is due to the cumulative disease burden? Seidel and colleagues found a trend towards significant difference in the accuracy of emotion recognition, among subjects with BD, their unaffected first-degree relatives, and healthy controls (Seidel et al. 2012). In contrast, de Brito Ferreira Fernandes and colleagues did not find any significant difference in emotional recognition among unaffected first-degree relatives and healthy controls (de Brito Ferreira Fernandes et al. 2016). A few other studies found no significant difference in emotional recognition between youth with familial risk of BD and healthy controls (Brotman et al. 2008; Christiani et al. 2019; McCormack et al. 2016; Meluken et al. 2019). To date, there are no studies that have probed into social cue recognition in unaffected first-degree relatives of BD or youth with familial risk of BD. Thus, prospective cohort studies in at-risk populations might be able to decipher whether social cue recognition deficits exist even before the onset of the illness or appear during the course of the illness.

There is accumulating evidence that culture can influence social cue recognition. The social situations are processed in a contextual, interpersonal way in the Chinese population rather than individualistic way as in the western population (Hong et al. 2003; Triandis, 2001). A cross-cultural study found that participants from Japan tended to interpret social situations and make social judgments based more on relationships when compared to participants from America (Matsuda

and Nisbett, 2001). In this context, the use of a valid instrument that is culturally adapted to the Indian context, like SoCueReTI, can be considered as a strength of this study.

In this study, all subjects with BD were on medications, predominantly lithium, divalproex sodium, or low dose antipsychotics (mean chlorpromazine equivalents being 37.5 ± 10.5 mg). It is not clear whether the observed social cue recognition deficits are a result of the direct influence of pharmacological agents or secondary to the effect of these agents on the control of mood symptoms. Given the absence of an unmedicated remitted BD group, the exclusive effect of medications on social cue recognition could not be measured in this study. At the same time, it can be quite challenging to find unmedicated remitted subjects with BD. Additionally, in schizophrenia, the evidence for antipsychotic related improvement in social cue recognition was inconclusive. While a study with a small sample size showed a differential improvement in social cue recognition with Olanzapine when compared to typical antipsychotics (Littrell et al. 2004), another study with a large sample size showed no such association (Sergi et al. 2007). To our knowledge, there are no studies that systematically compared the distinctive effects of antipsychotics or mood stabilizers on social cue recognition in BD.

4.2. Attributional bias in bipolar disorder

We found attenuated externalizing bias in remitted BD. It had no association with any of the illness burden variables or social cue recognition deficits. A previous study had compared attributional bias among 3 groups, namely, euthymic, subsyndromal depressed, and clinically depressed (based on HDRS) subjects with BD. It showed that euthymic subjects obtained much lower scores in aggression bias when compared to subjects with subsyndromal depression and clinical depression. It was also found that there was no significant difference in attributional bias between subsyndromal depressed and clinically depressed subjects with BD, but the severity of depression significantly correlated with global functional impairment (Lahera et al. 2012). Similarly, a positive association was found between the severity of subsyndromal depressive symptoms and impaired ToM in subjects with BD (McKinnon et al. 2010). Taking all this into consideration, exclusion of the subjects who had subsyndromal or syndromal depression using a narrow definition of euthymia (HDRS ≤ 8, YMRS ≤ 6), could be considered as a strength of our study. Interestingly, studies that had examined attributional bias in BD reported that extreme attributions (positively and negatively valenced) were found to be associated with a longer recovery time, lower likelihood of recovery, and a higher likelihood for a transition from depression to hypomania or mania (Stange et al. 2013a, Stange et al. 2013b).

In a meta-analysis, it was found that women had a smaller self-serving attributional bias when compared to men during adulthood (Mezulis et al. 2004). But in this study, neither age nor gender showed any trend for such association. It should be noted that the self-serving bias was found to be smaller in the individuals of the Asian culture (Japan, Pacific Islander, India, China and Korea) when compared to those of the USA or western culture, though there was a significant variability in the magnitude of bias among the different Asian cultures (Bond et al. 1982; Mezulis et al. 2004). In the Asian culture, self is perceived as interdependent; sharing responsibility for success and assuming responsibility for failure is considered the most adaptive way to maintain self-esteem. Moreover, there is a higher likelihood of being liked by others if they have more self-effacing or self-enhancing attributions rather than self-serving attributions. Hence studies in the future should also consider this cultural context in the interpretation of attributional bias.

4.3. Social functioning in remitted bipolar disorder

In the present study, social functioning was negatively correlated with social cue recognition deficits, especially in low-intensity vignettes, even after controlling for duration of illness and number of episodes. It has also been reported previously that marital and work/ school role domain functioning was negatively correlated with social cue recognition deficits (Cusi et al. 2012). It was found that subjects need to have a higher degree of processing capacity to identify social cues in high attention-demanding tasks, namely low-intensity vignettes (Corrigan and Green, 1993) . Probably, the insensitivity to subtle covert or overt cues about the goal, rules, and affect of a social situation, could have a substantial role in guiding complex interpersonal interactions.

In our study, there was no association between attributional bias and social functioning which is in contrast to a previous study that had reported a significant association (Lahera et al. 2015). It should be noted that in this study, the selected subjects with BD had a lesser number of mood episodes and duration of illness when compared to the study by Lahera and colleagues. A study carried out by our research group in the same study population, showed that ToM did not predict social functioning in remitted BD (Palaniappan and Easwaran, 2020).

Subjects with BD have a greater degree of deficits in identifying negatively valenced emotions when compared to positively valenced emotions (Vogel et al. 2016). Various studies have demonstrated that accurate identification of facial affect especially happiness, fear, and disgust, are associated with better social functioning. Deficits in

emotional discrimination had been associated with impairments in daily life, autonomy, relationships, and occupational areas of functioning during the remitted phase of BD (Vlad et al. 2018). Thus, facial affect recognition could be one important prerequisite or even a part of the ability to identify the social cues correctly in a complex social situation.

A meta-analysis carried out in euthymic BD reported impairment in multiple neuropsychological domains like executive functions, working memory, verbal memory, and psychomotor speed, with relative preservation of verbal ability (Mann-Wrobel et al. 2011). While there was one study that did not find any association between neurocognition and community functioning in euthymic BD (Malhi et al. 2007), a meta-analysis found a weak association (Depp et al. 2012). In schizophrenia, social cognition seems to mediate the relationship between neurocognition and functioning (Schmidt et al. 2011), but in BD, social cognition moderated the relationship between neurocognition and functioning. This implies that neurocognition contributed to a better community functioning in subjects with BD who had poor social cognition (scoring 1 S.D below the mean) but not in those with good social cognition (Ospino et al. 2018). It is noteworthy that these studies have explored the role of emotion perception and ToM on functioning but have not looked into the role of social cue recognition on social functioning in euthymic BD.

In subjects with BD, deficits in neurocognition and emotional recognition were found to moderate or even be a prerequisite for a certain aspect of social cognition processing, especially ToM (Olley et al. 2005; Wolf et al. 2010). At this juncture, we need studies to explore the roles of these factors on social cue recognition and social functioning in euthymic BD (Cusi et al. 2012; Green et al. 2008). A few studies that evaluated the effects of social cognitive treatments like Social Cognition and Interaction Training (SCIT) (Lahera et al. 2013; Zhang et al. 2019), had reported improvement in attributional bias, emotional processing, ToM, and functioning. However, these studies had not examined social cue recognition. So, interventional studies, incorporating strategies to improve social cue recognition, are needed in the near future.

4.4. Limitations

The present study has not examined the influence of confounding variables like neurocognition, emotional perception, and medications on social functioning . Similarly, this study did not assess for the presence of personality disorders and thus its influence on the attributional style cannot be ruled out. Additionally, since the present study was done on subjects with bipolar disorder type 1 (in remission), without a history of psychotic symptoms, the findings cannot be generalized to those with a history of psychotic symptoms. Though the history of psychotic symptoms was looked for meticulously, we cannot rule out the possibility of recall bias. However, this study has given a preliminary inference that social cue recognition deficits and attributional bias may be independent of the lifetime history of psychotic symptoms, and thereby inherent to BD itself. Apart from this, the remission status was ascertained based on clinical health records and caregivers who had reliable information regarding their health status. It would have been more methodologically rigorous if the subjects with BD were recruited after ascertaining 8 weeks of remission status based on serial administration of HAMD & YMRS. In addition, though the psychometric properties of FAST are well established in BD, a scale that measures functional impairment based not only on the information from the subjects with BD but also from other corroborating reliable informants, would have added credibility to the findings. Also, social functioning was not measured in healthy controls in this study, which may be a notable limitation. Finally, the small sample size could have limited the interpretation of study findings.

Conclusion

Social cue recognition deficits and attenuated externalizing bias were found during the remitted phase of BD, even in those who did not have a history of psychotic symptoms. Further studies comparing BD subjects with or without a history of psychotic symptoms might help us to explain the influence of psychotic symptoms over these deficits. Though there seems to be an association between social cue recognition deficits and social functioning impairment in BD (even during remission), further replication studies may be required to understand the role of social cue recognition in social functioning, thereby aiding in the development of effective psychosocial interventions in bipolar disorder.

Funding

This research did not receive any specific grant from funding agencies in the public, commercial, or not-for-profit sectors.

Intellectual property

We confirm that we have given due consideration to the protection of intellectual property associated with this work and that there are no impediments to publication, including the timing of publication, with respect to intellectual property. In so doing we confirm that we have followed the regulations of our institutions concerning intellectual property.

Research ethics

We further confirm that any aspect of the work covered in this manuscript that has involved human patients has been conducted with the ethical approval of all relevant bodies and that such approvals are acknowledged within the manuscript.

Authorship

All listed authors meet the ICMJE criteria. We attest that all authors contributed significantly to the creation of this manuscript, each having fulfilled criteria as established by the ICMJE. We believe these individuals should be listed as authors because:

1. Krishnapriya Easwaran was involved in conceptualization, design & data collection. She was instrumental in writing draft and gave valuable inputs for framing the paper. She was also involved in final approval of the version and will take responsibility for integrity of the contents and data.

2. Pradeep Palaniappan had been involved in conceptualization, design of the study; analyzed the results; and had given valuable inputs to content of the paper. He also had involved in final approval of the version and take responsibility for integrity of the contents.

We confirm that the manuscript has been read and approved by all named authors. We confirm that the order of authors listed in the manuscript has been approved by all named authors.

6. Contact with the Editorial Office: The Corresponding Author declared on the title page of the manuscript is: Pradeep Palaniappan. We understand that this Corresponding Author is the sole contact for the Editorial process (including EVISE and direct communications with the office). He/she is responsible for communicating with the other authors about progress, submissions of revisions and final approval of proofs. Theory of Mind Deficits and Their Influence on Functional Impairment in Remitted Phase of Bipolar Disorder

Pradeep Palaniappan[1], Krishnapriya Easwaran[1]

ABSTRACT

Background: Functional impairment has been convincingly established in the euthymic/ remitted phase of bipolar disorder (BD). Though deficits in social cognition, especially theory of mind (ToM), predict functional impairment, the association has not been consistently proven.

Methods: Thirty remitted subjects with BD (as per DSM 5) and 30 age- and gender-matched healthy controls were screened for eligibility and the sociodemographic details and ToM scores, that is, first-order ToM, second-order ToM, and Faux pas, were collected. In subjects with BD, functioning was assessed using Functioning Assessment Short Test (FAST) and illness variables were collected.

Results: No significant difference was found in occupation or education between the groups. Remitted subjects with BD had statistically significant deficits in all domains of ToM, that is, first-order ToM (r = 0.65), second-order ToM (r = 0.69), and Faux pas (r = 0.75). Significant correlations existed between first-order ToM and FAST total score, as well as second-order ToM and FAST total score, but the correlations dropped after controlling for duration of illness and number of depressive episodes. Quantile regression analysis showed that the only factors which predicted global functional impairment was a higher number of episodes ($\beta\tau$ = −0.45, SE = 3.51, t = 0.13, P = 0.04), while all other illness variables and ToM failed to predict the global functioning.

Conclusion: Though there seems to be an association between ToM and functioning, only illness variables predicted functional impairment in subjects with BD. We need prospective studies to delineate the contributors to functional impairment.

Keywords: theory of mind, functioning, bipolar disorder, euthymic

Key Messages: Subjects with BD continue to have significant ToM deficits even during the remitted phase; the only factor which predicted global functioning was a higher number of episodes; first-order ToM, second-order ToM, or faux pas did not predict global functioning.

Social cognition is a multifaceted construct concerned with the cognitive processes involved in knowing about themselves and understanding other people's behavioral intentions. Theory of mind (ToM) is one such social cognition construct (also called mental state attribution), which involves the ability to understand other's behavior by assessing self and other's mental states such as feelings, desires, and opinions and to act accordingly.[1] Typically, ToM is subdivided as first order and second order, based on the complexity of inference. In a first-order "false-belief" task, the ability to understand that someone can hold a belief that is different from the actual state of affairs is assessed. In a second-order false-belief task, participants have to infer the (false) beliefs of one character about the (false) beliefs of a second character.

ToM deficits were evident among individuals in all the three phases of bipolar disorder (BD), namely manic, depressive, and euthymic phases.[2,3] While one might expect relatively lesser ToM impairments in the remitted phase, the deficits observed were certainly not negligible. Three meta-analyses[4–6] estimated the effect sizes of ToM deficits in the remitted state to be in the moderate range

(0.5 <*d* <0.8), with no significant difference when compared to subsyndromal mood state, but lesser than the deficits seen during acute mood (mania) state (*d* =1.23).[4] Though the influence of illness variables over ToM vary across studies, in some studies, global cognitive impairment and history of psychotic symptoms seem to worsen the degree of ToM deficits.[7–10]

Multiple studies had consistently shown that the unemployment rate was as high as 55% in BD.[11] Functional outcomes in BD are affected by various factors such as personality, current level of depressive symptoms[12] as well as age, course, insight into positive symptoms, and lifetime substance use disorders.[13] However, there is increasing evidence indicating that social cognitive deficits contribute substantially to functional outcomes in individuals with schizophrenia,[14] but there is less research evidence in BD. While some studies have shown positive association [15,16] between ToM deficits and functional impairment in BD, others have not.[17–20,21] Among ToM tasks, a strong association was found between poorer faux pas performance and lower Functional Assessment Short Test scores in one study,[22] but such association was not consistent in other studies.[17,23] It is also possible that the association was significantly influenced by subsyndromal depressive features.[24]

Social cognition, especially ToM, seems to be under a substantial cultural influence. Individual cultural schemata and interpersonally shared cultural models determine how humans interpret each other's experiences and guide their actions.[25,26] Functional magnetic resonance imaging studies demonstrate that, based on the cultural background of the test subject, neural correlates of ToM abilities may differ significantly.[27,28] As tools developed to assess social cognition in one culture may not be useful in another culture, assessment of ToM using culturally validated tools in the Indian population is necessary.[29]

In view of multiple methodological issues like administration of different tests to assess functioning and social cognition, heterogeneous populations, low sample size, assessment at different stages of illness, presence of subsyndromal mood symptoms, and paucity of data on neurocognition, more research in this area will improve our understanding about ToM and its effect on functioning in remitted BD.[21] Thus, our primary aim was to compare the ToM abilities among remitted subjects with BD and healthy controls. The secondary aim was to find any association among illness variables, the ToM, and functioning in subjects with BD, and if any exist, then to find out which factors predict the functioning in BD. We hypothesize that subjects with BD have ToM deficits even during the remitted phase of illness and that ToM will predict functional impairment in BD.

Materials and Methods

This is a cross-sectional study with a control group, in which we recruited euthymic/remitted subjects with BD and healthy controls based on eligibility criteria.

Recruitment of Participants

We recruited 30 subjects with BD (diagnosed by DSM 5) from the outpatient psychiatric services of a tertiary care medical college, during the period of May 2017 to September 2018, with prior informed written consent. We included subjects with BD who were 18 to 60 years old; of either gender; fulfilling DSM 5 criteria for bipolar affective disorder, either Type 1 or Type 2, using structured clinical interview for DSM5 (SCID 5); who are able to read and understand Tamil (local vernacular language) and who are currently in remission as defined by scores on the 17-item Hamilton Rating Scale for Depression (HAMD; score ≤8) and Young Mania Rating Scale (YMRS; score ≤ 6) for a period of eight weeks. We included this stricter definition of euthymia to minimize the influence of subsyndromal mood symptoms on the ToM tasks.[21,30] We excluded subjects with BD if they had history of psychotic symptoms during the episodes, substance use disorders (except nicotine), or other psychiatric axis I comorbidities (using Mini International Neuropsychiatric Interview, MINI plus 5.0); clinically determined severe cognitive impairment, mental retardation or neurodegenerative disorders; general medical illness that could impair cognitive performance; received electro convulsive therapy in the past six months, or severe visual or hearing impairment impairing test performance. Relatives of patients who were hospitalized for medical illness were screened for eligibility as controls. Age-, gender-, and education-matched healthy controls were included who did not have any lifetime psychiatric diagnosis (as established by MINI plus 5.0), neurological illness, or severe cognitive impairment that could impair the test performance. Ethics clearance was obtained from the Institutional Ethics Committee. The investigator (E.K) had undergone supervised three-day training organized by the authors of the culturally validated social cognition tool, The Social Cognition Rating Tools in Indian Setting (SOCRATIS), focusing on tool administration and scoring.

Assessments

With written informed consent, sociodemographic data and relevant illness variables were collected from the participants and cross-checked with the health records. Current mood symptoms were assessed using the 17-item HAMD and YMRS.

SOCRATIS, well-validated in Indian settings,[29] was used to measure three areas of social cognition, namely ToM, social perception, and attribution bias. The ToM task included two first-order and two second-order false belief picture stories, two metaphor-irony stories, and five faux pas recognition stories, which were presented as cartoon sequences. These story-based tasks examine the ability, at different complexity levels, to "meta-represent" mental states of others. Based on test performance, the tool scores ToM as first-order ToM (FOT) index (FOTI), second-order ToM (SOT) index (SOTI), and faux pas composite index (FPCI). If the subject scores less index scores, it suggests severe ToM deficits.

Functioning status was assessed in subjects with BD using Functional Assessment Short Test (FAST),[31] which assesses six specific areas of functioning: autonomy, occupational functioning, cognitive functioning, financial issues, leisure time, and interpersonal relation-

ships, with higher scores indicating higher functional impairment.

Statistical Analysis

All calculations were performed using R software. The normality of data was checked using the Shapiro–Wilk test, which showed that the data were non-normally distributed. Between-group differences (BD vs. healthy controls) among sociodemographic variables were tested with the Mann–Whitney *U* test for continuous variables and Fisher's exact test for discrete variables. Between-group ToM scores (FOTI, SOTI, FPCI) were tested for any statistically significant difference using Mann-Whitney *U* test, with the significance level set at P =0.05. Effect size (for nonparametric tests)[32] was calculated using Cohen $r = z/\sqrt{N}$. In order to understand the correlation among illness variables, ToM, and functioning (FAST domains and global), Spearman's correlation was used. Partial correlation was used to find the degree of correlation between ToM and functioning (FAST scores) in subjects with BD, after controlling for illness variables of interest. Quantile regression was carried out with illness variables and ToM variables as independent variables while using FAST (individual and total scores) as the dependent variable. The goodness of fit of the quantile regression model was assessed by comparison with the null/base model (statistical significance set at P < 0.05). Based on $\beta\tau$ coefficients, the relative contribution of each independent variable over the FAST scores was deciphered.

Results

Sociodemographic and Illness Details

The mean age was not statistically different (U = 375, P = 0.27) between BD (35 ± 8.48) subjects (n = 30) and healthy controls (36.27 ± 7.01) (n = 30) (**Table 1**). There was no statistically significant difference in gender, education, or occupation between subjects with BD and healthy controls. The average duration of illness was approximately 6.5 years, with time spent in depressive episodes (40.05 ± 26.85 weeks, median = 32) being longer when compared to manic episodes (18.17 ± 18.28 weeks, median = 12). The mean HAMD scores (3.67 ± 1.24) and YMRS scores (4.10 ± 1.19) suggested the remitted/euthymic status of BD (**Table 2**).

ToM Scores

In subjects with BD (**Table 3**), the mean score of FPCI (0.30 ± 0.37) was the lowest, followed by SOTI (0.55 ± 0.29), then by FOTI (0.64 ± 0.29). Mann–Whitney *U* test indicated that subjects with BD had deficits in FOT (U = 152, P < 0.001), SOT (U = 128, P < 0.001), and faux pas recognition (U = 77, P < 0.001) when compared to healthy controls, which were statistically significant. Effect size estimates ($r = z/\sqrt{N}$) showed large effect ($r \geq 0.5$)[32] for all the three domains of ToM, namely, FOT (r = 0.65), SOT (r = 0.69), and faux pas recognition (r = 0.75).

Functioning in Subjects with BD

Mean FAST scores indicated that interpersonal (9.17 ± 4.2), occupational (7.37 ± 4.38), and cognitive (7.40 ± 4.28) domains of functioning were more affected than financial (1 ± 1.11), autonomy (1.30 ± 1.91), and leisure (1.30 ± 1.02) domains of functioning. Correlation between illness variables, ToM variables, and FAST (individual item based and total) scores was evaluated using Spearman's rho correlation (**Table 4**). There seems to be a significant (P < 0.05) negative correlation between FOT and all domains of FAST, indicating that more the FOT deficits (lesser FOTI), more is the functional impairment in all domains (higher FAST domain scores) (**Table 4**). But such a significant correlation was not observed for

TABLE 2.

Illness Variables in Subjects with BD (*n* = 30)

Characteristics	Mean ± SD

FPCI and FAST domains. While the duration of illness (months) was positively correlated significantly with all domains of functioning (P < 0.05), the number of depressive episodes was positively correlated with only four domains of FAST, namely, autonomy, occupational, interpersonal, and cognitive domains. In view of the significant correlation between functioning and multiple variables (illness variables and ToM variables), we performed partial correlation analysis. After controlling for illness variables (i.e., number of episodes, number of depressive episodes, and duration of illness), the significance of the correlation between FOT and functioning (total score) dropped, but still remained significant (r = −0.44, P = 0.05), while it lost significance for SOT (r = −0.17, P = 0.48).

Predictors of Functioning in Subjects with BD During the Remitted Phase

In order to improve the model accuracy and prevent dilution of the model, we used the significantly correlated variables (total number of episodes, number of depressive episodes, duration of illness, FOTI, SOTI) as independent variables and FAST (total and sub-items) as a dependent variable into the final models (**Table 5**), while controlling for all other variables of interest. With respect to global functioning (FAST – total), the model showed goodness of fit (ΔF (5, 24) = 10.04, P = 0.03) in which total number of episodes ($\beta\tau$ = −0.45, SE = 3.51, t = 0.13, P = 0.04) had shown statistically significant contribution, while FOTI had shown trend towards significance ($\beta\tau$ = −22.57, SE = 14.36, t = −1.57, P = 0.06).

With regard to interpersonal functioning (FAST), the model showed goodness of fit (ΔF (5, 24) = 5.18, P = 0.002), in which all independent variables lost significance, except FOTI, which showed trend towards significance ($\beta\tau$ = −12, SE= 6.2, t = −1.93, P = 0.06). Among other models, the models which showed goodness of fit were FAST occupational (ΔF (5, 24)= 6.60, P = 0.0005), FAST cognitive (ΔF (5, 24) = 12.26, P = 0.0003), and FAST leisure (ΔF (5, 24) = 6.18, P = 0.0008) as dependent variables, in which none of the independent variables showed a significant contribution (**Table 6**).

Discussion

Our findings suggest that significant ToM deficits (FOT, SOT, and faux pas) are present during euthymic/remitted state of BD when compared to healthy controls. A significant association existed between global functioning (FAST–Total) and most of ToM variables, that is, with FOT (P < 0.001), SOT (P = 0.003), but not with faux pas (P = 0.17). A higher number of episodes predicted poor global functioning, while ToM did not predict global functioning in subjects with BD during the remitted phase.

ToM (first-order, second-order, and faux pas recognition) deficits seem to persist even during the remitted phase of the BD. This is in line with multiple metanalyses[4–6] that had also shown that ToM deficits persist irrespective of the form (cognitive or affective) and type of assessment tools.

The link between ToM and functioning has been explored in all the symptomatic phases of BD, that is, depressive,[18,33–35] manic,[18,33], and mixed phases.[35] Studies that explored the association between ToM and functioning in euthymic/remitted BD had shown mixed results, with some reporting significant association[15,16,18,22,24,36] and others not.[17,20] A possible link exists between depressive symptomatology and global functioning, where depressive symptoms explain 17%–35% of the variance in the global functioning.[18,33]

Our results show that FOT is most consistently correlated with all the domains

of functioning (autonomy, financial, occupational, cognitive, interpersonal, and leisure). But there was no consistent correlation with higher-order ToM such as faux pas stories and SOT tasks in our study. These results are in line with existing literature that shows that out of 12 studies, only two[16,22] showed a positive association between faux pas (higher-order ToM) and functioning, especially social functioning.[21] In our study, the only illness variable which significantly predicted global functioning was a higher number of episodes, while all other illness variables and ToM tasks (FOT, SOT, faux pas) lost their contribution to variance in global functioning impairment. The interesting question which arises now is which factor(s) mediates the influence of illness variables over functional impairment in BD. The absence of any significant prediction of functional impairment by ToM[17,23] makes us wonder whether alternate mediators like neurocognition would mediate the influence of illness variables on functioning.[37] On the contrary, a recent study has shown that social cognition moderates the effect of neurocognitive deficits over community functioning.[38] In view of the mixed results, prospective studies looking into the association of illness variables, social cognition, neurocognition, and functioning needs to be done.

Recently, social cognition and interaction training (SCIT) has been investigated in schizophrenia[39,40] and has shown promising preliminary results. But to our knowledge, only two studies exist in BD.[41,42] The study which compared the effects of SCIT and treatment as usual on social cognition in outpatient subjects with BD[42] had shown that SCIT caused small but significant improvement in ToM, facial emotional recognition, and

hostility attribution biases, but not in social functioning. The authors proposed that improvement in BD may be better if SCIT is modified by including tasks involving comprehension of more complex social situations rather than lower order facial emotional recognition.

Though many studies had shown that subsyndromal depressive symptoms influence the social and occupational functioning,[16,17,33] our study did not show such a correlation (FAST-interpersonal or FAST-occupational), possibly because of our stricter definition of euthymia and the higher HAMD scores in other studies. In one such study,[22] low functioning (FAST > 11) and high functioning (FAST ≤ 11) remitted bipolar groups were compared for verbal social cognition using comprehension faux pas test, which showed that verbal social cognition and subsyndromal depressive symptoms significantly predicted poor functioning in the low functioning group but not in the high functioning and control groups. Such an association between subsyndromal depression and functioning was not universally proven in all studies.[43,44] At the same time, though subsyndromal depressive symptoms may have a lesser influence on ToM tasks, in many studies it has been found that subsyndromal depressive symptoms have a mediating effect between emotional perception deficits and social functioning.[22–24,33,36,43–45]

Based on the correlation between functional impairment and illness variables like longer duration of illness,[30] higher number of episodes, especially depressive episodes, and longer time spent in depressive episodes in our study, we hypothesize that functional impairment could be a consequence of the progressive nature of the illness rather than subsyndromal depressive symptoms. There is some evidence in the short- or long-term (3 to 10 years) prospective studies that the severity and frequency of bipolar depressive episodes contribute to cognitive decline and poor psychosocial functioning,[46] possibly through dysregulated neuroinflammation.[47] Similar inconsistent evidence also suggests that the frequency and severity of manic episodes may lead to poor psychosocial functioning and cognitive impairment,[48] but our study did not find such association. It is possible that this causal relationship could not be established with the cross-sectional nature of the current study and thus, it may need longitudinal studies using more objective rating scales rather than subjective, self-report scales like FAST.[33]

Limitations

This study was less powered to detect a statistically significant association, and this could have influenced our statistical interpretations. Second, confounding variables such as intelligence, which could influence the social cognition scores, were not formally assessed. This could have been partly mitigated by the use of SOCRATIS, which assesses intellect and memory by use of control questions, which are scored during the final scoring of the tool. This is also mitigated by a careful, clinical evaluation of premorbid intelligence. Third, we did not evaluate the neurocognitive variables like processing speed, attention, and verbal recall which could interfere or influence the social cognition task performance. Fourth, the above findings are restricted to patients in the remitted phase of bipolar I disorder without a history of psychotic symptoms. Though subjects with BD with a history of psychotic symptoms have been known to have more ToM deficits when compared to those without a history of psychotic symptoms,[8,9] we intentionally excluded them to avoid contamination of results and thereby to find the deficits that are exclusive to BD. Thus, the generalization of our findings to other types/phases of BD may not be possible and that would require a study that looks into differential social cognition findings across other bipolar diagnoses/phases. Finally, it is known that accurate predictions cannot be guaranteed in a cross-sectional study and rather should be based on a longitudinal study. Temporality assumption (dependent variable has to occur after the independent variable) cannot be assured in a cross-sectional study. But still, findings of a cross-sectional study can pave the way for testing those variables in later longitudinal cohort studies.

Conclusions

There seems to be an association between ToM deficits and global functioning in subjects with BD during

TABLE 6.

the remitted phase, but they lose their ability to predict when illness variables such as a higher number of episodes are taken into account. Caution needs to be exercised in interpreting our findings, in view of the cross-sectional nature of the study and the low sample size. Thus, prospective studies on the effect of ToM deficits on functioning are needed to understand the role of preexisting social cognition deficits, especially ToM deficits, if any, in BD.

Received: June 05, 2020; Initial review: September 16, 2020; Accepted: February 09, 2021.

Objective: To compare the efficacy of epinephrine plus vasopressin vs epinephrine plus placebo in the pediatric intensive care unit (PICU) cardiopulmonary resuscitation (CPR).

Design: Randomized, double-blind controlled clinical trial.

Setting: PICU in a tertiary care institute from February, 2019 to May, 2020.

Participants: Children aged one month to 13 years who required CPR during PICU stay. Patients in whom vascular access was not available or return of spontaneous circulation (ROSC) was achieved by defibrillation without epinephrine were excluded.

Intervention: Patients were randomized to receive vasopressin 0.1 mL per kg (=0.8 unit per kg) or placebo (0.1 mL per kg normal saline) in addition to epinephrine (1:10000) 0.1 mL per kg. The drugs were given as bolus doses every three minutes until the ROSC or up to a maximum of five doses, whichever was earlier.

Outcome Measure: The primary outcome was the proportion of patients who achieved ROSC. The secondary outcomes were survival rate and functional status (at 24-hour, PICU, hospital, and 90-day post-discharge), need for organ supports, length of stay (PICU and hospital), and adverse effect(s) of the study drugs.

Results: 90 patients (epinephrine plus vasopressin group, *n*=45 and epinephrine plus placebo group, *n*=45) were analyzed on intention-to-treat basis. There was no significant difference in the primary outcome between epinephrine plus vasopressin (*n*=25, 55.5%) and epinephrine plus placebo groups (*n*=24, 53.3%) (Relative risk 1.04, 95% CI 0.71 to 1.52). There was no significant difference in survival rate at 24-hour (*n*=7, 15.6% vs. *n*=8, 17.8%), at PICU, hospital, and 90-day post-discharge (*n*=1, 2.2% vs *n*=1, 2.2%). There was no difference in other secondary outcomes. No trial drug-related serious adverse events were observed.

Conclusion: A combination of epinephrine plus vasopressin did not improve the rate of return of spontaneous circulation in the pediatric intensive care unit cardiopulmonary resuscitation as compared with epinephrine plus placebo.

Keywords: *In-hospital cardiac arrest*.

Trial Registration: CTRI/2019/01/017200.

Published online*:** February 19, 2021;PII:*** S097475591600287

Cardiac arrest is a dreadful event in pediatric intensive care unit (PICU). Cardiopulmonary resuscitation (CPR) involves chest compression and manual ventilation at appropriate intervals. Return of spontaneous circulation (ROSC) is the initial therapeutic goal in cardiac arrest and is a measure of initial success. Vasopressor medications are often used during CPR. These medications increase aortic diastolic pressure, thereby improving coronary perfusion pressure, which facilitates ROSC [1]. Epinephrine is the most widely studied and the first line vasoactive drug as per the pediatric advanced life support (PALS) guidelines [2]. Vasopressin, a potent vasoconstrictor, is well studied in adult cardiac arrest [3]. The recent advanced cardio-vascular life support guideline recommends that Vaso-pressin, combined with epinephrine, may be considered in adult cardiac arrest resuscitation [3]. Though the pediatric in-hospital cardiac arrest (IHCA) outcome has improved from 39% to 77% in high-income countries, data from low-and middle-income countries are lacking or are under-reported [2]. Animal studies, case series, and feasibility pilot studies have shown encouraging results for the use of vasopressin in pediatric cardiac arrest [4-6]. This study hypothesized that epinephrine plus vasopressin would be associated with a higher rate of ROSC as compared to epinephrine plus placebo in the pediatric intensive care unit cardiopulmonary resuscitation.

METHODS

This randomized, double-blind controlled clinical trial was undertaken in PICU of a tertiary care academic hospital from February, 2019 to May, 2020. Ours is a 19 bedded

level-III PICU, receiving critically ill children 24 hours a day throughout the year. Though our PICU is a predominantly medical ICU, it also receives complicated surgical and trauma patients. The PICU has facilities for providing multimodal hemodynamic and neuromonitoring, mechanical ventilation, and high-frequency ventilation. It is also equipped with an in-house blood gas analyzer with a co-oximeter module, osmometer, therapeutic plasma exchange, and renal replacement therapy. During the study period, the baseline mortality in our PICU was 20%, and the average length of PICU stay was six days, with a bed occupancy rate of 80%.

The trial was approved, and its progress was reviewed yearly by the institute ethics committee. Written informed consent was obtained from the parent/legally authorized representatives of all patients getting admitted to PICU at the time of transfer-in, stating that their child might be enrolled in the study if the child required CPR during the PICU stay. Children aged one month to 13 years, admitted in PICU, and who required CPR during their PICU stay were enrolled. Children who had a cardiac arrest outside of PICU and were shifted to PICU for post-cardiac arrest care were not enrolled. Children with either of the following conditions were also excluded (*i*) patients in whom vascular access was not available (*ii*) ROSC was achieved by defibrillation without the requirement of Epinephrine.

A computer-generated, unstratified, block randomization with variable block sizes of four, six, and eight was used with an allocation ratio of 1:1 by a person not involved in the study. Individual assignments were kept in serially numbered boxes. Each box contained ten identically looking one mL ampoules of either vasopressin or placebo (normal saline). The original label in each ampoule was removed and replaced by an opaque paper. Each box was serially numbered and allocated to the patient according to the random sequence. The serially-numbered trial drug boxes were kept in a separate place in PICU to avoid the wrong allocation in the stressful environment. Only one trial drug box was kept in the crash cart, which contained all the emergency drugs and equipment required for CPR. The nurses were instructed to open the trial drug box, which was kept in the crash cart during CPR. The investigator ensured the replacement of the trial drug box in the crash cart according to the serial number once the trial drug was used. Multiple simulation sessions were carried out and discussed before the start of the study. Injection normal saline (sodium chloride 0.9%, 1 mL, Serum Institute of India Pvt Ltd), injection epinephrine (Bioaderna, 1 mg per 1 mL, Health Biotech Ltd) and injection vasopressin (Vascel 20, 20 Unit per mL, CELON laboratories Pvt Ltd) were used in this study. The institute's central pharmacy supplied the trial drugs. The participants, treating team and nurses administering the medications, and the investigators, were unaware of the treatment assignments. The person who collected and entered the data into the datasheet and the study statistician were unaware of the treatment assign-ment throughout the analyses. The treatment assignment was disclosed, after the first draft of the result was finalized.

All patients received CPR in accordance with the PALS-2015 guidelines established by the American Heart Association (AHA) [2]. This includes the support of airway, breathing, including supplemental oxygen, evaluation of cardiac rhythm, high-quality CPR with minimally interrupted chest compressions, electrical defibrillation if appropriate, and medications except for the trial drugs. The resuscitation team members were trained to provide CPR as per the PALS 2015 guidelines [2]. The facility for standby extracorporeal membrane oxygenation (ECMO) is not available in the study site (PICU). Our hospital has no approved guidelines for 'Do not resuscitate' instructions. Epinephrine plus vasopressin group received intravenous epinephrine (1:10000) 0.1 mL per kg and vasopressin (1:1.5 dilution in normal saline) 0.1 mL per kg (=0.8 unit per kg; maximum dose of 5 mL, 40 unit). Epinephrine plus placebo group received intravenous epinephrine (1:10000) 0.1 mL per kg and placebo (1:1.5 dilution in normal saline) 0.1 mL per kg. The trial drugs were given as bolus doses, concurrently if two vascular accesses were available or within 10 seconds gap if one vascular access was available. The trial drugs were given at an interval of every three minutes until ROSC or a maximum of five doses, whichever was earlier. Three mL normal saline flush was given after adminis-tration of each dose of the trial drug. Subsequently, if needed, epinephrine was continued as per protocol. Post-resuscitation care was provided to the patients who achieved ROSC as per the unit protocol (from PALS-2015 guidelines) [2]. All patients were followed up until death or 90 day post-discharge. The functional status of the survivor was assessed by using the pediatric cerebral performance category (PCPC) scale and pediatric overall performance category (POPC) scale (lower the score, better the neurological outcome) [7]. Data regarding the cardiac arrest events and their outcomes were collected as per the Utstein style template and in the predesigned proforma [8-10].

The primary outcome was the proportion of patients who achieved ROSC. The secondary outcomes were (*i*) survival rate (at 24 hours, PICU, hospital, and 90-day of discharge), (*ii*) functional status (at PICU, hospital, and 90-day of discharge), (*iii*) need for organ support(s), (*iv*) length of stay in PICU and hospital, and (*v*) adverse effect(s) of the study drugs if any. ROSC was defined as the restoration of a spontaneous perfusing rhythm that results

in more than an occasional gasp, fleeting palpable pulse, or arterial waveform [2,3,10]. Sustained ROSC was defined as not requiring chest compressions for 20 consecutive minutes after obtaining ROSC and signs of perfusion [2,3,10]. The probability of adverse trial drug reaction was assessed by Naranjo algorithm [11].

The ROSC rate varies between 47% and 64.6%, as reported by previous studies [12,13]. We assumed that the primary outcome of interest in the control group was 50%. We calculated the sample size based upon the assumption of 30% improvement in the primary outcome by the intervention with 80% power at the 5% significance (two-sided) and 1:1 allocation. Thirty-nine patients were required in each group by calculation. With a 10% attrition rate, the final sample size was estimated as 86 [12-14]. The sample size was calculated using the software nQuery version 4.0.

Statistical analysis: Data were analyzed according to their assigned groups (intention to treat analysis). The distribution of data was checked with the Kolmogorov-Smirnov Z test. Continuous variables were compared between the two groups by Student's *t*-test for normally distributed or by the Mann-Whitney *U* test for skewed data. Proportions were compared by the Chi-square test (or Fisher's exact test if expected cell frequencies were less than five). Kaplan-Meier curve and log-rank test were used to analyze 'time to event' data followed by Cox proportional hazard regression analysis to adjust for the prespecified baseline factors (age, sex, and PRISM-III score). The relative risk and hazard ratio, with a 95% confidence interval, was calculated as appropriate. All tests were two-tailed, and a *P* value of less than 0.05 was considered statistically significant. IBM SPSS software 20.0 (IBM Corp) and Epi Info 7 (7.0.9.7, CDC) were used for data analysis.

RESULTS

The study flow is depicted in **Fig. 1**. Ninety patients were enrolled (epinephrine plus vasopressin, *n*=45, and epinephrine plus placebo *n*=45) after the screening of 118 patients. The baseline characteristics and clinical variables are described in **Table I**. The median (IQR) time to first cardiac arrest since admission was similar between groups [2 (1-7) vs 2 (1-5) day; *P*=0.75]. The most common (80%) arrest rhythm was pulseless electrical activity (PEA). Hemodynamic abnormality (67.8%) was the most common event that led to arrest, followed by respiratory events (23.3%). Respiratory failure was an underlying illness in 76 (84.4%) patients and sepsis in 60 (66.7%) patients. The median (IQR) duration of CPR was similar between groups [18 (10-30) vs 15 (6–30) minutes; *P*=0.96].

The proportion of patients who achieved ROSC was similar in epinephrine plus vasopressin group and epinephrine plus placebo group [RR (95% CI) 1.04 (0.71-1.52); *P*=0.83]. The time to achieve ROSC and the proportion of patients requiring ongoing CPR was similar between two groups during the first 30 minutes of CPR [Log rank *P*=0.99] **(Fig. 2)**. Among ROSC achieved patients (*n*=49), the median (IQR) time taken to ROSC was similar between two groups [10 (4-14) vs 6 (5-10) minutes, *P*=0.21]. The proportion of patients who underwent CPR beyond 30 minutes was also similar between two groups [RR (95% CI) 0.50 (0.19-1.35); *P*=0.16] and none achieved ROSC. There was no significant difference in the proportion of patients who achieved sustained ROSC in the study groups [44.4% vs 53.3%; *P*=0.40]. The survival to hospital discharge was similar in both groups [*n*=1 each]. Mean (SD) diastolic blood pressure (DBP) was similar in epinephrine plus vasopressin group as compared to epinephrine plus placebo group during CPR (38.1 (11.5) mm Hg vs 37.1 (13.4) mm Hg, *P*=0.77). There was no significant difference in the other secondary outcomes between study groups **(Table II)**. In epinephrine plus vasopressin group, one patient developed pulseless ventricular tachycardia which converted into asystole

Data in no. (%) or [a]mean (SD). CNS: central nervous system; SD: standard deviation; $EtCO_2$: end-tidal carbon dioxide; CPR: cardiopulmonary resuscitation; [b]Patient had one or more conditions; [c]had one or more interventions. Hence, the cumulative totals do not necessarily equal. Three patients also received EtCO2 monitoring after placement of endotracheal tube during CPR; [d]P=0.002.

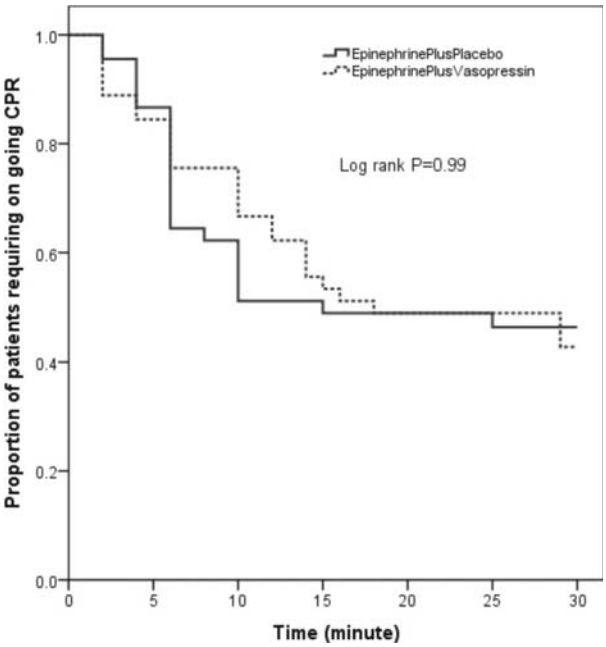

Fig. 2 Kaplan Meier curves showing time to return of spontaneous circulation (ROSC) and the proportion of patients requiring on-going cardio pulmonary resuscitation (CPR) between the two study groups.

during the third cycle of CPR. There were no serious trial drug-related adverse events observed.

DISCUSSION

This randomized controlled trial enrolled 90 patients who underwent CPR in PICU. We found no significant difference in the proportion of patients who achieved ROSC and survival rate between the Epinephrine plus Vasopressin group and Epinephrine plus Placebo group. In our study, the overall rate of achieving ROSC was 54.4%, and survival to hospital discharge was 2.2%. This observation contrasts with the data from high-income countries, where the rates were more than 80% and 40%, respectively [15]. The potential reasons could be the uniform reporting registries, universal healthcare programs, training of health care workers, and accessibility to extracorporeal membrane oxygenation (ECMO).

The outcome of a pediatric cardiac arrest depends upon many factors, including the initial presenting rhythm, the place of cardiac arrest, early recognition of the arrest, and the underlying conditions. In the previous studies done in high-income countries, asystole (55%) was the initial arrest rhythm, and respiratory failure was the common precipitating factor [1,9]. Nevertheless, they enrolled patients not only from PICU but also from the emergency department and general ward [1,9]. In contrast, this study

Table II Primary and Secondary Outcomes of the Study Groups

Variables	*Epinephrine plus vasopressin group (n = 45)*	*Epinephrine plus placebo group (n =45)*	*Relative risk (95% CI)*	*P value*
Primary outcome				
Proportion of patients achieved ROSC	25 (55.5)	24 (53.3)	1.04 (0.71-1.52)	0.83[a]
Proportion of patients achieved sustained ROSC	20 (44.4)	24 (53.3)	0.83 (0.54-1.28)	0.40[a]
Secondary outcomes				
Survival rate at 24 – hour	7 (15.6)	8 (17.8)	0.88 (0.35-2.21)	0.78[a]
At PICU discharge	1 (2.2)	1 (2.2)	1.00 (0.06-15.50)	1.00[c]
At Hospital discharge	1 (2.2)	1 (2.2)	1.00 (0.06-15.50)	1.00[c]
At 90-day post-discharge	1 (2.2)	1 (2.2)	1.00 (0.06-15.50)	1.00[c]
Functional status				
PCPC score – 1 (mild)	-	1 (2.2)	-	-
POPC score – 4 (severe)	1 (2.2)	-	-	-
Organ support therapy among patients achieved ROSC[a,b]				
Mechanical ventilation, h	1.5 (0.5-12)	5 (1.3-33)	-	0.07[b]
Vasoactive therapy, h	1.5 (0.4-8)	4 (1.3-19)	-	0.07[b]
RRT, h[c]	1 (1-14.3)	50 (1-137)	-	0.13[b]
PICU stay, h	1.5 (0.5-12)	5 (1.3-33)	-	0.08[b]
Hospital stay, h	1.5 (0.5-12)	5 (1.3-33)	-	0.08[b]

Data are presented as no.(%) except [a]median (IQR). ROSC: return of spontaneous circulation; CI: confidence interval; IQR: interquartile range; RRT: renal replacement therapy; PCPC: pediatric cerebral performance category; POPC: pediatric overall performance category. [b]25 in epinephrine plus vasopressin group and 24 in epinephrine plus placebo group; [c]seven in epinephrine plus vasopressin and six in epinephrine plus placebo group received RRT support after ROSC.

enrolled patients only from PICU, where stringent monitoring helped identify the arrest much earlier, before progressing to asystole. Similar to our study setting, Rathore, et al. [12] reported bradycardia (52.2%) and sepsis (71%) as the initial arrest rhythm and underlying diagnosis, respectively. They reported a higher ROSC rate (64.6%) and survival to hospital discharge (14%). However, only 21% of CPR occurred in PICU in that study. In our study, patients were enrolled only from PICU. So, the study population was different. Generally, PICU patients are sicker and the majority of them have multiple organ dysfunction requiring organ support. Also, the initial rhythm is an important factor in predicting the outcome; bradycardia rhythm with a pulse is more likely to recover than pulseless non-shockable rhythms [12].

At present, only a limited number of vasopressors are available for use in pediatric CPR, and insufficient data supporting their use [2]. The pediatric guidelines were extrapolated from adult clinical trials and animal studies. Vasopressin acts via the V-1 receptor in the arterial wall and increases the aortic diastolic pressure, thereby improving coronary perfusion pressure. In contrast to epinephrine, there are no β_1 mediated chronotropic and inotropic actions; hence it enhances the myocardial oxygen delivery and reduces the myocardial oxygen consumption during CPR and in the post-resuscitation period [1,16]. Another advantage of vasopressin includes the continuation of vasoconstrictive effects, even in severe acidosis, accompanying cardiac arrest. Hence, vasopressin can act as a better vasopressor during CPR, particularly in patients with sepsis-associated myocardial dysfunction and severe acidosis [16]. However, vasopressin has a longer duration of action than epinephrine, where the persistent vasoconstriction may worsen the myocardial dysfunction in the immediate post-resuscitation period. Post cardiac arrest myocardial dysfunction can be caused by various factors, including the underlying pre-arrest cardiac status, duration and quality of CPR, and the presence of other organ dysfunction(s). So, it is difficult to establish the causal relationship between post-cardiac arrest myocardial dysfunction and vasopressin use. However, no probable serious adverse event due to the trial drug was observed in this study.

The feasibility pilot study in pediatric cardiac arrest by Carroll, et al. [6] reported no significant difference in ROSC, survival to hospital discharge, and neurological

WHAT IS ALREADY KNOWN?

- Few studies have shown promising results of vasopressin use in pediatric in-hospital cardiopulmonary resuscitation.

WHAT THIS STUDY ADDS?

- The combination of cpinephrine and vasopressin did not improve the rate of return of spontaneous circulation, survival, and favorable neurological outcome as compared to Epinephrine alone.

outcome at discharge between vasopressin and control groups (who did not receive vasopressin). Nevertheless, they reported a higher survival rate at 24 hours in the vasopressin group. Their study was limited by non-randomization, small sample size, and addition of vasopressin only after non-response to epinephrine.

Similarly, Duncan, et al. [1] explored the use of vasopressin in pediatric in-hospital arrest from the American Heart Association National Registry of CPR data [1]. Patients who received vasopressin had a longer median arrest duration as compared to those who did not. They also noted that, on multivariate analysis, those who received vasopressin had a reduced ROSC; however, there was no difference in survival at 24 hours. Vasopressin was used as a "drug of last resort" for many of their patients [1], in contrast to our study, where it was used from the time CPR was initiated.

In comparison with an adult, children often present with a non-shockable rhythm, which requires high-quality chest compressions [15]. A systematic review that included 26 RCTs and 21704 participants found that vasopressin did not improve the ROSC rate but improved the survival to hospital admission compared to epinephrine [17]. However, the combination of epinephrine and vasopressin did not show any significant outcome benefits as compared to epinephrine alone [17]. However, most of the included studies were conducted over two decades back. Hence, these findings may not reflect the current practice in the growing era of extracorporeal life support (ECLS) availability.

Though all healthcare providers in our study have been trained in CPR, the intra- and inter-personal variations in chest compression were not monitored objectively. The temporal profiles of end-tidal carbon dioxide and DBP were not analyzed with the outcome of the study. Though our study found similar DBP in both the groups, the pediatric-specific target DBP during CPR is yet to be studied. However, evidence suggests that those who achieve DBP of 25 to 30 mm Hg during CPR have a higher chance of ROSC and survival [15]. Hence, goal-directed CPR targeting the end-tidal carbon dioxide and DBP needs to be considered in future study design. The availability of ECMO service during CPR or after achieving ROSC could have improved the survival to discharge. Recent studies showed that extracorporeal CPR (E-CPR) in pediatric cardiac arrest was associated with shorter resuscitation time and higher survival rate, ranging from 33-64% [18-20]. The AHA recommends considering E-CPR during in-hospital pediatric cardiac arrest, when standard resuscitation has failed, especially in a potentially reversible cause of cardiac arrest [2].

The study concludes that a combination of epinephrine and vasopressin did not improve the rate of return of spontaneous circulation, survival, and favorable neurological outcomes in pediatric intensive care unit cardiac arrest resuscitation as compared to epinephrine and placebo.

Abstract

In 2017, Tamil Nadu, a southern state, had the second highest number of dengue cases from India. In the present study, the serotype-specific differences in the clinical manifestations and laboratory parameters among hospitalized children with dengue were investigated and molecular characterization of the circulating dengue virus (DENV) serotypes during 2017 in Tamil Nadu was performed. Eighty children with dengue-like symptoms consecutively admitted to a tertiary care hospital and positive for DENV NS1 antigen were investigated for DENV serotype utilizing a real-time reverse transcriptase based polymerase chain reaction assay. Complete envelope (E) gene sequencing of the DENV strains was performed. Seventy samples were positive for serotyping (25 DENV-1, 17 DENV-2, six DENV-3, and 22 DENV-4). DENV-4 infections were associated with elevated levels of liver enzymes; Alanine aminotransferase ($P = .021$) and aspartate aminotransferase ($P = .001$). However, none of the serotype was associated with any specific clinical features and severe dengue. Asian and American/African genotypes of DENV-1 were cocirculating. The circulating genotype was cosmopolitan for DENV-2 with multiple lineages, genotype III for DENV-3 and genotype I for DENV-4. Unique mutations were present in the 2017 DENV-4 isolates. The present study suggests the association of DENV-4 with elevated liver enzymes in children hospitalized for dengue. Further, the study reports the genetic diversity of DENV circulating in Tamil Nadu during 2017. The study calls for continuous monitoring of the circulating serotypes and genotypes at regional level in India which might result in a region wise database useful in predicting future outbreaks.

1 | INTRODUCTION

Dengue is the commonest arthropod borne viral disease that affect millions of individuals globally each year and has been listed by the World Health Organization (WHO) as one of the major threats to mankind.[1] Infection with any of the four serotypes of dengue virus (DENV) results in a range of clinical presentations. Symptomatic dengue infections are categorized into nonsevere dengue and severe dengue (SD). The nonsevere dengue cases are again classified into those without warning signs (DwoWS) and with warning signs (DwWS). The case fatality rate is less than 1% if proper intervention is initiated at an early stage of the disease.[2] Disease severity is influenced by both virus and host factors. Immune status determined as primary infection or secondary infection with a different serotype of DENV has been reported to be associated with dengue severity by various epidemiological studies. Age, gender, nutritional status, host immune response, and host genetics contribute to differences in the clinical outcomes.[3,4] Among the viral factors, infecting serotype and the genotype within each serotype also contributes to disease severity.[3] Replacement of the circulating serotype/genotype of DENV with a different one contributes to outbreaks of higher magnitude.[5,6]

In the last decade, highest number of dengue cases were reported during 2017 in India. Within India, West Bengal and Tamil Nadu accounted for approximately 30% of the reported dengue cases.[7] Before 2017, Tamil Nadu witnessed large number of cases during 2012 and DENV-1 was the most common serotype despite the presence of other serotypes. Replacement of American/African (AM/AF) genotype with Asian genotype of DENV-1 was observed during 2012 in Tamil Nadu.[8] However, the serotypes and genotypes circulating during 2017 were not known. The present study was aimed at identifying the serotype-specific differences in the clinical symptoms and laboratory parameters in DENV infected children. Moreover, the study also intended to identify the dominant circulating serotype(s) and genotype(s) associated with dengue in Tamil Nadu during 2017.

2 | MATERIALS AND METHODS

2.1 | Study subjects

The study was a cross-sectional prospective study conducted at PSG institute of Medical Science and Research, a tertiary care teaching hospital located in western Tamil Nadu between August and December 2017. Children aged between 6 months to 15 years who fulfilled the inclusion criteria were consecutively enrolled in the study. Children admitted in the hospital with undifferentiated fever of less than 5 days duration with clinical suspicion of dengue and positive for the presence of NS1 antigen were included in the study. Exclusion criteria include: negative test for the presence of NS1 antigen, fever beyond 5 days, unwillingness to participate in the study and patients who were not admitted. The parents or the legal guardians were explained about the study purpose and an informed consent was obtained from them. The parents or the caretakers of the patients were interviewed for their demographic characteristics such as gender, age, and previous dengue episodes. The patients were observed for clinical symptoms including warning signs till their discharge and clinical features and lab data were collected in a predesigned data collection tool. Based on the clinical symptoms and laboratory parameters, the patients were categorized into dengue without warning signs (DwoWS), dengue with warning signs (DwWS), and severe dengue (SD) based on the WHO 2009 guidelines.[9] Plasma or serum samples collected from the participants at the time of entry into the study, were separated and stored at −80°C. The samples were transported in dry ice to ICMR-National Institute of Virology for identifying the serotype. The study was approved by the institutional human ethics committee (IHEC) of PSGIMS&R, Coimbatore, Tamil Nadu. Molecular characterization of the circulating DENV was performed at ICMR-NIV as a part of Apex referral laboratory activity for the year 2017 which was approved by the IHEC of ICMR-NIV.

2.2 | Serological assays

Serological assays were performed in the hospital laboratory. Presence of DENV NS1 antigen was tested by a antigen capture ELISA kit (Panbio Dengue Early ELISA) as per the manufacturer's protocol. Dengue-specific immunoglobulin M (IgM) and immunoglobulin G (IgG) antibodies were tested using ELISA kits (Panbio IgM [01PE20] and Panbio IgG capture ELISA kit [01PE10]) according to the instructions provided with the kit. The IgG capture ELISA kit used in the study detects high-titer IgG antibodies which is usually present in secondary infections. Test positive for IgG indicates secondary infection while test negative indicates primary infection.

2.3 | Detection of dengue virus serotypes

RNA was extracted using an RNA extraction kit (QIAamp viral RNA mini kit, Qiagen, Hilden, Germany) according to the manufacturer's protocol and used for DENV serotyping. Serotyping was performed by using an in-house real-time reverse transcription polymerase chain reaction (RT-PCR) assay. The sequences of the primers and probes were given in Table S1. Primer and probe sequences, the reaction mixture composition and cycling conditions for real-time RT-PCR have been reported previously.[10] The PCR cycle at which the fluorescence signals crossed the threshold values were detected for each sample and samples that had a cycle threshold (C_t) value ≤37 were considered as positive.[10]

2.4 | Isolation of dengue virus from clinical samples

Virus isolation was performed in samples which were positive for DENV RNA with increased viral load (C_t value ≤25) using C6/36 cell

line as reported previously.[10] Virus stocks were stored at −80°C in aliquots for further use.

2.5 | Sequencing of complete envelope gene of dengue virus

Randomly selected representative virus isolates from each serotype were used for sequencing of complete E gene (seven DENV-1, ten DENV-2, one DENV-3, and nine DENV-4 isolates) using primers reported earlier.[11-13] The sequences of the primers were provided in Table S1. RNA extraction, cDNA synthesis, reverse transcription, PCR amplification, gel purification, and sequencing was carried out as described earlier.[10]

2.6 | Phylogenetic analyses of dengue virus isolates

MEGA7.0 was used for multiple sequence alignment and phylogenetic analyses.[14] Seven DENV-1, ten DENV-2, one DENV-3, and nine DENV-4 sequences (GenBank accession number for the virus isolates provided in Table S2) from the current study along with the earlier Indian (44 DENV-1, 79 DENV-2, 39 DENV-3, and 31 DENV-4) and global sequences (36 DENV-1, 43 DENV-2, 54 DENV-3, and 47 DENV-4) from GenBank representing different genotypes were used for the phylogenetic analyses. Kimura-2 Parameter model was used to estimate the genetic differences and maximum likelihood (ML) method was used for the construction of the phylogenetic trees. A bootstrap test with 1000 replications was used to evaluate the reliability of position of the branches.[10]

2.7 | Statistical analyses

To compare univariate categorical data, Fisher's Exact tests or Pearson's X^2 was used. Parametric and nonparametric data from subjects infected with different dengue serotypes were compared using one-way analysis of variance and Kruskal-Wallis tests, respectively. Modified Poisson regression with adjustment for relevant clinical covariates, that is, age, gender, and fever at total day was utilized for performing the regression analyses. Data for one serotype was compared with other three serotypes. Except platelet count, the values of other laboratory parameters at the time of admission were used for comparison. The nadir for platelet count was used for comparison. A probability (*P*) value of <.05 was considered statistically significant. All the statistical analyses were carried out using statistical software R version 3.4.4.

3 | RESULTS

3.1 | Demographic profile of the study subjects

A total of 430 children with undifferentiated fever were admitted with clinical diagnosis of dengue fever of which 236 children fulfilled the inclusion criteria, 80 consecutively admitted children were enrolled in the study and were followed up prospectively. On analyzing for the serotype, 10 samples were negative and hence excluded and only 70 subjects were analyzed. Almost equal proportion of boys and girls were observed and the median age was 9 years (6 months to 15 years) (Table 1).

TABLE 1 Demographic profile of the dengue cases infected with different dengue virus (DENV) serotypes

Patient Demographics									
	DENV–1 (n = 25)		DENV–2 (n = 17)		DENV–3 (n = 6)		DENV–4 (n = 22)		*P* value*
Variables	N	%	N	%	N	%	N	%	
Gender

Age, median (range)	9 (0.9–16)	–	6 (0.3–15)	–	9 (6–15)	–	10 (4–14)	–	.236
Fever day at presentation, median (range)	4 (1–8)	–	5 (2–9)	–	4.5(3–5)	–	4.5 (1–8)	–	.442
Fever at total days, median (range)	5 (4–8)	–	5 (3–9)	?	4.5 (4–5)	–	5 (3–8)	–	.188

*X^2 test was used to compare categorical variables (gender and locality) and one–way analysis of variance was used to compare the continuous variables (age, fever day at presentation and fever at total days).

3.2 | Serotype-specific differences in the clinical features, lab parameters and disease severity

All four serotypes were observed to be circulating in the study population with the prevalent serotype being DENV-1, (n = 25, 35.7%), followed by DENV-4 (n = 22, 31.4%), and DENV-2 (n = 17, 24.3%). DENV-3 was identified in 8.6% (n = 6) of the subjects. Apart from a slight female preponderance among DENV-1 infected children, gender, age, and duration of fever were not different between the children infected with different serotypes (Table 1).

A similar modified Poisson regression analysis adjusted for age, gender, and day of fever was performed for various lab parameters. A statistically significant increase in liver enzymes, aspartate aminotransferase (median with range 131.5 [22-1156] $P = .001$) and alanine aminotransferase (median with range 63 [14-594] $P = .021$) were found in DENV-4 infected children compared to children infected with other serotypes. There was no significant difference in the level of liver enzymes between primary and secondary infections. The mean ± standard deviation of liver enzymes, SGPT and SGOT in children with primary and secondary dengue were 99.18 ± 123.91, 66.83 ± 79.09 ($P = .255$) and 172.25 ± 225.03, 139.38 ± 164.15 ($P = .443$). Other hematological parameters including platelet count during the hospital period were not significantly different among children infected with different serotypes (Table 2).

After adjustment for age, gender, and duration of fever, we observed no statistically significant correlation between the infecting serotype and the clinical features (Table 3). A majority of the children had secondary dengue infection (n = 52 [67.5%]). However, immune status was not associated with disease severity (Table 3).

Classifying the children based on disease severity according to WHO 2009 criteria, there were 38 cases with DwoWS, 26 with DwWS, and 6 had SD. There was no significant association between disease severity and infecting serotype (Table 3).

3.3 | Results of virus isolation

A total of 51 samples were used for virus isolation. Virus isolation was positive in 34 samples (seven DENV-1, 13 DENV-2, two DENV-3, and 12 DENV-4). Complete E gene of the representative virus isolates (seven DENV-1, ten DENV-2, one DENV-3, and nine DENV-4) was sequenced.

3.4 | Circulating genotypes of DENV-1

DENV-1 was classified into five genotypes as described earlier.[15] Since there were confusions with regard to the Roman number based nomenclature, geographical names were provided.[16] Seven DENV-1 virus isolates were sequenced. The ML method-based phylogenetic tree (Figure 1) revealed that five isolates grouped with the Asian genotype (GI). Two isolates clustered with the American African (AM/AF) genotype (GV). Asian genotype isolates obtained during

DwWS	7	28.0	6	35.3	5	83.3	8	36.4
Severe dengue	2	8.0	2	11.8	–	–	2	9.1
Relative risk adjusted for age, gender and fever days at admission[a]	1.1 (0.76–1.6)		1.03 (0.43–2.46)		0.79 (0.22–2.89)		1.41 (0.66–3.0)	
DwWS + SD vs DwoWS								

Note: X^2 test was used for comparison between different serotypes.
Abbreviations: DENV, dengue virus; DwoWS, dengue without warning signs; DwWs, dengue with warning signs; SD, severe dengue.
[a]Modified Poisson regression was used for calculating the relative risk adjusted for age, gender, and fever days at admissionadmission.

2017 from Tamil Nadu clustered with Indian strains isolated during 2012-2017 from Kerala, Maharashtra, and Tamil Nadu and strains from Sri Lanka and Singapore. Five lineages, India-I to India-IV and Afro India, have been described within the AM/AF genotype earlier.[12] The present study isolates clustered with India-IV lineage strains. Comparison of amino acid sequences of the Indian isolates belonging to Asian genotype with the isolates from Singapore and Sri Lanka revealed that most of the 2017 isolates from Tamil Nadu had three conservative changes (T329S, L475P, and L484M) and one nonconservative change (F337I) that were not observed in earlier isolates (Table S3).

3.5 | Circulating genotype of DENV-2

DENV-2 was classified into five genotypes as described earlier.[17] Further, subclassifications within the cosmopolitan genotype was performed as described recently.[18] For DENV-2, ten isolates were sequenced for E gene. All sequenced isolates grouped within the cosmopolitan genotype. Within cosmopolitan genotype, Tamil Nadu isolates clustered with strains from two lineages—Cosmopolitan I (C-I) and C-III. Within C-I, five isolates were part of C-IA sublineage, and one isolate was part of C-IB (Figure 2). Amino acid sequence analysis within the 2017 Tamil Nadu isolates revealed that C-I strains had Q at 52nd position while it was H in C-III isolates. C-I had a V at 141st position of E protein while isolates from C-IB and C-III had I. Isolates from C-IB and C-III had I at 322nd position while V was present in C-IA (Table S4).

3.6 | Circulating genotypes of DENV-3 and DENV-4

Five genotypes have been reported for DENV-3.[19] One DENV-3 isolate was sequenced which clustered with earlier isolates from India, China, Pakistan, Singapore, and Senegal into GIII genotype and lineage C (Figure S1). For DENV-4, there were five genotypes.[20] Recently, an additional genotype (GVI) has been proposed.[21] Nine DENV-4 isolates were sequenced. All the 2017 isolates from Tamil Nadu grouped within the GI genotype. In the G1 genotype, 2017 isolates from Tamil Nadu along with the strains from India, Pakistan, and Sri Lanka formed lineage C. Strains from Cambodia, China, Singapore, and Thailand formed the lineage B while those from China, Japan, Philippines, and South Korea formed lineage A (Figure 3). Comparison of amino acid sequences of the E protein from the current study isolates with earlier India isolates revealed the presence of altogether 53 unique nonconservative changes in the nine 2017 isolates from Tamil Nadu (Table S5).

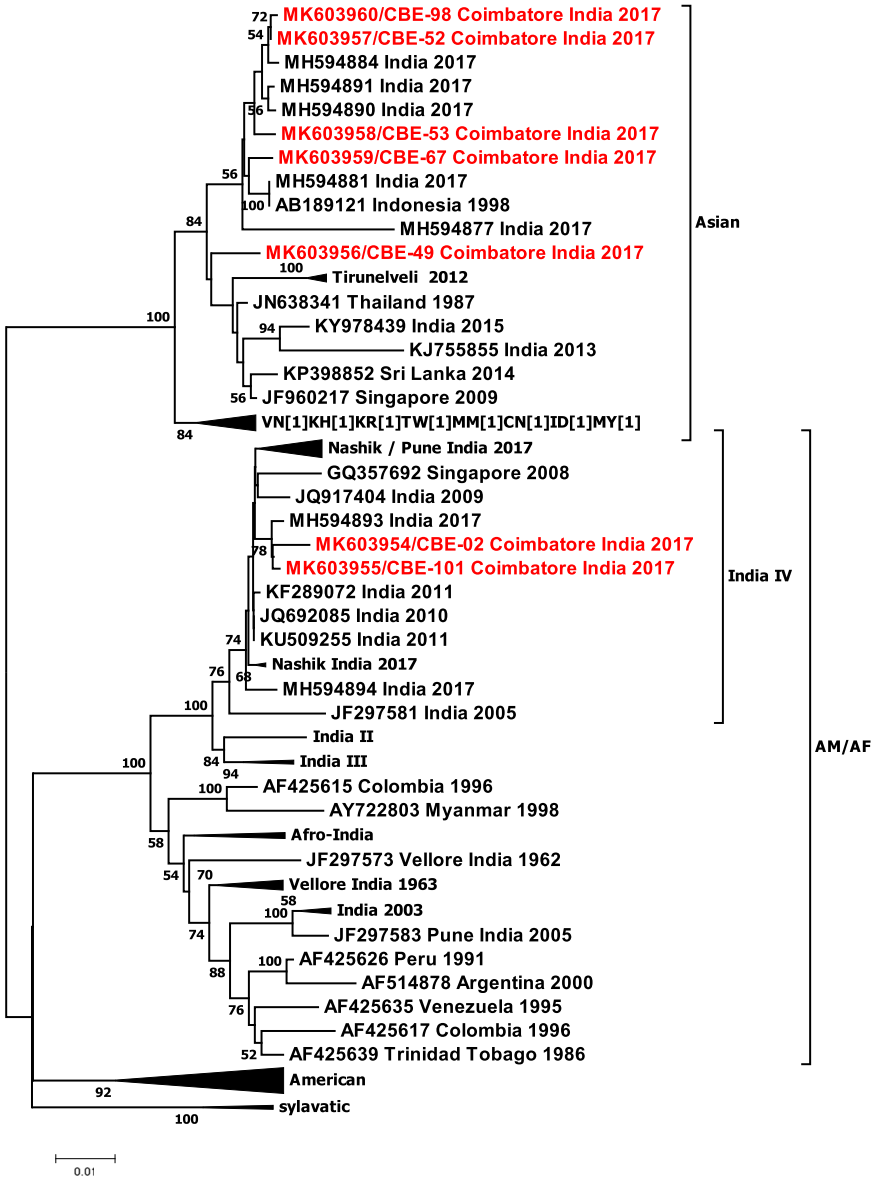

FIGURE 1 Phylogenetic tree of dengue virus-1 (DENV-1) based on E gene sequences All the current study sequences (n = 7) highlighted in Red. Apart from the current sequences, 36 global sequences and 44 Indian sequences were used for generating the phylogenetic tree KH Cambodia/VN-Vietnam/KR-Korea, Republic of/TW-Taiwan/MM-Myanmar/CN-China/ID-Indonesia/MY-Malaysia. Among the five genotypes, Asian, American/African (AM/AF) and Sylavatic genotypes were only shown

4 | DISCUSSION

Forty percent of world's population lives in places endemic to DENV infection and at least 12 000 to 24 000 deaths happen annually in children aged below 15 years.[2] During the study period, admission of 430 undifferentiated fever cases with clinical features suggesting dengue in the pediatric services of one tertiary care hospital alone explains the magnitude of the disease in this endemic region. Circulation of all the four serotypes of DENV has been reported from different regions of India. In 2017, DENV-1 and DENV-3 were more prevalent in Maharashtra, Western India.[10] DENV-1 was the most prevalent serotype while DENV-4 was the least observed one in the 2012 dengue season in Tamil Nadu.[8] In contrast to 2012, DENV-1, DENV-2, and DENV-4 were the prevalent serotypes during 2017 in the study region and could have accounted for the large number of cases from the state. Persistent circulation of DENV-1 might have led to herd immunity permitting the emergence of other serotype viruses. Circulation of multiple serotypes suggests the hyperendemic nature of dengue in this region. The study also suggests the emergence of DENV-4 along with DENV-1 and DENV-2 in Tamil Nadu during 2017.

Studies in the past on disease severity and infecting serotypes have discordant results. A study based on the data from 1994-2006 in Thai children has suggested the association of DENV-2 infection with severe dengue.[22] Further the same study revealed that the risk of SD was more in secondary infections with DENV-2 and DENV-3.[22] A study on adult patients from Singapore revealed that infection with DENV-1 had an increased risk of dengue hemorrhagic fever than DENV-2, whereas a study from Vietnam revealed no difference in the risk of developing severe disease among hospitalized adults infected with DENV-1 and DENV-2.[23,24] A study from Brazil reported that patients infected with DENV-1 serotype had higher risk of severe clinical and laboratory features compared to those infected with DENV-4.[25] A systematic review analyzing the factors associated with

FIGURE 2 Phylogenetic tree of dengue virus-2 (DENV-2) based on E gene sequences All the current study sequences (n = 7) highlighted in Red. Apart from the current sequences, 79 global sequences and 43 Indian sequences were used for generating the phylogenetic tree

dengue shock syndrome, the most severe form of dengue, has revealed DENV-2 as a risk factor.[3] Contradicting all the studies, a study from Bali reported lack of association between DENV serotypes and disease severity.[26] In the present study, as there were less number of children who progressed to SD during hospital stay, for the purpose of analysis, children with SD and DwWS were grouped together and compared with DwoWS. Overall, there were more children with DwoWS than DwWS/SD and none of the serotypes showed any statistically significant increased risk for developing DwWS/SD. Immune status was also not associated with DwWS/SD. However, DENV-4 infections were significantly associated with elevated levels of liver enzymes. A study on pediatric dengue cases from Thailand also has reported that DENV-3 and DENV-4 infection tended to have abnormal elevation of liver enzymes.[27] This observation was contrary to a study from Northern India which has reported an association of elevated levels of liver enzymes with DENV-2.[28] Whether this association of elevated enzymes with DENV-4 can generalized to other regions depends on multiple factors such as the circulating genotype of DENV-4, host immune status, and age of the patients and a study with larger sample size is needed to further confirm the finding.

Phylogenetic analyses indicated the circulation of DENV-1 Asian and AM/AF genotypes, multiple lineages of cosmopolitan genotype of DENV-2, DENV-3 GIII genotype and DENV-4 GI genotype with unique mutations in Tamil Nadu. Cocirculation of DENV-1 Asian and AM/AF genotypes has been reported from Maharashtra in recent years while cocirculation of multiple lineages of DENV-2 cosmopolitan genotype has been reported from Northern India.[10,29,30] A recent study reported that the proportion of Asian genotype among the DENV-1-positive cases in Tamil Nadu had decreased from 90% in 2012 to 57% in 2017.[29] It is possible the DENV-1 Asian genotype viruses might have evolved over the years to become a virus with less epidemic potential phenotype. However, further comparative susceptibility studies in vectors and animal models are needed. In

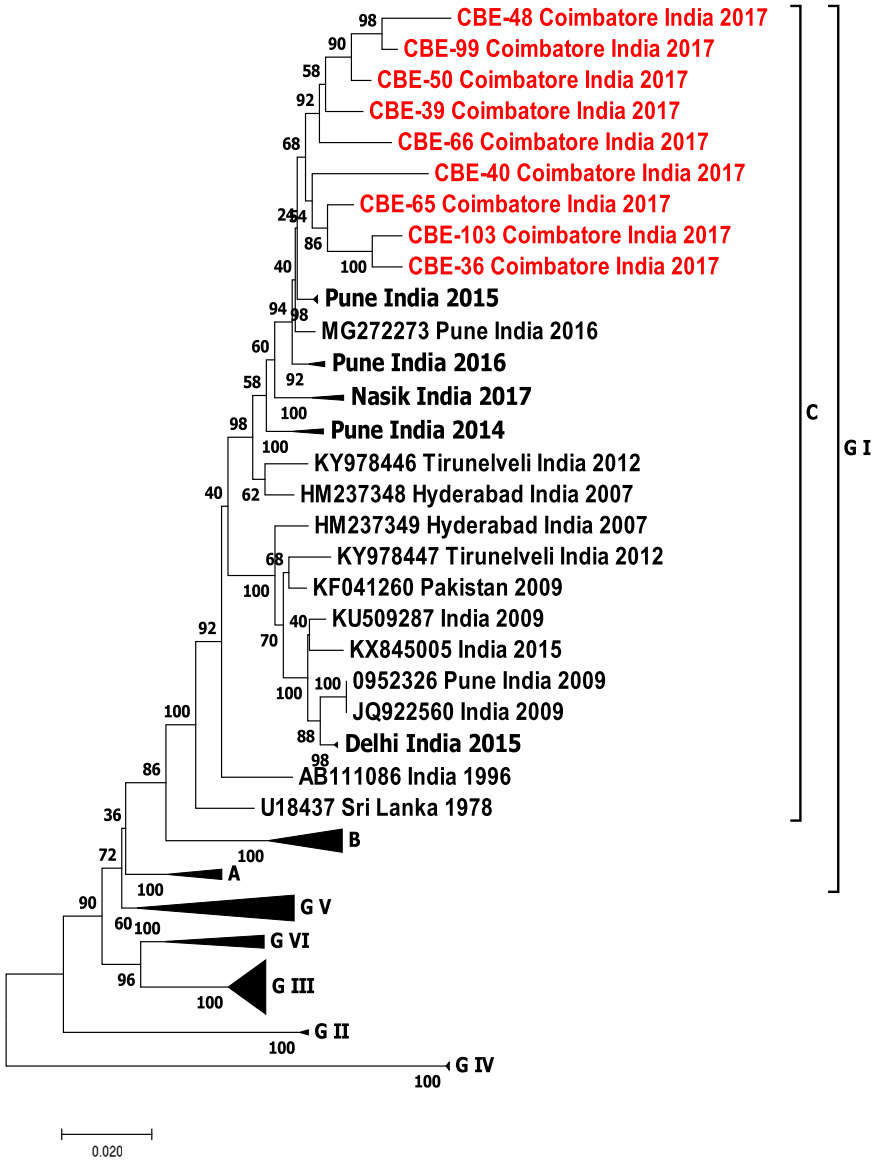

FIGURE 3 Phylogenetic tree of dengue virus-4 (DENV-4) based on E gene sequences. All the current study sequences (n = 9) highlighted in Red. Apart from the current sequences, 47 global sequences and 31 Indian sequences were used for generating the phylogenetic tree

the present study, E gene sequencing of DENV-4 isolates revealed unique mutations which were not observed in earlier Indian DENV-4 strains. The envelope protein has three structural domains I-III. Mutations in the domain II and domain III have more significance since domain II contains the fusion loop which is essential for the interaction between the host endosomal membrane and the virus envelope leading to virus membrane fusion while domain III contains epitopes that are essential for serotype-specific neutralization. Mutations in these domains might affect virus entry as well as the neutralization by serotype/genotype-specific antibodies.[31,32] DENV evolution is shaped by purifying selection in which deleterious mutations affecting viral fitness are removed with time. Further, mutations which confers fitness advantage to DENV in nature were positively selected and contributes to adaptive evolution of DENV.[33] Further follow up studies in the region are needed to discern how these mutations shape up the DENV-4 evolution. It is possible that differences in the viral factors as well as host factors might influence the variable outcomes in different studies. Monitoring the circulating serotypes and genotypes in different regions might result in a region wise database useful in predicting future outbreaks of higher magnitude when changes are observed with regard to the dominant serotypes and new genotypes.

The strength of the present study is that the subjects enrolled were belonging to only to pediatric age, they were prospectively followed up for the outcome and disease severity was classified based on latest guidelines recommended by WHO. Few limitations are, the small sample size, study participants were only hospitalized children from a particular geographic area, hence cannot be extrapolated to general population or other parts of the country. All the patients were recruited within 5 days of fever onset and hence early hospitalization and effective fluid management might have influenced the final outcome. Nonhospitalized cases with undifferentiated febrile illness, which forms the major proportion of DENV cases, were not included in the study and investigation of both hospitalized as well as nonhospitalized cases might help in

identifying the DENV serotypes associated with DwWS and severe dengue.

To conclude, the study reports the activity of all the four serotypes in Tamil Nadu during 2017 with the dominance of DENV-1, DENV-2, and DENV-4. Persistent cocirculation of DENV-1 Asian and AM/AF genotypes, cocirculation of multiple lineages of DENV-2 cosmopolitan genotype and emergence of DENV-4 GI genotype with unique mutations were observed. DENV-4 infection was associated with elevated levels of liver enzymes among hospitalized children. Serotypes and immune status were not associated with disease severity among children hospitalized for dengue.

[illegible]

[illegible] Coronavirus disease 2019 (COVID-19), in children has varied clinical presentations from asymptomatic infection to severe pneumonia, multi system inflammatory syndrome in children (MIS-C) and rarely death. To date, limited data has been published on the profile of COVID-19 infection among Indian children. The objective of this study was to analyze the clinical spectrum, laboratory parameters, treatment and it's outcome in children less than 15 years admitted with COVID-19 infection.

[illegible] This was a cross sectional study done in a tertiary care hospital. Children with COVID-19 infection detected by Reverse transcriptase polymerase chain reaction (RT-PCR) were included.

[illegible] Out of 167 children, 93 were males (55.6%) and median (Interquartile range- IQR) age of children admitted were 9 (4-13) years. Family cluster (71%) was the dominant source of infection. Majority were asymptomatic (60%, N=100). The predominant symptoms were fever (29%), cough (16%) and rhinorrhea (4.1%). Seven (4.1%) children had comorbidities and two (28%) among them had moderate to severe disease. Median (IQR) total leucocyte count was 7 (4-10) ×103 µl and platelet count was 390 (275-500) ×103 µl. Leukopenia was observed in 58% (N=81), lymphocytosis in 32.8% (N=46) and thrombocytopenia in 3.5% (N=5). Inflammatory markers were raised in 10-15% of children. Peri-bronchial cuffing was the common abnormality (N=14, 17.5%) in chest X-ray (CXR) and peripheral heterogeneous opacities were noted in severe disease. Children with moderate to severe symptoms were treated with remdesivir and steroids.

[illegible] COVID-19 infection in children was often benign and increased severity was noted among those with comorbidities. Leukopenia, lymphocytosis were commonly observed. High inflammatory markers were noted in severe disease. Nil fatality among our study group.

[illegible] COVID-19, Children, Chest X-ray, Leukopenia, Lymphocytosis, Laboratory profile

[illegible]

In the pre-coronavirus disease-19 (COVID-19) era human coronavirus (HCoV) was one among the causes of bronchiolitis in infants and upper respiratory infection in children.[1] Previous outbreaks of Severe acute respiratory syndrome (SARS) and Middle east respiratory syndrome (MERS) caused by coronavirus were associated with less mortality in children.[2] Similarly COVID-19 which causes severe acute respiratory syndrome (SARS-CoV2) in adults causes milder illness in children. The incidence in children is around 8.7% in below 19 years according to CDC.[3] The hypothesis behind the less severe disease in children being differences in innate and adaptive immunity, pre-existing antibodies to corona virus, more frequent respiratory infections, protective effects of other live vaccines, different expression of angiotensin converting enzyme-2 (ACE-2) receptors and less intense exposure.[4] Very rarely it may lead to Acute respiratory distress syndrome (ARDS), Multi organ dysfunction (MODS) and death. Multi system inflammatory syndrome in children (MIS-C), a post viral immune dysregulation following SARS-

CoV-2 infection is common among children and adolescents which may rarely lead to significant morbidity and mortality if not treated early.[5]

Hematological and biochemical markers of COVID-19 were well studied in adults. This cannot be extrapolated as such for children. The aim of the study was to present the detailed clinical, laboratory profile, treatment and outcome of 167 children below 15 years of age admitted with COVID-19 infection.

M□□□□□□

This was a descriptive observational study and followed the Strengthening the reporting of observational studies in epidemiology (STROBE) guideline.

This study was done at PSG Institute of Medical Sciences and Research hospital which is one of the largest designated tertiary care hospitals in Coimbatore, India which caters to patients from around 250 km radius. Institutional ethics committee approval was obtained. Informed consent was taken from parents or patients included in prospective analysis (N=107) and waiver of consent was obtained for those taken retrospectively (N=60). All children less than 15 years admitted with COVID-19 infection between March 2020 to February 2021 were included in our study. Positive cases were confirmed by Reverse Transcriptase Polymerase Chain Reaction (RT-PCR) validated as per ICMR standards. Both nasopharyngeal and oropharyngeal swabs were taken for confirmation. The severity of illness were categorized into mild, moderate, severe and critical as per the COVID-19 clinical management-Interim guidance.[6] Mild illness is defined as symptomatic COVID-19 positive patients without evidence of pneumonia, moderate as with clinical signs of pneumonia and no signs of hypoxia and severe as clinical signs of pneumonia and SpO_2<90%. Critical disease is with ARDS, sepsis or septic shock and MODS.

Fever was defined when the temperature was >38°C, the source of infection was identified by recording which family member developed the symptoms first. Basic hematological and radiological investigations were taken for most of the patients admitted except in few because of logistical issues. Investigations were repeated in patients showing persistent symptoms.

All the necessary information was collected from electronic records on the hospital database. Chest X-ray findings were analyzed and reported by a single radiologist. Information on baseline demographics, clinical features, symptoms, signs, laboratory reports, imaging, treatment and outcome were recorded. Laboratory values were interpreted with age specific reference ranges. If the patient had a serial investigation for a particular parameter, the highest value was taken into consideration. Asymptomatic and mildly symptomatic children were given supportive care. Those presented with sore throat, fever beyond 3 days, lower respiratory symptoms, pneumonia (confirmed by clinical and radiological signs) were treated with antibiotics. Steroids were used only in severe cases.

Statistical analysis

Data was entered in Microsoft excel (Microsoft corporation, Redmond, USA) sheet and analyzed using SPSS software version 24. Descriptive statistics were used to summarize the data. Continuous variables were described as median and interquartile range. Categorical variables were described as frequencies and percentages. Chi square test was used to assess the relationship between gender and incidence of COVID-19. Mann-Whitney U-test was used to assess the correlation between severity of illness and inflammatory markers. A p value of <0.05 was considered significant.

□□□□□□□

A total of 167 children admitted with COVID-19 positive reports were included in our analysis. The baseline demographic and clinical characteristics of these children are shown in Table 1.□

Demographic and clinical characteristics

The median age (IQR) of children admitted were 9 (4-13 years) and male children (N=93, 55.6%) outnumber females with a male: female ratio of 1.25:1. There was no relationship between gender and incidence of COVID infection in children (p=0.12, Chi square test). Family cluster as the source of infection was identified in 71% (N=119) (Table 1).

Fever was the predominant symptom in 29.3% (N=49) followed by cough (N=27, 16.1%) and rhinorrhea (N=7, 4.1%). Diarrhoea was noted in 3.5%, abdominal pain in 1.1% and loss of taste was present in 1.1%. Very few had fever beyond 24-48 hours after hospital admission. Among the admitted, 7 (4.1%) had preexisting comorbid conditions (Table 2). In them, a child with a germ cell tumor and a hemolytic anemia had moderate to severe illness. More than half were asymptomatic, 38% (N=64) had mild symptoms, 0.5% (N=1) had moderate symptoms and 1.1% (N=2) had severe symptoms. Out of 4 children admitted in ICU, 2 had comorbidities (hemolytic anemia and germ cell tumor) one among them required oxygen support by mask (germ cell tumor), a 2-months-old without any comorbidity had respiratory distress and hypoxemia supported by mechanical ventilation and a child with head injury was admitted for monitoring (Table 3). There was a significant association between comorbidity and severe illness (p=0.014, Fisher's exact test).

Radiological and laboratory finding

CXR was performed in 48% (N=80) of children and out of which 78% (N=63) were normal. Few had prominent

central peri bronchial cuffing (N=14, 17.5%) and peripheral heterogeneous opacities were noted in 3.7% (N=3). CT was done only in patients with moderate to severe illness which showed ground glass opacities (Table 4). On admission, the median (IQR) WBC count was 7 (4-10)×10^3/µl. Leukopenia, lymphopenia and lymphocytosis were noted in 58%, 11.4% and 32.8% respectively. Thrombocytopenia was seen only in 3.5%. Inflammatory markers IL-6, ferritin, D-dimer were raised in 10%, 6% and 13% respectively (Table 5). Moderate to severe group exhibited significantly higher IL-6, ferritin and D-dimer than milder group (p=0.04, p=0.04, p=0.06, Mann-Whitney U-test) (Figure 1-3). Hypoalbuminemia was noted in 3.5% and liver enzymes were elevated in 7-8%.

Treatment and outcome

Intravenous antibiotics and remdesivir were given in 3 children. Steroid was given only in a child with a Germ cell tumor. An infant with severe respiratory distress (0.5%) was treated with mechanical ventilatory support considering High frequency nasal cannula (HFNC) having high aerosolization risk during the initial phase of pandemic. In all others symptomatic treatment was given accordingly. Those with severe illness have recovered and discharged by 2nd to 3rd week of admission. There was nil mortality among our study group (Table 6).

Table 1: Demographic and clinical characteristics of children with COVID-19

Characteristics	n (%)

□□□□ □ □□□□ □

The main focus of this study was to analyze the clinical, laboratory profile, treatment and it's outcome of 167 children admitted in the designated tertiary care COVID unit which admits children from asymptomatic infection to critical disease. When compared to adults, paediatric age groups were reported with less severe disease. As the schools were closed and outdoor activities were restricted the primary source of infection in children were household contacts. Majority of children in our cohort were asymptomatic (60%), and few had variable severity of symptoms from mild to severe. As per WHO-China joint mission on COVID-19, 2.5% of cases under 19 years had severe infection and 0.2% had critical disease.[7] A large

report from China stated that 10.6% ,7.3% and 4.2% children between 0-1, 1-5, 6-10 years had severe infection respectively.[8] High risk groups for severe infection are infants below 1 year and those with underlying medical conditions like neurological problems, metabolic disorders, congenital heart disease, diabetes, asthma, chronic lung disease, sickle cell disease and obesity.[9] Similarly, in this study a 2-months old infant and a child with comorbidity developed severe disease. Incidence of severe disease among comorbid children was high (14%) in this study. This is in accordance with a systematic review of 42 studies on severe COVID-19 infection where the clinical manifestations were severe in 5.1% of children with comorbidities and 0.2% without comorbidities.[10] Among children admitted in US and Canadian PICU with COVID-19, 83% had pre-existing comorbidities and out of which 73% had respiratory symptoms and 38% required mechanical ventilation.[11] Hence, children with comorbidities need careful monitoring during the first 2 weeks of illness.

Most common symptoms in our patients were fever, cough and rhinorrhoea followed by gastrointestinal symptoms which were consistent with previous reports.[6,12] Dermatological and neurological manifestations were not observed in our children.

Central peri bronchial cuffing was the common CXR abnormality noted in our study. 92% of them with the above finding neither had respiratory symptoms at admission nor during hospital stay. Hence, the central peri bronchial cuffing may be a nonspecific finding and further evaluation may be required only if there are worsening symptoms and signs. Another study from Spain had shown similar findings in CXR in 86% of it's patients.[13] In our study those with peripheral heterogeneous opacity in CXR had significant clinical symptoms and ground glass opacities in CT. This was identical to COVID pneumonia causing diffuse interstitial infiltrates involving the periphery of the lung.[14]

Similar to few meta-analysis and systematic review on COVID-19, leukopenia (58%) and lymphocytosis (32.8%) were most commonly observed in our study.[15] Lymphopenia (11.4%) and thrombocytopenia (3.5%) were comparable to that of study by Meena et al.[12] Though lymphopenia was frequently seen in adults with severe disease and high mortality, it was rarely observed in children. It may be because of milder illnesses in children.[16] Hence, these hematological findings along with clinical features similar to COVID should raise a strong suspicion of COVID-19 infection and it will be a useful predictor for planning treatment in children with moderate to severe illness.[12,16]

Inflammatory markers were raised in 15-25% of our children. Studies found that higher the CRP, IL-6 and ferritin more severe was the disease.[16] Liver enzymes were increased in 7-8% which is consistent with other studies and its prognostic significance is still uncertain.[17]

Children with severe infection can develop serious complications like acute respiratory distress syndrome, renal failure, myocarditis, shock, acute renal failure, coagulopathy, MODS and later MIS-C. In our study population only a single child developed respiratory failure and none had MODS. Antivirals and steroids were used in very few. Guidelines on COVID-19 treatment in children evolved only later and most were extrapolated from adult studies during our study period. Two children were readmitted with MIS-C manifestations after 3-4 weeks and both had very minimal symptoms during the 1st admission. More studies are needed to determine the children at risk for MIS-C. No mortality was encountered among the admissions in our study.

Hence our present study included the majority of asymptomatic children, these clinical and laboratory data may be helpful in supporting COVID-19 diagnosis in children when diagnostic tests are not available and it provides the true representation of disease spectrum of paediatric population. Limitations of this study was small sample size and single centre study.

□□□□□□□□□

COVID-19 infection was milder among the majority. Infants and children with comorbidities had increased risk of severe disease. Inflammatory markers were helpful in predicting the severity of illness. Antivirals and steroids were needed in very few children. Since the disease has many new variants it might present differently in future. Hence, clinicians need to have a high index of suspicion for early diagnosis and management to have a good outcome and recovery.

□□□□□□ □□□□□M□□□□□

We thank the entire COVID-19 team along with their subordinates for their effortless management and for their contribution of data and radiologist for reporting the X-ray and CT.

Abstract

Objective The objective of this study is to study the profile of apolipoprotein E (*APOE*) gene polymorphism and lipid profile among intrauterine growth restriction (IUGR) and appropriate for gestational age (AGA) neonates. This is an observational study. This study was done at the neonatal unit of a teaching hospital in South India. All consecutively born IUGR neonates (cases) of more than 32 weeks' gestational age and AGA neonates (controls) were enrolled for the study. Genomic DNA extraction was done from a total of 102 peripheral venous blood samples. Genotyping of the APOE rs429358 and rs7412 defining the ε2, ε3, and ε4 alleles was done by polymerase chain reaction–restriction fragment length polymorphism method. Prefeed venous blood was collected and analyzed for lipid profile estimation. The allelic frequencies of cases versus control were ε2—9 (8.7%) versus 3 (2.9%); ε3—88 (84.6%) versus 81 (79.4%); and ε4–7 (6.7%) versus 18 (17.6%). The frequency of ε4 isoform allele, associated with adult onset of metabolic diseases was less among the IUGR group. The mean total cholesterol (TC), Low-Density Lipoprotein (LDL), High-Density Lipoprotein, and triglyceride (TG) were 107.59 ± 35.99, 51.69 ± 24.68, 21.75 ± 9.58, and 151.22 ± 61.84 mg/dL, respectively, in the IUGR group. The mean TC and LDL levels in IUGR group were marginally higher than AGA neonates (107 ± 35.99 vs. 100.37 ± 22.69 mg/dL and 51.69 ± 24.68 versus 46.9 ± 19.51 mg/dL, $p > 0.05$). In both groups, the mean TC and TGL levels were elevated in the ε4 isoform subgroup ($p > 0.05$). In our study, the ε2 allele was the second most predominant APOE isoform and the ε4 allele of the *APOE* gene associated with adult-onset diseases was not increased among IUGR neonates. Neonates with ε4 allele showed an abnormal lipid profile in both study groups suggesting a possible association.

Introduction

The term intrauterine growth restriction (IUGR) has been defined as the subnormal rate of fetal growth with respect to the growth potentials of a specific fetus in accordance to the gender and race. These neonates are born with clinical features of in utero malnutrition and may or may not have a birth weight less than 10th centile for the particular gestational age.[1] Approximately 78% of all IUGR infants delivered globally are seen in Asian continent with highest incidence seen in India.[2] The IUGR infants are prone for short-term and long-term complications making them high-risk neonates. Few of the short complications include perinatal asphyxia, persistent pulmonary hypertension,

Background: Objective of study was to compare the clinical features and laboratory parameters at admission and differentiate severe dengue from scrub typhus in children.

Methods: Retrospective analysis of case records and comparison of clinical and laboratory parameters at admission of all children with a diagnosis of severe dengue and scrub typhus was done.

Results: A total of 72 children were included (severe dengue =40; scrub typhus =32) during the study period. The mean (SD) age of children with severe dengue and scrub typhus was 7.9(3.8) and 11.8(5.8) years, respectively. Majority of children with severe dengue presented with hypotension, 21(52.5%) vs 3(9.4%) in scrub typhus. Children with severe dengue had a relatively low ANC ($2.6\pm1.97x10^3/mm^3$ vs $3.9\pm2.06x10^3/mm^3$), low platelet count ($50.23\pm35.55x10^3/mm^3$ vs $140\pm95.0x10^3/mm^3$) and low mean ESR at 1hour (8.1±6.82mm vs 33.88±13.79mm) than scrub typhus.

Conclusions: Compared to scrub typhus, severe dengue was significantly associated with hypotension, lower ANC, ESR and platelets.

Keywords: Eschar, Fever, Low ESR, Rash, Thrombocytopenia, Scrub typhus, Severe dengue

Introduction

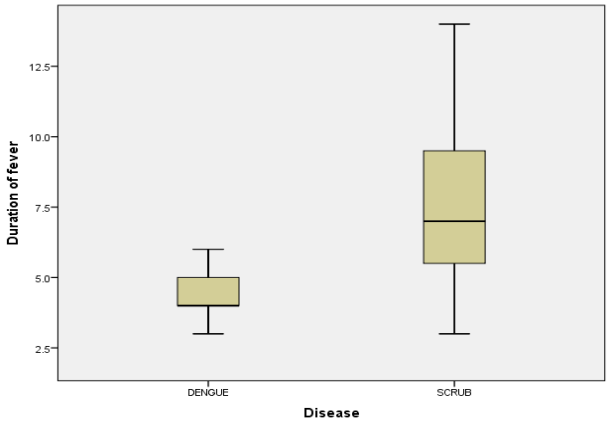
Globally 390 million dengue infections per year are reported, of which 96 million manifests clinically carrying high morbidity.[1] Dengue viruses (DV) belong to the family flaviviridae and is transmitted by vectors Aedes aegypti and Aedes albopictus.[2] Scrub typhus (ST) is another hemorrhaegic fever caused by Orientia tsutsugamushi that is spread by the bite of trombiculid mite. ST is increasingly recognized in tropical countries contributing upto 50% of patients with undiagnosed acute febrile illnesses.[3] In many parts of India, these two infections together comprise more than half of all acute undifferentiated febrile illnesses, more so in south Indian states due to the favorable tropical climatic conditions. Their similar clinical features and laboratory findings often pose diagnostic difficulty for the treating physician.[4] Early diagnosis of the illnesses is life saving to improve patient outcomes and promote timely public health interventions. In this retrospective study we have compared the clinical features and laboratory parameters of children with severe dengue and scrub typhus and attempted to derive the parameters that differentiate severe dengue from scrub typhus.

Methods

This retrospective study conducted over a period of 1 and ½ year (January 2015 to June 2016) in the department of pediatrics of PSG Institute of Medical sciences and research, a tertiary care teaching hospital in South India. Case records of all children (≤18 years) discharged with a

diagnosis of severe dengue and scrub typhus were identified, and those who had a serological confirmation were included for analysis. Severe dengue was diagnosed based on revised WHO criteria and included in the study.[5] Children with or without warning signs, without serological confirmation were excluded. The data was recorded on specified data collection form. The data included demographic parameters, clinical features, and laboratory parameters (CBC, RFT, LFT, serology, culture if any). The serological diagnosis of Dengue fever was based on dengue IgM-ELISA (Panbio dengue IgM & IgG capture ELISA) where values <9 PanBio ELISA units were considered negative, 9-11 equivocal, and more than 11 positive, as per the manufacturer's instructions). Similarly, serological diagnosis of scrub typhus was based on scrub typhus detect^{TM}IgM ELISA system. Children with SD were treated with normal saline, monitored for complications and treated according to the physician's discretion. Children with ST were treated with antibiotics and offered symptomatic care for the illness. The Institution's Human ethical committee approved the study.

Statistical analysis



Kolmogorov-Smirnov test was used for testing normality of the data. Normally distributed continuous variables were compared using *t*-test and non-parametric variables using Wilcoxon signed-rank and Mann-Whitney U tests. Chi-square analysis was done for comparisons of proportional data among groups. Multiple logistic regression models were used to assess the association of severe dengue and scrub typhus with relevant clinical and laboratory parameters.

□□□□□□□

A total of 7926 children got admitted as inpatients during the study period of which 6737 children were admitted for evaluation of fever. 747 children were serologically confirmed as dengue fever of which a total of 40 children were diagnosed with severe dengue fever with mean (±SD) age 7.9 (±3.80) years, and male: female ratio was 1.1:1. The mean (±SD) duration of fever at admission was 4.5(±1.13) and the mean (±SD) duration of hospital stay was 5.58 (±1.13) as in Figure 1.

Among children with severe dengue, 31(77.5%) had vomiting, 27(67%) had abdominal pain and 23(57.5%) had oliguria as presenting complaints. A majority of them (31; 77.5%) had evidence of plasma leakage, and 17(42.5%) had skin and mucosal bleeds at admission. None of the children had any alternate provisional diagnosis at admission other than severe dengue based on the clinical presentation.

A total of 32 children were serologically diagnosed as scrub typhus with mean (±SD) age of 11.8 (±5.83) years, and male:female ratio was 2.2:1. The mean (±SD) duration of fever at admission was 7.34 (±2.46) days. Of 32 children, 14 (43.8%) presented with vomiting and 11 (34.4%) presented with abdominal pain at admission. On examination, 5 (15.6%) had maculopapular rash and 15 (46.9%) had hepatosplenomegaly. Only 8 (25%) were found to have eschar to support the clinical diagnosis of scrub typhus. Other clinical parameters are presented in Table 1.

□Expressed as Mean ±SD, NS-Non significant

We compared the clinical and laboratory characteristics among children with severe dengue and scrub typhus as shown in Table 2. We found that the mean age at presentation and duration of fever was higher among scrub typhus compared to severe dengue, 7.97±3.8 years

vs 11.8±5.83 years (p = 0.001) and 4.5±1.13 days vs 7.34±2.46 days (p<0.001), respectively. A greater proportion of children with dengue presented with vomiting, abdominal pain, oliguria, skin bleeds, edema and hypotension. There existed a statistically significant difference in the proportions of the above-mentioned variables between both groups (p<0.05). Interestingly erythematous rash was present in equal proportions between both groups (15% vs 15.6%, p = 0.14).

Table 2 Comparison of clinical features between dengue and scrub typhus

	Dengue fever	Scrub typhus	p value
Hemoglobin# (g/dL)	13.3±1.70	12.24±1.63	0.003
Hematocrit#	41.45±5.78	37.6±5.14	0.001

ANC# (x10^3/cu.mm)	2.6±1.97	3.9±2.06	0.002
Platelet# (x10^3/cu.mm)	50.23±35.55	140±95.0	<0.001
ESR#	8.1±6.82	33.88±13.79	<0.001
SGPT#	138.75±213.75	91.9	0.31

Expressed as Mean ±SD

The mean haemoglobin (and hematocrit) values were higher among children with dengue (13.3±1.7 vs 12.24±1.63, p = 0.003). The white blood cell (WBC) count and absolute neutrophil count (ANC) were markedly different in both groups. The children with dengue had a relatively low WBC count and ANC (5.19±3.03x10^3/mm^3, 2.6±1.97x10^3/mm^3 respectively) on comparing children with scrub. The platelet count at admission was lower in children with dengue when compared to scrub typhus (50.23±35.55x10^3/mm^3 vs 140±95x10^3/mm^3, p<0.001). Also, the mean Erythrocyte Sedimentation Rate (ESR)at 1hour was lower in children with dengue fever compared to scrub typhus (8.1±6.82mm vs 33.88±13.79mm, p<0.001). The mean serum Alanine Transaminase (ALT) levels were higher in children with severe dengue compared to scrub typhus (138.75±213.75 vs 91.9IU/L). But this difference did not achieve statistical significance (p = 0.19).

From the data obtained at admission, variables between these two illnesses that had statistically significant difference were applied to a logical regression model. We found a high probability of severe dengue compared to scrub typhus was associated independently with hypotension, lower ANC, low ESR and platelets as in Table 3. With a probability cut-off of >90%, the predictive model gave a sensitivity of 100%, specificity of 87.5%, positive predictive value of 88.8% and negative predictive value of 100%, for dengue compared to scrub typhus with ANC 0.93 (0.79-0.99) as shown in Figure 2.

Table 3 Multivariate logistic regression analysis of clinical and laboratory parameters between dengue and scrub typhus

Parameter	Increase/decrease	Multivariate odds ratio (95% CI)	p value
ANC	2x10^3/cu.mmincrease	1.98 (1.18-3.30)	0.012
Platelet count	40000/cu.mmdecrease	2.47 (1.63-4.23)	<0.001
ESR	6mm decrease	5.69 (2.88-15.97)	<0.001

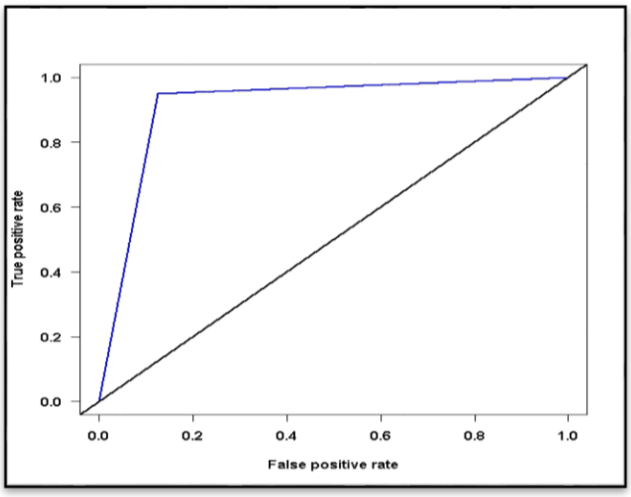

Figure 2 Receiver operating characteristic curve for ANC in predicting dengue fever from scrub typhus

Discussion

Dengue fever and scrub typhus caused by different vectors present in similar demographic distribution and clinical features. Any delay in recognition of these infectious diseases results in significant morbidity and mortality as well. Management of severe dengue is largely supportive with emphasis on fluid resuscitation and hemodynamics monitoring, whereas in scrub typhus the early initiation of antibiotics is mainstay.

Making the correct diagnosis with the available preliminary investigations while awaiting confirmatory test results might help in better management and relieve parent's anxiety. In this retrospective study we attempted to compare the clinical and laboratory parameters between these two similar diseases at initial presentation to the health care facility.

The mean age at presentation of children with severe dengue was less as compared to scrub typhus (7.9 +/- 3.80 vs 11.8 +/- 5.83) and the mean age at presentation of the latter was comparable to that reported previously by Kumar M et al.[6]

The male:female ratio of children with severe dengue was less than that of scrub typhus (1.1:1 vs 2.2:1). This difference in gender ratio could probably due to similar exposure risk for mosquito bites in-doors and higher prevalence of chigger exposure while playing outdoors by boys. A similar observation was made by Bhat NK et al, who documented a higher male to female ratio (1.44:1) in scrub typhus. Among the symptoms and signs between the study groups at presentation, mean duration of fever, abdominal pain, edema, oliguria and hypotension were strikingly different. Though these differences have been witnessed in children with scrub typhus in previous studies their incidence was much lesser in the present study, when compared to children with severe dengue.[7]

In our present study, there was significant difference in clinical features among the study groups. Children with severe dengue had a short mean duration of fever (4.5 +/- 1.13 vs 7.34 +/- 2.46 days) at presentation. Majority of children (77.5%) with severe dengue in our study presented with vomiting and edema. Two third had abdominal pain and oliguria and almost half of them presented with skin bleeds and hypotension at admission. Almost ninety percent of children presented with significant hepatomegaly and none had splenomegaly. Pothapregada S et al, in his clinical profile of children with dengue also observed a similar occurrence with fever (94.6%) being the commonest symptom and persistent vomiting as the frequent warning sign (75.1%).[8] Among children with scrub typhus, almost half of them had hepatosplenomegaly. Clinical features like rash, edema, respiratory distress, oliguria was less observed in children with scrub typhus. Only twenty-five percent of children with scrub typhus had eschar in our study population. Rose W et al, found 40.8% of their children having the characteristic eschar at the presentation but most studies project a lesser percentage.[9] Babu et al, in their prospective study found only 34.6% of serologically confirmed scrub typhus to have eschar.[10] Absence of eschar could be secondary to previous exposure to ricketssial antigen and variation in cutaneous immune response and that could be possible reason for absence of eschar in majority of our study children.

In our study, we found that the striking difference in clinical parameters between the two groups was hypotension, lower ANC, low ESR and significantly low platelet values and thus provides the best ability to differentiate between severe dengue fever and scrub typhus. ANC has been statistically high in children with scrub typhus than severe dengue. The predominance of lymphocytes with leucopenia and severe thrombocytopenia might be an additional pointer to the diagnosis of severe dengue. In the guideline of Indian academy of pediatrics on ricketssial diseases, marked leukocytosis with the shift to the left in later stages, raised ESR and thrombocytopenia were laboratory features suggestive of these infections, as noted in children with ST in the present study.[11] Liver dysfunction has been observed in children with severe dengue and scrub typhus.[12] Similar to the present study, Kumar J et al noted a 10-fold increase in the mean serum ALT levels in children with DF and could be used in differentiating these diseases.[13]

Few limitation of our study is the retrospective model, small sample size and restricted to a hospital – based population. The observation and predictive model may not be applicable to differentiate other febrile illnesses in children and the clinical utility the model needs to be tested prospectively and also validated. In a resource limited setting among endemic areas, our predictive model could be utilized to differentiate hemorrhagic fever due to scrub typhus and severe dengue, helping to initiate appropriate treatment.

Abstract

Background: Chronic abdominal pain is a common gastrointestinal symptom in children that significantly lowers their quality of life. In adults, Gall bladder (GB) hypomotility / dyskinesia is associated with many functional abdominal disorders but there is scarcity of evidence on its role in childhood gastro-intestinal disorders. Aim of the study is to evaluate the GB motility in children with chronic functional abdominal pain (FAP).

Methods: Children aged 5-15 years with chronic abdominal pain fulfilling ROME-III criteria and healthy controls were included and all study participants were subjected to ultrasonographic evaluation of the gall bladder volume in fasting state and post - Fatty test meal (FTM) and its ejection fraction was calculated.

Results: Sixtysix children including 31 with chronic FAP underwent sonographic evaluation for GB motility. The mean ejection fraction (EF) of cases and controls were 51.72±17.76% and 57.3±23.26% (p value - 0.158). The mean EF of cases with upper abdominal pain and lower/peri-umbilical abdominal pain were 41.7±17.1% and 57.2±15.9% respectively (*p* value < 0.0001). Increasing BMI had no significant association with GB motility among the participants.

Conclusions: There is lack of significant association between children with chronic FAP and GB hypomotility. Children with upper abdominal pain have lesser GB EF, suggesting a possible abnormal GB motility.

Keywords: Childhood functional abdominal pain, Gallbladder, Ultrasonography

Introduction

Chronic abdominal pain is a common gastrointestinal symptom in children presenting to outpatient department. In United states and Europe, its prevalence rates ranges from 0.3 – 19% among school-going children and accounts for about 2% to 4% of all pediatric office visits.[1,2] Though it is not associated with any organic gastrointestinal pathology, children with FAP have a significantly lower quality of life and it contributes for school – absenteeism.[3] In 1999, the term abdominal pain related-functional gastrointestinal disorders in pediatric ROME II criteria, which included functional dyspepsia, functional abdominal pain (FAP), irritable bowel syndrome and abdominal migraine. These terminologies were further redefined based on duration of symptoms before diagnosis in ROME III criteria.[3]Many functional gastrointestinal disorders like functional dyspepsia, irritable bowel syndrome and disorders of Gall bladder (GB) has been studied for any possible association with abnormalities in GB motility, but the results are inconclusive.[4] In adults, GB hypomotility/dyskinesia is well established in idiopathic constipation and functional dyspepsia, but there is scarcity of evidence on its role in childhood functional abdominal disorders.[5,6] Our study

was designed to study the GB motility in children with functional abdominal pain.

M□□□ □ □□

This crosssectional study was done in the outpatient department of pediatrics, PSG institute of medical sciences from January 2016 to August 2017. Children aged 5-15 years attending the OPD of the institution with chronic abdominal pain fulfilling ROME-III criteria, without any obvious cause for abdominal pain and with no previous abdominal surgeries were included in the study. Healthy children who visited the hospital for routine health visit or vaccination were included as controls. Institutional Human ethical committee approved the study and all study participants were included after obtaining informed consent. A detailed history including dietary and allergy history was obtained and clinical assessment was done. They were documented in a pre-designed data collection tool.

A total of 31 cases and 35 controls were recruited in the study and all study participants were subjected to ultrasonographic evaluation of the gall bladder in fasting state. A radiologist experienced in pediatric Sonography performed the evaluation using Philips iU22 xMATRIX ultrasound system. The Gall bladder was assessed for its area, thickness and volume, where area was derived by trace method and maximum GB width and length were measured using transverse and longitudinal images of the GB.

The volume of GB was calculated in fasting and 30-minutes following a fatty test meal using Dodd's formula, Volume (in cm^3) = 0.52 x [L x W x A], where L is the greatest length, W- greatest transverse width, and A-greatest anteroposterior diameter of the GB. The gallbladder ejection fraction (EF) for each examination was obtained from two-volume data using the following equation. Where V_0 = gallbladder volume in fasting state, Vn = gallbladder volume after the fatty test meal,

□□□□□□□□□□□□□□□EF (%) = [(Vo-Vn) / Vo] X 100

For the purpose of this study, Children with ejection fraction of less than 40% were considered to have gallbladder hypomotility.

Statistical analysis was done using statistical package for the social science version-19 (SPSS) software. The fasting and post-prandial GB volume was expressed as mean ± SD and students t test was used to compare their means between groups. Chi-squared testing was applied to look for possible association between EF and BMI. A p-value less than 0.05 was considered significant.

□□□□ □□□□

There were a total of 66 children included in this study. The mean age of cases and controls were 10.14±2.71 years and 11.54±1.94 years respectively. The mean height of the cases group was 132.9±15.9 (range – 100 to 165cms) and that of controls was 145.14±11.6 (range – 110 to 159cms). The mean weight of cases and controls were 27.3 ± 10.5 Kg and 33.8 ± 6.6 Kg respectively. The mean body mass index (BMI) was 14.9±2.8 kg/m^2 (range of 11.3 to 26.3 kg/m^2) in case group and 15.9±1.8 kg/m^2 (range from 11.9 to 19.5 kg/m^2) in the control group. Out of 31 cases there were 11 boys (35.5%) and 20 (64.5%) girls respectively and in 35 controls there were 23 (65.7%) boys and 12 (34.3%) girls respectively (Table 1).□

*Student's T-Test

The ejection fraction of GB were compared among children with functional abdominal pain who presented predominantly with upper or lower / peri-umbilical regions, to identify any possible association between the site of abdominal pain with GB motility. The mean ejection fractions of cases with upper abdominal pain and lower/peri-umbilical abdominal pain were 41.7±17.1% and 57.2±15.9% respectively (p value <0.0001), but the former did not qualify for the definition of GB hypomotility i.e. EF<40% (Table 3).

Predominantly Lower	8.67±4.40	3.13±1.0	57.87±16.12
P-value*	0.497	0.25	0.019

*Student's T-Test

In order to identify any possible association between increasing BMI and GB contractility among cases, they were sub-grouped as, BMI<16 and BMI ≥ 16. There was equal number of children (n=4) in each subgroup with EF<40%, suggestive of GB dysmotility and their mean EF were 54.28 ± 17.99 % and 48.19 ± 17.53 % respectively (*p*-value < 0.001) (Figure 1).

[illegible]

[illegible]

In our study, we found no significant difference in the gall bladder volume (in fasting state and post Fatty test meal) among the cases and controls with equal number of children in both groups with GB ejection fraction <40%. Children who presented with upper abdominal pain had significantly lesser ejection fraction than those with lower abdominal pain. Many adult studies have recognized GB hypomotility in obese patients than non-obese patients. Sari et al found a positive correlation between fasting gallbladder volume and body mass index and body fat weight in obese women than non-obese women, but no such studies were available for comparison in children.[7] In the present study there existed no significant association in GB dysmotility and increasing BMI among cases.

The exact pathogenesis for FAP remains unclear, but visceral hypersensitivity, abnormal brain - gut interaction, immune dysregulation and altered gut motility has been postulated for the occurrence of the symptoms.[8,9] Gall bladder dyskinesia has been associated with various gastrointestinal symptoms like bloating, dyspepsia, post prandial epigastric pain and upper abdominal fullness.[10]

Mehra et alm observed gall bladder hypomotility in children with functional constipation, thus strengthening the claim of GB dyskinesia as a possible claim for functional abdominal symptoms in children.[11] Several imaging modalities like oral choledochocystography and syntigraphy are utilized to assess GB contraction but Sonography has been reliably used for assessing the GB area and volume, their changes following a fatty meal.[12] Ultrasonography could be preferred for its noninvasive nature and no radiation exposure that accompanies other modalities.

In our study we found 8 (26.7%) of the children with FAP healthy and 9 (25%) controls with mean GB Ejection fraction <40% suggesting that GB hypomotility could possibly be unrelated for the abdominal pain. Interestingly children who had predominant upper abdominal pain had low GB Ejection fraction compared to the children with lower abdominal pain (41.73±17.13% vs 57.87±16.12%) as noted by Hofeltd et al, in their study where a majority of children (96.67%) who underwent laproscopic cholecystectomy for biliary dyskinesia had upper quadrant pain.[13] A similar study with more subjects with FAP localized predominantly to upper abdominal could establish an association with GB motility.

Few limitations in our study are firstly the children were consecutively enrolled and sample size of the study is too small for drawing strong conclusions. Secondly the co-existing infection like H. pylori or parasitic infection of gut could possibly have an impact on the abdominal pain that was under evaluation. Nonetheless the present study is the first of its kind that has meticulously evaluated the GB volume and contractility in children with FAP and has found a possible association of GB dyskinesis with upper abdominal pain.

[illegible]

To conclude, abnormality in GB motility could be a cause for FAP presenting predominantly as upper abdominal pain in children thus necessitating its evaluation and a larger well-controlled study might help in better understanding of the entity.

Analysis of Incidence and Risk Factors for Retinopathy of Prematurity among Preterm Neonates in a Tertiary Care Neonatal Unit.

Gayathri S*, and Booma V Mohan.

Department of Pediatrics, Coimbatore Medical College Hospital, TheTamilnaduDr.MGR Medical University, Tamilnadu, India.

ABSTRACT

Advances in neonatology has achieved several milestones in reducing the morbidity and mortality among high risk newborns. Preterm care is one such major domain where expanding knowledge and technology has ensured a higher survival chance. Reduced mortality comes but with a greater co incidence of diseases exclusive in preterm neonates like Retinopathy of prematurity, anaemia of prematurity, bronchopulmonary displasia etc. In our study we have made an attempt to identify the incidence and risk factors in preterm neonates associated with the development of ROP.100 preterm neonates who satisfied the inclusion criteria of birth weight ≤1750 grams and ≤34 weeks GA with or without risk factors and birth weight between 1750-2000 grams and 34-36 weeks GA with additional risk factors for ROP were screened in the Neonatal intensive care unit. Out of the 100 babies screened, only 21 babies developed ROP. Lower birth weight and gestational age were significantly associated with the incidence of ROP. Other risk factors that were found to be of statistical significance were oxygen administration, RDS, sepsis, shock and phototherapy by Chi Square analysis. Using multivariate analysis, shock, gestational age and APH were found to be significant factors.

INTRODUCTION

Retinopathy of prematurity (ROP), previously known as 'retrolental fibroplasia' because of its end stage appearance is a developmental vaso proliferative disorder that occurs in the retina of preterm infants with incomplete vascular proliferation. Incidence of ROP in India is reported to vary between 38 – 51.9%.[1-3] Out of the approximate 26 million annual live births in India, approximately 8.7 % of newborns are < 2000 grams in weight.[4]

There are about 45 million blind people in India out of which nearly 30 % are in Asia. Of the total blindness, childhood blindness accounts for 4%. India shares 20% of world's childhood blindness.[5] ROP affects 3,00,000 infants worldwide. The incidence of ROP in developing countries like India is reported to be around 24 – 47% among high risk preterms.[6]It is important not only in terms of economic burden but also in its severe social implication, which is very long in terms of blind years.

As regards our country, we are sitting at the summit of two volcanoes – one where all the latest state of the art health care facilities are available and the other, where even the basic health care is unavailable. ROP is known to grow in both these situations. Among the preventable causes of blindness in India, ROP figures very high in the agenda. Low birth weight and gestational age were found to be the most significant risk factor associated with ROP.

With neonatal units being equipped with state of the art technical support and well trained health care providers to provide quality care to the preterm neonates, ROP incidence is on the rise. By recognition of risk factors, early detection and timely intervention, blindness due to ROP is preventable.

Purpose of this study is to know the incidence of ROP and to correlate it with maternal and neonatal risk factors.

MATERIALS AND METHODOLOGY

Inclusion Criteria [7]

Preterm low birth weight babies admitted to NICU at CMCH with

- Gestational age < / = 34 weeks
- Birth weight < / = 1750 gms
- Gestational age between 34 – 36 weeks with risk factors for ROP
- Birth weight between 1750 – 2000 gms with risk factors for ROP

Exclusion Criteria

- Preterm babies who die before reaching the age for screening
- Babies who did not complete the follow up protocol
- Babies with major congenital anomalies / chromosomal anomalies

Study Design

Longitudinal study with short follow up done from October 2012 to September 2013. Data was collected by interviewing parents, from hospital records and by examination of the neonate. Sample size was 100. Variables studied were gestational age, postconceptional age, sex, birth weight, oxygen administration and modes, presence of RDS, surfactant administration, sepsis, shock, anaemia, phototherapy, blood transfusion, exchange transfusion, maternal history of PIH and APH.

Statistical Methods Used

The data are reported as mean ± SD or as median, depending on their distribution. Differences in the quantitative variables between groups were assessed by means of unpaired t test. Comparison between

groups were made by non parametric Mann-Whitney test. Chi square test was used to analyze categorical variables and multivariate analysis was done to test dependent variables. P value of < 0.05 using a two tailed test was taken as statistically significant. All data were analyzed using SPSS software, version 16.0 for windows.

Definition of Risk Factors

Respiratory Distress Syndrome [8]

- Premature infant with clinical signs soon after birth including tachypnoea, retractions, alar nasal flaring, grunting, cyanosis
- X ray evidence : low volume lungs, diffuse reticulo nodular pattern, air bronchogram, white out lung

Apnoea [9]

Cessation of respiration for > 20 seconds or cessation of respiration of any duration when accompanied by bradycardia (< 100 bpm) and/ or cyanosis

Sepsis

- Clinical sepsis : lethargy, refusal feeds, apnoea, hypoglycemia, sclerema, seizures, respiratory distress, altered nasogastric tube aspirate, abdominal distension, shock etc
- Laboratory evidence : positive sepsis screen, culture positive sepsis, thrombocytopenia

Shock

- Pallor in the absence of bleeding, skin mottling, cold and cyanosed extremities, capillary refilling time > 3 seconds, absent peripheral pulses, tachycardia, narrow pulse pressure, fall in mean arterial pressure

Anaemia [10]

- Hematocrit < 40% in ventilated babies, <30% in babies requiring CPAP and <20% in babies breathing room air is taken as anaemia.

Blood Transfusion

- Transfusion of packed cells, platelets, fresh frozen plasma or whole blood

Procedure

After obtaining oral informed consent from the parents, neonate is screened in the NICU using an indirect ophthalmoscope. Baby is preferably fed one hour prior to examination in order to avoid vomiting and aspiration. Pupils are dilated using a combination of cyclopentolate 0.5 % and phenylephrine 2.5 % drops two to three times about 10 – 15 minutes apart. Excess eye drops must be wiped off to avoid systemic absorption. The changes in the retina were graded according to the International Committee for Classification of Retinopathy of Prematurity (ICROP) guidelines 2005.[11](table 1)

Timing of Screening [7]

- First retinal examination is performed not later than 4 weeks postnatal age in infants born > 28 weeks of gestation or 31 weeks of age whichever is later. (table 3)
- Infants born < 28 weeks of gestation and birth weight < 1200 grams are examined at 2 – 3 weeks of postnatal age

Follow Up Protocol [12]

ISSN: 0975-8585

If no ROP was detected at initial examination, the infants were re-evaluated once every 2 weeks until vascularization is complete. If ROP was detected, the examinations were performed weekly for stage 1-2 disease and more frequently for stage 3 disease, till the disease started resolving or progressed to threshold stage. Babies showing evidence of regression were followed up till vascularization was complete.

RESULTS

Results obtained by Chi Square analysis are shown in table 2. Multivariate analysis is shown in table 3.

Table 1: Classification of ROP

Location	Zone I	Circle with optic nerve in centre and a radius of twice the distance between optic nerve and macula
	Zone II	From edge of Zone 1 to nasal oraserrata nasally and equator temporally
	Zone III	Lateral most cresent shaped area from Zone II to oraserrata temporally
Severity	Stage 1	Presence of thin white demarcation line between the vascular and avascular retina
	Stage 2	The line becomes prominent to become a ridge with length and width
	Stage 3	Presence of extra retinal fibrovascular proliferation arising from the ridge extending into the vitreous
	Stage 4	Partial retinal detachment: not involving the macula (4A) or involving the macula (4B)
	Stage 5	Complete retinal detachment
Plus disease		Presence of dilatation and tortuosity of posterior retinal vessels; associated with vitreous haze and papillary rigidity
Extent		Extent of involvement of retina expressed as clock hours

DISCUSSION

The present study reflects the problem of ROP in a tertiary care neonatal unit. Incidence of ROP in the present study is 21%. Out of the 21 babies, only one baby developed ROP requiring surgery and remaining 20 babies developed ROP not requiring surgery (includes both regressing ROP and ROP requiring follow up). Birth weight of ROP babies ranged from 930 – 1750 grams (mean 1363.81±251.41) while that of non ROP babies ranged from 900 – 1900 grams (mean 1396.33±277.42). Lower birth weight was significantly associated with the incidence of ROP ($p = 0.007$). Incidence of ROP was 20 % among babies ≤1500 grams.Incidence of ROP in babies < 34 weeks was found to be 23%. Lower gestational age was found to significantly associated ($p =0.023$) with development of ROP. Gestational age, birth weight, oxygen, respiratory distress syndrome, surfactant, sepsis, shock and phototherapy were found to be significantly associated with ROP by Chi Square analysis. Shock, gestational age and antepartum hemorrhage were found to be significant through multivariate analysis. These results show that ROP incidence is influenced by almost every illness and treatment carried out in the preterm neonate. Effective management of ROP requires a team effort by a pediatrician, ophthalmologist and the NICU staff. Thus implementing an intelligent screening policy in every NICU will help to reduce effectively one of the preventable causes of childhood blindness.

CONCLUSION

Regular screening program that includes all preterm neonates satisfying the screening guidelines should be followed strictly. Along with regular screening, effective control of administration of oxygen, monitoring of oxygen saturation, management of RDS, following strict asepsis and prompt recognition and management of shock with fluids and inotropes and careful administration of phototherapy based on the bilirubin normogram must be followed.

Sleep pattern and problems in healthy toddlers

Jayavardhana A, Devaprasath .S

Dept of Pediatrics, PSGIMSR, Coimbatore, India

Corresponding author: Jayavardhana A

Abstract

Objective: Sleep habits and sleep disturbances vary with age biological, psychological and socio-cultural environment. To understand this normality we conducted a questionnaire based survey among parents of healthy toddlers in Coimbatore city.

Method: A questionnaire cum interview based study elicited responses from the parents. This questionnaire focused on demographic factors, sleep pattern, practices and related problems with open ended and close ended questions**.**

Key words: sleep pattern, sleep problems, toddlers

Introduction

Sleep related problems and are not uncommon in children and may persist in adulthood (1). Disrupted or deficient sleep impacts every aspect of a child's growth and development.(2-5) sleep problems can be a result of both types of sleep issues (disorders and problems), it is important to have a better understanding of sleep pattern issues prevalent in pediatric community . Sleep disorders are readily identified if a child has prominent snoring or excessive daytime sleepiness, yet many sleep related problems may go unrecognized. One reason is that sleep issues are not frequently raised by care givers during health visits (6, 7). In addition, pediatric health care providers have limited training in pediatric sleep (8), cursory questions related sleep and limited patient contact time. One study of two general pediatric clinics found that a discussion of sleep issues is rare, diagnosis uncommon, and treatment guidelines lacking (9). Many studies suggest that night-time sleep pattern in childhood is mainly determined by the environment (10, 11). Multiple factors within the home have been shown to influence the sleep duration and pattern. In an sample of over 5000 children aged from birth to 36 months, a regular bedtime routine and limited TV exposure were among the strongest predictors of longer sleep at night (12). As there are also marked ethnic and socio-economic differences in the sleep duration of young children (13), it is essential to know the sleep pattern of the community. This study therefore aimed to analyze the sleep pattern of healthy toddlers in Coimbatore city.

Material and methods

Healthy toddlers (1-3 years) attending PSG well baby/vaccination clinic at PSG hospitals Coimbatore, India were included for this cross sectional prospective study. Toddlers with chronic medical illness and on any sedative drugs were not included. The Institutional ethics committee approved the study. Written informed consent was taken from parents / caregivers. A questionnaire is adapted and translated in Tamil from two previous studies (14, 15). This questionnaire focused on demographic factors, sleep duration, bedtime rituals and sleep related disturbances with open ended and close ended

www.ijbamr.com P ISSN: 2250-284X , E ISSN : 2250-2858

questions among participants. Parents are asked to recall the child's sleep behaviors over a "typical" recent week. Items are rated on a 3-point scale: "usually" if the sleep behavior occurred 5 to 7 times per week; "sometimes" for 2 to 4 times per week; and "rarely" for 0 to 1 time per week. The questionnaire was administered via interview by trained health assistant.

Categorical variables were summarized by proportions while the continuous variables were summarized by means and standard deviations. Frequency data applied for responses from open ended questions. Data analysis was done using SPSS15.

Results

Demographic factors

A total of 186 completed responses from parents of toddlers were collected over six month period. Responses from parents only were taken final statistical analysis. The mean age of the toddlers was 20(+ 4.5) months with sex ratio of 55:45 of boys and girls.

Sleep duration

The total reported average duration of sleep in the study population was 11.5+2.5 hours including day time sleep. Mean duration of day time sleep was about 1.30+30minutes.18 % of the kids had no regular day time sleep. The median time for falling asleep 8.30 pm (range 7 to 11.30pm) and wake up time 6.30am (range 4.30 to 8.30am). Early sleep onset time reported in children who are not taking regular day time nap. Only 30 % of kids usually had regular sleep duration and timings.

Sleep practices

Co -sleeping with either one or both parents was prevalent among 82% of the total sample. About 12% of kids were sleeping with grant parents and others. About 6 % of parents allowed their kids to sleep in separate bed in the same room. Working parent's babies slept late in the night (median time 9.30pm) and woke up late in the morning (median time 7.40am) due to more playing in the night and undisturbed sleep in the morning hours. Commonly reported bedtime routines are bed time stories 40%, songs with patting (28%), swaddling and rocking (30%). Significant number of babies (45 %) watching television before falling asleep.

Table -1 sleep problems

Sleep problems	Boys N=102 (54.8%)	Girls N=84 (45.2%)	Total (N=186)
Over all	45	40	85 (45.6%)
Bed time resistance	23	27	50 (27%)
Irregular timings	19	23	42(23%)
Fragmented sleep	15	18	33(18%)
Frequent Night waking	24	20	44(24%)
Bruxism	10	7	17(9%)
Day time drowsiness	30	20	50(27%)
Restless leg syndrome	10	6	16(9%)
No sleep problem	52	49	101

Quality of sleep and sleep disturbances

About 20% of parents perceived that their child is not sleeping well due to reasons such as bed time resistance, irregular timings, fragmented sleep, frequent awakenings due to probable night terrors and night mares , teeth grinding and difficulty in falling asleep and getting up. They encountered one or more such issues regularly. The reported above sleep disturbances (one or more) in the study group were 45.6% though many parents felt such disturbances were not significant (refer table no-1). Bruxism was reported in 9 % of children. About 25% children reported to frequent night waking without any obvious reasons.Only 15 percent of babies

www.ijbamr.com P ISSN: 2250-284X , E ISSN : 2250-2858

between one to two years required 1 or 2 night feeds and bowel movements which were rare after two years. Day time drowsiness reported in 27%. As co-sleeping with parents either single or both parents observed in 83 percent of samples sub group comparisons were not done.There were no significant sex differences in the study group.

Discussion

Sleep plays vital role in the neuro-cognitive development of children. Enquiring parents about their children's sleep pattern should be part of every child care visits. Evaluating sleep pattern and disorders requires an understanding of changes in sleep occurs with developmental maturation. Children sleep pattern also varies with age, ethnicity and cultural background. There are only few studies from India evaluated sleep pattern among preschool children. This study was done in Coimbatore a tier 2 city where in both parents are mostly working. In the past, children were generally considered to be so called "good-sleepers", but recent reports do not support this myth (16).Most sleep problems may start in late infancy and become a major issue for toddlers. Adequate and sound sleep is crucial for successful learning in children. Daytime behaviors in children may also be influenced by nighttime problems.The overall prevalence of sleep disorders in children of our study is 45 %.The sleep problems reported in similar studies from other countries varies from 20-50%.Bed time resistance and irregular timings were the most common concerns reported in this study. Frequent night waking lead to increased day time drowsiness in this group (50%). Our study results were comparable to a sleep study from Iran using BEARS tool in Preschool and School-aged children (17). A Similar study from Singapore reported identical pattern of sleep duration and sleep related problems in mixed Asian population.

The prevalence of co-sleeping among Indian children is comparable to studies from all Asian and culturally similar countries (19, 20). As children's sleep patterns are more likely to be influenced by the sleep patternsof co-sleeping parents, it is essential that co- sleeping adults to practice well sleep hygiene.Sleep problems were more common in developing countries than develope countries. The lower rate of sleep problems reported from developed countries may be explained in view of higher levels of knowledge of sleep hygiene and screening programs. (19, 21).The following are the limitations. Small cross-sectional questionnaire based study and may not represent entire community. Accuracy of self reporting is not clear in this study.

Conclusion

Toddlers sleep largely depends with parent's child rearing practices and sleep ecology. Sleep related problems are common and most issues are not perceived as serious illness warranting medical attention. Addressing babies sleep pattern and educating sleep hygiene in early years of life should be a part of health care visits as sleep determines development and behavior.

Abstract

Multidrug resistance in Salmonella Typhi has emerged as a significant problem. Given the difference in the sensitivity patterns reported for Salmonella Typhi, this study aimed to evaluate antimicrobial susceptibility patterns of Salmonella Typhi in a tertiary care hospital, coimbatore in south India. Salmonella Typhi positive blood cultures from children up to 14 years of age, over a period of 18 months from June 2011 to November 2012 were analyzed . Kirby-Bauer disc diffusion method was used to evaluate antimicrobial susceptibility. Results: Of the total of 50 isolates studied, all the isolates were susceptible to ceftriaxone, most were responsive to Ampicillin, Chloramphenicol, Cotrimoxazole, and Ciprofloxacin. Out of 50, only 4 cases were sensitive to Nalidixic acid. Isolates that showed high nalidixic acid resistant (*34/50*) had elevated minimum inhibitory concentration (MIC) for ciprofloxacin, ranging from 0.135 to 0.91 µg/mL (average 0.25 ± 0.11 µg/mL) RSC. Only 2 isolates were multi drug resistant. Though multi drug resistance is less common, high level of nalidixic acid resistance and elevated MIC for fluoroquinolones is a concern in this population.

Key words: Antimicrobial susceptibility, Salmonella typhi, multidrug resistant typhoid fever

Introduction

Typhoid fever is a bacterial disease, caused by Salmonella typhi. It is transmitted through the ingestion of food or drink contaminated by the faeces or urine of infected people. It is a worldwide problem and widely prevalent in the tropical developing countries with an estimated 12-33 million cases (1) and 6 lakhs death occurring annually (2). Major contribution is from Asia (3) and it is endemic in the most parts of Indian subcontinent (4). Appropriate antibiotic therapy reduces mortality from 30% to less than 1% (5). Multidrug resistant (MDR) enteric fever (resistant to chloramphenicol, ampicillin and co-trimoxazole) has emerged across the world in the recent times (6). Salmonella Isolates with reduced susceptibility to fluoroquinolones have now reported in the Indian subcontinent and other regions (7, 8).The current worldwide increase in antimicrobial resistance and lack in the development of new antibiotics have serious public health and economic implications. The reason for increasing resistance is multifactorial, but the main cause is the high level of inappropriate antibiotic usage. About 80% of antibiotics are used in the community and the rest are used in hospitals (9, 10). It is estimated that 20-50% of all antibiotics use is inappropriate, resulting in an increased risk of side effects, higher costs and higher rates of resistance in other community pathogens (11). In this context, it was essential to find out the current sensitivity pattern of the Salmonella strains isolated from blood in our region.

Materials and Methods

It is a cross-sectional, hospital based study spanning over a period of 18 months from June 2011 to November 2012. Inpatients and outpatients of department of Paediatrics of PSG IMSR with confirmed diagnosis of Salmonella typhi including locales in and around Coimbatore including referred cases up to 14 years of age were included. Institution human ethics committee approved the study. All the suspected cases of typhoid fever on the basis of clinical features of high grade fever, headache, hepatosplenomegaly, and with other Constitutional symptoms were investigated. Blood culture was performed by collecting 5cc venous blood and diluting it 4 times under normal circumstances and 10 times if treated with antibiotics, and then injecting into a bulb containing 20-30cc of 5% bile broth. The bulb is incubated for 24-48 hrs at 37^0C and subcultures were made on McConkey's medium. Cultures were declared negative after incubation for 10 days. Antibiotic sensitivity pattern was assessed by the Kirby-baeur disc diffusion method where discs containing antibiotics were placed onto an agar plate upon which bacteria were growing. If the bacteria is sensitive to the antibiotic a zone of inhibition is seen around the disc. Minimum inhibitory concentrations (MIC) of isolates resistant to chloramphenicol, ampicillin and nalidixic acid were determined by agar dilution test using purified antibiotic powders. Data were evaluated using descriptive statistics.

Results

A total of 50 cases of salmonella typhi isolates from blood culture were included for analysis. Out of these, 36 (72%) were males and 14(28%) were females. Of the 50 cases 39(78%) were between 5-14 years and 11(22%) cases were less than 5 years. Fever was noted in all the cases (100%). Average duration of symptoms before admission was 4.5 days. Other predominant symptoms were pain abdomen (26%), diarrhea (28%), vomiting (22%) and cough (14%). Hepatomegaly(60%) and Splenomegaly(68%) were the major clinical findings. Toxic look was present in 18 % of cases. Leucopenia (<4000cumm) was present in only 5 cases. In the present study (table-1), all the isolates were susceptible to ceftriaxone(100%) , most were responsive to Ampicillin (48/50,96%), Chloramphenicol (47/50,94%),Cotrimoxazole (45/50,90%) and Ciprofloxacin (48/50,96%).Out of 50,only 4 cases were sensitive to Nalidixic acid. Isolates that showed high nalidixic acid resistant (*34/50*) had elevated MIC for ciprofloxacin, ranging from 0.135 to 0.91 µg/mL (average 0.25 ± 0.11 µg/mL) RSC. Only 2 isolates were multi drug resistant (simultaneous resistance of bacteria to chloramphenicol, ampicillin and trimethoprim-sulfamethoxazole) in this study. No mortality in the study group. Mean duration of hospital stay was 6.5$\pm$ 3days. Mean defervescence time after initiation of antibiotic therapy in ceftriaxone treated group (36/50) was mean 4.5+2 days and ciprofloxacin (14/50) treated group was 5$\pm$3 days.

Table -1, showing antibiotic sensitivity pattern

Antibiotics	Sensitive N=50	Intermediate	Resistant
chloramphenicol;	46(92%)	1(2%)	3(6%)
ampicillin;	45(90%)	3(6%)	2(4%)
ceftriaxone;	50(100%)	0	0
ciprofloxacin;	34(68%)	14(28%)	2(4%)
trimethoprim-sulfamethoxazole	40(80%)	5(10%)	5(10%)
nalidixic acid;	4(8%)	12(24%)	34(68%)
multidrug resistance	-	-	2(4%)

Discussion

Typhoid fever is endemic in most parts of the India and it remains a major public health problem in many similar developing countries. This organism is highly adaptable and has remarkable mechanisms of survival and transmission in the host (12). Growing drug resistance is an important factor in the morbidity and mortality of the typhoid fever. Reports from different parts of India documented an increasing resistance of *S*. Typhi strains to commonly used first line drugs especially ciprofloxacillin (13, 14, 15). The resistance pattern varies with geographical locations. This study was done in tertiary care teaching hospital Coimbatore, India.

All the isolates in our study were sensitive to ceftriaxone in contrast to the recent studies (16, 17) that recorded resistance to ceftriaxone. Nalidixic acid sensitivity has been validated as a screening test for susceptibility to ciprofloxacin. High level of nalidixic acid resistance is associated with a high MIC of ciprofloxacin, which is associated with treatment failure(18,19). In this present study, 34of 50 isolates were nalidixic acid resistant and were associated increased resistance to ciprofloxacin. The fluoroquinolones resistance is said to be due to altered DNA gyrase sub-unit but, recently plasmid-mediated resistance pattern has also been reported (20). In developing countries such as India, ciprofloxacin continues to be the mainstay in the treatment of typhoid fever as it is orally effective and economical.

The emergence of ciprofloxacin resistance is a concern in many developing countries. There is no significant difference in response to fever in children treated with ceftriaxone and ciprofloxacillin in this study. Only 4% multidrug resistant isolates in this region is notable. This study has few limitations. As it was small hospitals based study, these findings may not truly reflect the sensitivity pattern in the community. Despite the fact that multi drug resistance is less common, high level of nalidixic acid resistance and elevated MIC for fluoroquinolones in the pediatric age group warrants rational prescription of antibiotics.

PREVALENCE OF SEROPOSITIVITY AGAINST HEPATITIS B VIRUS IN PREVIOUSLY IMMUNIZED ADOLESCENT CHILDREN

Kumaraguru Rajamani[1], Jayavardhana Arumugam[2]

[1]Resident, Department of Paediatrics, PSG Institute of Medical Sciences & Research.
[2]Associate Professor, Department of Paediatrics, PSG Institute of Medical Sciences & Research.

ABSTRACT

BACKGROUND

Less is known regarding the duration and long term protection offered by Hepatitis B vaccination and whether there is a need for booster doses of hepatitis B vaccine. This study determines the level of antibodies to Hepatitis B surface antigen and analyses the prevalence of seropositivity.

METHODS

A total of 30 children in the age group of 10-15 years were included for anti-HBs titres assessment. All were vaccinated for hepatitis B (3 doses) during infancy.

RESULTS

Only 30% of the children had anti-HBs titres in the protective range, majority are between 10 and 100 mIU/mL. Remaining 70% of the children had anti-HBs titres in the subprotective range (less than 10 mIU/mL).

CONCLUSION

This small study warrants further research on the necessity of booster doses of Hepatitis B and seroprotective levels of titres in Indian population.

HOW TO CITE THIS ARTICLE: Rajamani K, Arumugam J. Prevalence of seropositivity against hepatitis B virus in previously immunized adolescent children. J. Evid. Based Med. Healthc. 2016; 3(55), 2850-2853. DOI: 10.18410/jebmh/2016/622

INTRODUCTION: India is a country with intermediate prevalence of Hepatitis B infection. The Hepatitis B virus apart from causing a serious infection which may be fatal also causes a chronic carrier state and also increases the risk of cirrhosis and hepatocellular carcinoma.[1] The Government of India with a view to bring down the incidence of this infection has introduced the Hepatitis B vaccine in the national immunisation schedule. There are around 110 countries which have included the vaccine in their vaccination schedules. The introduction of the vaccine has brought down the incidence of the disease and also the incidence of cirrhosis and hepatocellular carcinoma.

The longterm effects of the vaccination and the need for further boosters are still under study and various studies have given a wide range of results.[2,3,4,5,6,7] While some studies say the anamnestic response is good and rule out the need for boosters,[2,4,5,6] some have come out that the anamnestic response may not be so good in all the vaccines and stresses the need for pre-vaccination testing and booster doses.[7,8] There are no studies from India in this regard. This study tries to throw light on the protectiveness and seropositivity of the Hepatitis B vaccine in the Indian children aged 10–15 years who were vaccinated with the three primary doses of the vaccine before 1 year of age. This study may be a starting point for further studies in this regard from India.

MATERIALS AND METHODS: This descriptive, hospital-based study was done at PSG Hospitals, Coimbatore, India during September 2014 to August 2015. Institutional human ethics committee approved the study. Children aged 10-15 years who had received three hepatitis B vaccination doses before one year of age and who had records of the same were recruited for the study. Since this was a pilot study a convenient sample of 30 subjects were included for final analysis from 40 recruits. Records were verified for the immunisation status and confirmed. After getting proper consent for the study from the parent and obtaining assent from the children, 3 mL of blood sample was taken and anti-HBs levels were determined by Chemiluminescence immunoassay technique. Children with history of Hepatitis B infection, Hepatitis B infection in the parents, children with chronic renal failure on dialysis, history of blood transfusion and immunocompromised children status were excluded from study. A total of 30 samples were collected for study purpose. An anti-HBs level of ≥10 mIU/mL was considered to be a protective antibody level. Children with values <10 mIU/mL were considered to have inadequate antibody titres.

DOI: 10.18410/jebmh/2016/622

Data were collected and stored in Microsoft Excel and results were given in proportions.

RESULTS: Out of the 30 subjects included in this study, 14 were males (table-1). The mean age was 12.2 years (Figure-1). Of the 30 subjects, 9 had anti-HBs levels greater than 10 mIU/mL (30%) out of which 5 had titres between 10 and 100 mIU/mL (Figure-2). These 30% are considered to be having protective titres. The rest 21 have titres less than 10 mIU/mL and are considered to have inadequate protective antibody levels (70%). One subject had a titre of 0 mIU/mL. Hence, among the study population of 30 children aged 10 to 15 years who were vaccinated for hepatitis B during infancy, only 30% had protective titres of anti-HBs antibody. Of the 9 subjects who had protective levels of anti-HBs antibody, 4 were males and 5 were females (Table 1). Of the protected, 1 was in the age group on 10–11 years, 4 between 11–12 years, one between 12–13 years, 2 between 14–15 years and one was between 15–16 years (Figure 2).

Subjects (n=30)	Anti-HBs >10 mIU/mL	Anti-HBs <10 mIU/mL
Male (n=14)	4	10
Female (n=16)	5	11

Table 1: Sex wise Distribution of Subjects and anti-HBs Titres

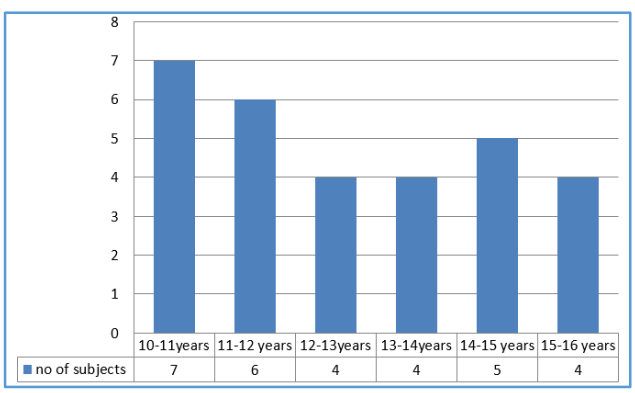

Figure 1: Age wise Distribution of Subjects

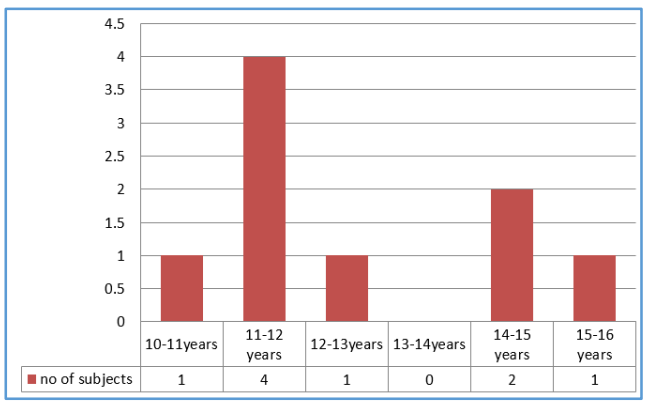

Figure 2: Age wise Distribution of Protective anti-HBs titres (>10 mIU/mL)

DISCUSSION: This study aimed at finding out the protectiveness against hepatitis B infection 10-15 years after complete vaccination and whether there is a need for further booster doses. Though there are only a very few studies available in this regard, none has come out from India. The studies from various regions have found out a variable percentage of protection by estimating the anti-HBs levels in the serum.[2,3,4,5,6,7] Since the vaccine failure has a genetic determinant also, it is necessary to know the protective levels of anti-HBs in Indian children ten years after completing the three doses of hepatitis B vaccine.

Our study has found that only 30% of the children who have completed the three doses of vaccine at infancy have protective titres of anti-HBs antibodies after 10 years of age. This is lower than the percentage of protection found in many studies.[2,4,5] Table-2 gives comparison of seroprotection against Hepatitis B across various countries.

Sl. No.	Study done by	Place	Year	Age group	Protection percentage
1	Reza Norouzirad et al	Iran	2011	1-18 years	40.10%
2	Amy B. Middleman et al	Houston	2011	16-19 years	24%
3	E. Spada et al	Italy	2014	10-17 years	60.30%
4	Hiva Saffar et al	Iran	2014	20 years	42.60%
5	Paul K. S. Chan	China	2010	17-23 years	18.90%
6	Hammitt et al	Alaska	2007	14-15 years	5%
7	Present study	India	2015	10-15 years	30%

Table 2: Seroprotection against Hepatitis B 10 years after Primary Vaccination

A study from Ahvaz city in Iran by Reza Norouzirad et al evaluated the anti-HBs levels in 840 healthy individuals in the age group between 1 and 18 years who were vaccinated during infancy.[2] The percentage of study group who had protective levels of anti-HBs (>10 mIU/mL) 1 year after vaccination was 90%. The average number of subjects having protective levels of antibody titres between 1 and 5 years was 72.1% which declined to 40.1% in the age group between 11 and 15 years. In another study among 420 healthy children aged 16 to 19 years in Houston metropolitan area by Amy B. Middleman et al, it was found that only 24% of the children had anti-HBs levels in the protective range

>10 mIU/mL.[3] But this study further checked the anamnestic response by giving one booster dose of Hepatitis B vaccine and re-checking antibody titres. 92% of children in the study group developed protective antibody titres after receiving one booster dose of the Hepatitis B vaccine. This study thus concluded that though the antibody levels were less, there was an intact immune memory which was responsible for the rapid response after receiving the booster dose of vaccination. The study also compared two groups of vaccinees – one in whom the first dose of Hepatitis B vaccine was given within 7 days and another group in whom the first dose was given after one month and found statistically significant variation in the baseline anti-HBs antibody values between the two groups with the early vaccinated group having decreased titres. This is of interest to us because many of our children are given the first dose of Hepatitis B vaccination at birth.

In a study in Italy by E. Spada et al, 571 teenagers were included and their anti-HBs levels were tested at 10 and 17 years of age.[4] 60.3% of the subjects had protective antibody levels to HBsAg. Out of the remaining 227 subjects, 199 were administered a booster dose of Hepatitis B vaccine. The protective levels of antibody were found in 72.9% subjects at 17 years which included the persons who received the booster dose of the vaccine. Out of the 155 subjects who had anti-HBs levels <10 mIU/mL, 96 were given booster dose of the vaccine to which all except two responded. The remaining two subjects received also responded after three doses of the vaccine. This study also concludes that though the antibody titres may be less, the immune response is good after a booster dose.

Saffar et al conducted a study in Iran in which 176 individuals vaccinated for Hepatitis B at infancy were administered one booster dose of Hepatitis B vaccine at 20 years of age.[5] Pre-booster anti-HBs values and the pre and post booster cytokine values were taken. It was found that only 42.6% had protective pre-booster values of anti-HBs of more than 10 mIU/mL. Among the non-protected, the cytokine values showed a two-fold increase after a booster dose in around 80% of individuals confirming preserved cells mediate immunity.

The effect of giving three doses of boosters was studied in a study conducted in China by Paul K. S. Chan which found that out of 212 students aged 17 to 23 years, only 18.9% had protective anti-HBs titres. One month after a single booster, this went up to 85.5% and after three booster doses, this number reached 100% with 97.1% having anti-HBs titres above 100 mIU/mL.[6] This study demonstrates a declining immune memory in a substantial group of individuals and the requirement of three doses of booster vaccination to achieve protective antibody titres. This study recommends pre-booster testing of anti-HBs titres and vaccinate accordingly.

These studies give a wide range of protection against Hepatitis B infection and the durability of this anamnestic response is not completely understood. A variable proportion of the vaccinated persons over a period of time lose both the protective antibody titres and the anamnestic response. The 30% protective efficacy obtained in our study is line with that obtained in many of the studies. The low levels of protection in the present study may be due to genetically determined lack of response to vaccination or due to technical errors such as intragluteal injections and inappropriate storage conditions. Some of the studies have assessed the immune memory by giving a booster dose of Hepatitis B vaccine and found that most of the subjects had a good immune memory and responded very well to a single booster dose of the vaccine.

Interestingly, there is a study from Alaska which gives a considerably lower percentage of anamnestic response. This is particularly significant since this study included a significant number of American Indians along with Alaskan natives.

One of these studies included 37 children who were vaccinated with all three primary doses of Hepatitis B before 1 year and who had documented anti-HBs titres >10 mIU/mL before 18 months of age.[7] The anti-HBs levels of these subjects were done at 14 to 15 years of age and it was found that only 5% had protective levels of anti-HBs. The subjects with anti-HBs antibody levels <10 mIU/mL were boosted with a dose of vaccine and the titres of anti-HBs rechecked after 15 days. Anamnestic response to booster dose was only 51%.

The difference in the protective titre levels of antibodies in different populations studied, the waning of anamnestic response with age in certain populations and lack of studies in the Indian population warrants further studies in this regard. Our study gives a protective level of antibodies to HBs in only 30% of the studied subjects who completed three doses of Hepatitis B vaccine before one year of age. A larger study with a larger sample and also studies assessing the anamnestic response is required in Indian population to find out the necessity of booster doses in the general Indian population.

The study also exposes the need for testing anti-HBs titres and the need for booster doses of vaccination. If not possible in all, at least in the more vulnerable groups like health care workers and contacts of HBsAg positive individuals. First of this kind of study among south Indian population, estimating the protectiveness and seropositivity of the Hepatitis B vaccine is the major strength of this study. No estimation of HBsAg antigens and core antibodies levels and small number of subjects were limitations of the study.

ABSTRACT

BACKGROUND

Recent advances in perinatology have resulted in increased survival rate of preterm infants over the past two decades. Sensorineural hearing loss represent one of the serious neurodevelopmental sequelae among preterm infants. Brainstem Auditory Evoked Responses (BAER) is a noninvasive electrophysiological method for assessing the maturation of auditory system in newborn.

MATERIALS AND METHODS

Brainstem auditory evoked responses of 70 infants (35 preterm and 35 term) were recorded to analyse the impact of prematurity. Absolute latency and interpeak latencies were recorded using "Intelligent Hearing System Smart-EP". Student's t-test was used for statistical analysis.

RESULTS

The absolute latencies I, III, V and interpeak I-III, I-V were significantly prolonged among preterm babies (P value <0.05). There was a significant increase in absolute latencies I, III, V and IPL I-III among preterm babies with comorbidities (P value <0.05). Such difference in latencies was not seen among term babies with comorbidities.

CONCLUSION

Hence, it may be worthwhile to perform BAER recording in preterm babies and all babies with comorbid conditions to identify hearing abnormities at the earliest.

HOW TO CITE THIS ARTICLE: Aghil RB, Jayavardhana A. The impact of prematurity on infant brainstem auditory evoked responses. J. Evid. Based Med. Healthc 2016; 3(91): 4950-4953. DOI: 10.18410/jebmh/2016/1042

BACKGROUND

In India, around 8 million Low Birth Weight (LBW) infants are born each year.[1] The LBW infants include both preterm babies and Intrauterine Growth Retardation (IUGR) babies. Recent advances in perinatal care have resulted in increased survival rates of preterm infants. However, the preterm infants are at risk of developing several immaturity related problems. Sensorineural hearing loss represents one of the serious neurodevelopmental disorder among the high-risk newborns. The incidence is ten times higher in preterm babies than the overall incidence of 1 to 3 per 1000 live births in normal babies.[2] This undetected hearing loss can result in serious impairment in language and communication skills, cognitive development, social and emotional development. Number of methods have been evaluated to search for reliable and effective technique for determining auditory functions in the neonates. Brainstem Auditory Evoked Responses (BAER) records potentials from the ear and vertex in response to brief auditory stimulation. BAER is one of the noninvasive electrophysiological method in clinical practice to detect neonatal deafness.[3] The BAER is the best tool available to assess the hearing impairments in infants.

BAER depicts the conduction along the brain stem auditory pathway; hence, comparison of auditory evoked responses of preterm infants with term infants is expected to provide insights about the maturational-related response changes during neonatal period and pathological changes due to associated comorbid conditions.

AIMS AND OBJECTIVES

This study aimed at analysing the impact of prematurity and its comorbid conditions on infant brainstem auditory evoked responses. The objectives were to record brainstem auditory evoked responses of preterm and term infants with or without comorbid conditions.

MATERIALS AND METHODS

This prospective observational study was conducted in a Tertiary Care Teaching Hospital, Coimbatore. A total of 70 infants were included in the study of which 35 were preterm infants and 35 were term infants.

Inclusion Criteria

All the infants were selected from high-risk infant follow up clinic and Well-Baby Clinic. Preterm infants who have completed the post conceptional age of 40 weeks to 3 months of life and term infants up to 3 months of age were included.

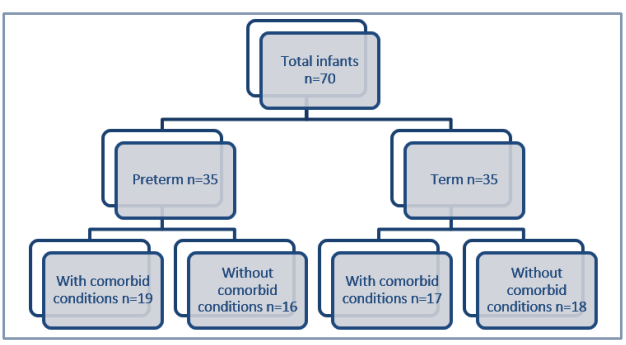
Exclusion Criteria

Babies with family history of hearing loss, ear malformations and syndromic conditions were not included. Both preterm and term group were further divided into two subgroups based on the presence and absence of comorbidities.

The comorbid conditions in preterm included those babies who suffered from Respiratory Distress Syndrome, Neonatal Jaundice, Birth Asphyxia and Sepsis. All babies with comorbid conditions were treated in neonatal intensive care unit at Coimbatore Medical College as per the standard protocols by neonatologists. Similarly, term group babies were further divided into two based on the presence of comorbid conditions such as sepsis, birth asphyxia, neonatal jaundice and meconium aspiration syndrome. The study was carried out after explaining the procedures in detail and getting informed written consent from the parents or caregivers of the babies. The study was approved by the Institutional Ethical Committee. Intelligent Hearing System (Florida) [Smart EP, Universal Smart box Jr.,™ Opti-Amp 8002] equipment was used for recording BAER in infants.

Procedure

The procedure was done while infant sleeping naturally, usually after a feeding. Some of the babies who had difficulty in going to sleep were given the sedative promethazine orally of dose 0.5 mg/kg body weight. The babies were made to lie comfortably on his or her mother's or grandmother's lap while doing the recording. The recording was made in the sound proof BAER recording room. The skin at the site of placement of surface electrode was prepared well. The conducting gel was applied and the surface electrodes were fixed at appropriate sites with the help of adhesive plasters.



Site of placement of surface electrodes include active electrode on forehead reference electrode over the right (M1) and left (M2) mastoid processes and ground electrode on the cheek. At all the above sites, the impedance was kept below 5W. The earpiece was inserted into the corresponding ear (right or left) of infants while recording. Each ear was tested separately. The acoustic stimuli were given in the form of broadband clicks. The restriction filters were set between 100-3000 Hz. A total of 2000 stimuli were given with the repetition rate of 10 stimuli/seconds. The analysis window was 10 milliseconds. Each recording was made in duplicate to ensure reproducibility. Every time when the acoustic stimuli was given, the auditory system in the infant generated an electrical response. These evoked responses were detected by the surface electrodes. The recordings were analysed by the equipment Intelligent Hearing System and recorded as waveforms. The absolute latencies of the BAER waveforms I, III, V and the interpeak latencies I-III, III-V, I-V were marked and the values were noted down.

Statistical Analysis

Independent t-test has been used for intergroup and subgroup comparison of the BAER parameters. Statistical software SPSS 17 version was used for the analysis of the data.

RESULTS

A total of 70 infants were studied, which had 35 preterm babies and 35 term babies (flowchart-1). The mean birth weight of preterm group is 1.53 (±0.260) kg and 2.84 (±0.360) kg in term babies. The mean age was 2.03 months for preterm, 2.61 months for term (at the time of study) and sex ratio among two groups were comparable.

Flowchart 1. Depicting Study Population

The distribution of comorbid conditions such as HIE, jaundice, respiratory distress, sepsis and multiple risk factors in the study group is depicted in Table 1.

Group With Comorbidities	Comorbid Conditions				
	HIE	Jaundice	Respiratory Distress	Sepsis	Multiple Risk Factors
Term (n=17)	2	3	4	4	4
Preterm (n=19)	4	4	3	2	6

Table 1. The distribution of co-morbid conditions

Absolute latencies and interpeak latencies were compared between the two groups. To find out the impact of comorbidities, subgroup analysis was done in both term and preterm groups. The BAER parameters of preterm and term infants are depicted in Table 2 and 3.

Absolute Latency ms	Preterm Right Ear	Term Right Ear	P-value	Preterm Left Ear	Term Left Ear	P-value
I	2.02±0.35	1.73±0.23	0.000*	1.99±0.37	1.78±0.32	0.017*

Table 3. Interpeak Latency in Preterm and Term Babies

*P-value less than 0.05 is significant.

BAER waveform I, III, V latencies were significantly prolonged among preterm babies than term babies. The interpeak latencies I-III, I-V were also significantly increased in preterm infants. The associated comorbid conditions significantly altered the wave latencies in preterm babies. The absolute latencies I, III, V and IPL I-III were significantly prolonged in preterm babies with comorbidities than in those without comorbidities. Though some latencies were prolonged in term babies with comorbid conditions, it had no statistical significance. The wave latencies among preterm group are depicted in Table 4.

Absolute Latency ms	With Comorbid R	Without Comorbid R	P value	With Comorbid L	Without Comorbid L	P-value
I	2.17±0.37	1.84±0.19	0.002*	2.18±0.37	1.75±0.20	0.000*

Table 4. Preterm With and Without Comorbidities in Both Ears

DISCUSSION

This study was done to compare the BAER parameters between preterm and term infants and also to find out the impact of comorbid conditions on waveforms. A recognisable BAER waveform can be recorded in preterm infants above 28 weeks of gestation.[4] The BAER waveform I arises from peripheral part of cochlear nerve.[4] The wave III originates from superior olivary nucleus in pons whereas wave V from Inferior Colliculus in midbrain.[4] The prolongation of BAER values in this study group was comparable with earlier studies.[5,6] We found that while comparing the BAER parameters among preterm and term babies, there was a significant prolongation of absolute latencies of wave I, III, V, interpeak latencies among preterm infants. Similarly, the interpeak latencies I-III, I-V were also significantly prolonged in preterm babies, which may be due to incomplete myelination of central brainstem auditory pathway in preterm infants.[5] In a similar comparative study done by Roopakala et al have found an increase in wave V latency, which they attributed to delay in maturation of central brainstem pathway in preterm infants.[7] The maturational defects in preterm infants they attributed are incomplete myelination of auditory nerves and pathway, decrease in axonal diameter, immaturity of neuronal synapses.[4] There is no sex difference in values in this present study as seen in many earlier studies except one from Pakistan by Shahid et al,[8] which suggested that high-risk male infants were more prone for auditory defects.[8] There is no significant BAER parameters difference between right and left ears in this study as observed in earlier studies.[5,9]

It has been found in our study that the association with comorbid conditions caused significant increase in all the absolute latencies I, III, V and IPL I-III in preterm infants. This impact of comorbidities on BAER waveforms was not present among term babies. This was probably due to prolonged exposure to extrauterine high-risk environmental conditions in preterm infants.[10,11] Babies who suffered from birth asphyxia and/or respiratory distress are exposed to prolonged periods of hypoxia, which may affect the myelination process. Studies conducted in animals have found that cochlear hair cells are sensitive to hypoxia.[12]

A study done by Agarwal among normal babies and babies with neonatal jaundice have found prolonged

absolute and interpeak latencies among 25% of the study group. The bilirubin specifically causes damage to the cell bodies of auditory nerve in spiral ganglion, brainstem cochlear nuclei.[12] These abnormalities had significant correlation with total bilirubin level.[13]

Neonatal sepsis and its related conditions like meningitis, ototoxic medications [aminoglycosides] may also lead to sensorineural hearing loss. These effects were demonstrated by Sun JH et al in a study among 248 infants using BAER.[14] The cytokines and toxin released during sepsis may cause damage to the developing auditory system.[15] Dowley et al noticed that neonatal sepsis was significantly associated with auditory neuropathy among high-risk newborn babies.[15] This impact of comorbidities is not seen in term infants and much of the changes in them are reversible.[16] Further evaluation of interaction between risk factors and neonatal hearing loss is warranted to implement more time weighted measures.

CONCLUSION

In this study, the brainstem evoked responses were found to be significantly prolonged among the preterm infants when compared to term infants. The associated comorbid conditions had great impact on the BAER latencies among preterm infants, but not in term infants. Regular follow up services should be done to assess the auditory maturation in such high-risk infants.

ABSTRACT

Introduction

Community acquired Methicillin-resistant Staphylococcus aureus (CA-MRSA) isolates are increasingly reported in many countries. Local epidemiological data are sparse.

Objective

To determine the frequency, clinical features, antibiotic sensitivity and outcome of infections caused by Community acquired Methicillin-resistant Staphylococcus aureus among children in a territory care teaching hospital, Coimbatore (south India)

Material and methods

Children(less than 15 years) with infections meeting the criteria of community-acquired were included. Demographic and clinical data were collected. Antibiotic susceptibilities were determined in the microbiology laboratory.

Results

The prevalence of CA-MRSA was around 35% among MRSA isolates. Skin and subcutaneous infections were the most common site (74%). All isolates were 100% sensitive to Vancomycin, Linezolid and Doxycycline. Drugs with poor sensitivity (< 5%) were Cefazolin, Penicillin, Ampicillin and Ceftriaxone. All cases except one recovered completely.

Conclusion

CA-MRSA isolates accounted for a high percentage of infections among Staphylococcus aureus in children. Community surveillance of these infections is essential to decide the appropriate empiric antibiotic treatment.

Introduction

Infections caused by Staphylococcus aureus, especially methicillin-resistant S. aureus (MRSA), are emerging as a major public health issue[1]. Methicillin-resistance of Staphylococcus aureus infections is reported to be a nosocomial origin[2]. Recent reports suggest that the epidemiology of MRSA is changing and community acquired methicillin resistance(CA-MRSA) is on the rise[3]. The risk factors for acquisition of MRSA are intensive care unit stay, prolonged hospitalization, severe chronic illness, invasive procedures, indwelling devices and long term antibiotics therapy[4,5]. The first case of community acquired methicillin resistant (CA-MRSA) in children was reported in 1988[6]. The emergence of MRSA as a cause of infection in the community in patients who have never been hospitalized and who have no other known risk factors for MRSA infection is a significant concern. Recent studies from India also confirmed the prevalence of CA- MRSA[7,8,9]. In this context we conducted a study on community acquired methicillin resistance in Staphylococcal aureus infections in Coimbatore children.

MATERIALS AND METHODS

This Indian council of medical research (ICMR) - STS funded study was conducted in Department pediatrics , PSGIMS&R, Coimbatore. The Institutional Human Ethics Committee has approved the study protocol and written informed consent was obtained. All children aged less than 15 years with any culture (pus or blood) positive for MRSA is included for analysis. MRSA identification and antimicrobial drug susceptibility was done in department of microbiology (NABH accredited laboratory) at PSG hospitals. The probable reasons for the methicillin resistance were analyzed clinically. Data extracted from the case records included demographics, Information on close contacts, infection type, culture site, antibiotic susceptibility, treatment, interventions, outcome and presence of risk factors for methicillin resistance. The duration of study period was one year (2011).

The infection is considered community acquired MRSA if the patient met all the following criteria.

1. The sample for culture is obtained during an outpatient visit or within 48 hrs of hospitalization.
2. The subject had no history within the past year of known risk factors for MRSA, including hospital admission, current intravenous drug use, surgery, dialysis, an indwelling catheter, or a percutaneous medical device.

Culture method

The samples were streaked on Blood and Mac-conkey agar. The plates were read after an incubation of 24 hours at 37 degree Celsius. The colonies suspected to be staphylococcus were subjected to catalase test, tube coagulase, mannitol fermentation, bacitracin and furazolidone sensitivity. Antibiotic susceptibility is tested on Muller Hinton agar by making lawn culture. The antibiotics tested were Cefoxitin, Erythromycin, Clindamycin, Co-trimoxole, Ciprofloxacin, Vancomycin, Linezolid, Gentamicin, Doxycycline, Rifampicin, Furazolidone, Novobiocin and Penicillin. All Staphylococcus species are catalase positive, furazolidone sensitive and bacitracin resistant. Those that are tube coagulase positive and mannitol positive are considered as S.aureus. The S.aureus those are resistant to Cefoxitin in zone size less than 22mm are considered as MRSA in this study.

Descriptive statistics were used in this study.

Results

Patient characteristics: During the one year period 290 cultures were positive for staphylococcus aureus including colonization. Of the 290 cultures, 140 isolates were MRSA infections. Among the 140 cases, 50 were identified as CA-

Volume : 4 | Issue : 2 | Feb 2014 | ISSN - 2249-555X

MRSA and included for final analysis. The remaining 90 cases had one or more risk factors for methicillin resistance. There were 32 boys and 18 girls (sex ratio: 1.78:1) in the final study group. The median age was 3.6 years. All children were from Coimbatore region and they had no identifiable risk factors for methicillin resistance. About the sites of isolation, 20 isolates from pus, 21 from blood and in 9 cases staphylococcus aureus was isolated from both.

Clinical presentation: Localized Skin infections were the most common sites of infection, accounting for 74% (37/50) of CA-MRSA infections. Septic arthritis (4/50) and lung infections (4/50) were involved in 16 % of cases. Scalded skin syndrome in 3 (6%) cases. Osteomyelitis and toxic shock syndrome contributed each case(2%). The other non specific symptoms observed were fever (26/50),vomiting (8/50),diarrhoea (7/50) and septic shock in one case.

Antimicrobial susceptibility: all isolates were 100% sensitive to Vancomycin, Linezolid and Doxycycline (Table-1). The drugs such as Rifampin, Ciprofloxacin, Cephalothin and Clindamycin had sensitivity around 80-90% of the tested isolates. The sensitivity rate was around 55-65 % for the following drugs Co-trimoxazole, Cloxacillin, Gentamycin and Erythromycin. Drugs had poor sensitivity were Cefazolin, Penicillin, Ampicillin and Ceftriaxone.

Outcome: All but one patient recovered without any major complications. The one patient who had toxic shock syndrome died of multi-organ dysfunction syndrome. Patients with skin and soft tissue infections were treated with topical mupiroicin and oral cloxacillin and erythromycin. Those who had systemic infections were treated with either vancomycin or linezolid.

Discussion

Our study revealed CA- MRSA infections in previously healthy children without known risk factors for MRSA infection in a territory care hospital in south India. In this study among the MRSA isolates 35% of cases were community acquired as those case did not have any risk factors for nosocomial spread. The overall prevalence among all Staphylococcus aureus infections was 17 % in children. MRSA is now endemic in many parts of India. The incidence of MRSA varies from 25 per cent in western part of India to 50 per cent in South India[10]. CA-MRSA has been increasingly reported from India[11]. Clinically, CA-MRSA usually causes skin and soft tissue infection, often with abscess and furuncle formation. However, it can cause serious life-threatening conditions, which in addition to necrotizing pneumonia include necrotizing fasciitis, joint infections bloodstream infection, and septic shock[12,13]. CA-MRSA may arise in either of 2 ways: hospital strains may be carried into the community, where they then spread person to person, or community MRSA may arise de novo when the methicillin-resistance gene complex is acquired by a methicillin-susceptible strain [14]. CA-MRSA strains were recognized as a novel pathogen that is genetically different from healthcare-associated MRSA with regard to genetic resistance determinants [14]. The genetic resistance determinants are mobile staphylococcal cassette chromosome mec type IV, and certain virulence factors, such as the Panton-Valentine leukocidin. Panton-Valentine leukocidin-positive S. aureus strains have been associated with severe SSTIs and pulmonary infections [15]. In this study we have done only risk factors analysis for Methicillin resistance. We could not do molecular analysis of MRSA isolates to determine their genotypes due to various reasons. In our study all the isolates were 100% sensitive for Vancomycin, Linezolid and Doxycycline as with earlier studies[16,17]. Strains of MRSA circulating in the community generally are susceptible to a number of non beta-lactam antimicrobial agents, although resistance patterns may vary temporally and geographically[17]. Antibiotic choice is more crucial for management of these infections and should be guided by the prevalence rate and its antibiotic susceptibility profile in the community[17,18].

Conclusion

In Coimbatore city , MRSA was prevalent among pathogens of community acquired infections in children, In areas with high prevalence of methicillin resistance, even community-acquired, a glycopeptide-containing regimen should be started as initial empirical antibiotic therapy.

ABSTRACT *OBJECTIVES: This study elicited parental perception of obesity in children as well as their understanding of the risk factors and morbidity associated.*

METHODOLOGY: Parents of children aged between 2 – 15 years with body mass index (BMI) more than 85th percentile for the age and sex according to Center for Disease Control (CDC) growth charts were chosen. Informed written consent was obtained. Child's height, weight and BMI were noted. Parents were administered a self reported Questionnaire, which included items in 3 areas namely Perception and concern about child's weight, child eating behavior and issues on weight control.

RESULTS: We analyzed the responses from parents of 60 children with BMI more than 85th percentile. Sex ratio male (53%): female (47%). Mean age -10 years, Median BMI is 28. 78% of the parents perceived their child as overweight and mothers perceived better than fathers. Of the 78%, 68% were obese and 10% were overweight. Parents attributed overeating (21%), reduced physical activity including television watching (30%) and familial (11%) for the cause of obesity. Parents were aware of complications to be hypertension (27%), diabetes (19%) and cardiac problems (21%). 45% of the parents were willing to adapt life style modification recommended for their children. Parents practiced some measures (diet - 20% & exercise -29%) to reduce weight whereas 19% believed only in medical treatment. Despite the awareness of obesity and its complications 21% of the parents were not taking any steps to reduce their ward's weight. Inconsistency in diet and physical activity (39%) were the common problems parents encountered while controlling child's weight.29% of the parents believed it is mother's responsibility to reduce child's weight and only 16% of the parents understood that it is a team effort involving parents, doctors and children.

CONCLUSION: Though 3/4th of the parents were aware about their child's overweight and the complications, their attitude and practices towards weight reduction were limited. As parents play a crucial role in preventing childhood obesity, education and motivation of the parents through family health education is essential.

Introduction

Obesity is one of the most prevalent forms of malnutrition. As a chronic disease, it is prevalent in both developed and developing countries and affecting children as well as adults. It is now so common that it is replacing the major traditional public health concerns including under nutrition.

The World Health Organization (WHO) estimates globally over 40 million under 5 children are overweight in 2011[1]. The International Obesity Task Force review of obesity in children and young people has documented the rise in prevalence of overweight and obesity from 102 countries using their own conservative definitions. The latest survey in India was conducted during 2007-2008 revealed that: 15.2 percent of boys and 14.4 percent of girls were overweight,5.4 percent of boys and 3.9 percent of girls (aged 2-17) were obese.[2] The same trend is noted in globally also: 32% were overweight in the Americas, including 8% who were obese; the corresponding prevalence was 20% and 4% in Europe; 16% and 6% in the Near and Middle East; and 5% and 1% in the Asia-Pacific region.[2]

A recent study conducted among 24,000 school children in south India showed that the proportion of overweight children increased from 4.94 percent of the total students in 2003 to 6.57 percent in 2005 demonstrating the time trend of this rapidly growing epidemic. At least 30% of obesity begins in childhood. Childhood obesity itself a predictor of adult obesity and morbidities due to it[4]. In children, a life style behavior which contributes to and perpetuates obesity is more open to change. Early reorganization and adequate treatment of this will prevent the globalization of obesity. Intervening with families is significant as parents play a crucial role in bringing a change. Therefore it is important to know the parental views about childhood obesity, their knowledge levels on obesogenic factors, complications and management. It is also beneficial for families with overweight children to seek professional help on time.

There have been a number of surveys[5-9] addressing attitudes and practices towards childhood obesity in western populations. However, studies related to parental attitudes and practices towards childhood in Indian population is lacking. Since the attitudes towards children are likely to be very different compared with adults, their management also varies. So we designed and conducted a study in our pediatric unit, on children of Body Mass Index (BMI) more than 85th percentile to assess the parental perception of their obesity.

Materials and methods

This Prospective cross sectional study was done in PSG hospitals Coimbatore. Parents of children aged between 2 – 15 years with body mass index (BMI) more than 85th percentile for the age and sex according to Center for Disease Control (CDC) growth charts were chosen. Child with obesity due to any known risk factors like drugs and syndromes were excluded. Informed written consent was obtained. Child's height, weight and BMI were noted. Parents were administered a self reported Questionnaire, which included items in 3 areas namely Perception and concern about child's weight, child eating behavior and issues on weight control. Descriptive statistics were used in this study.

Results

We analyzed the responses from parents of 60 children with BMI more than 85th percentile. The Sex ratio: males (53%): females (47%). Mean age -10 years, Median BMI is 28. Of the 60 children 54 were obese and 6 were overweight. The correct perception rate was 78% (either of the parents or care givers). The correct perception rate was more in mothers(46%) than fathers(27%).

Volume : 4 | Issue : 3 | Mar 2014 | ISSN - 2249-555X

Table – 1 shows perception rate .

S.no	Category	Father	Mother	Others
1.	Perceived child's overweight correctly (78%)	27%	46%	5%
2.	Not perceived correctly (22%)	5%	17%	0%

The BMI results in percentage among the study population were shown in Table-2.

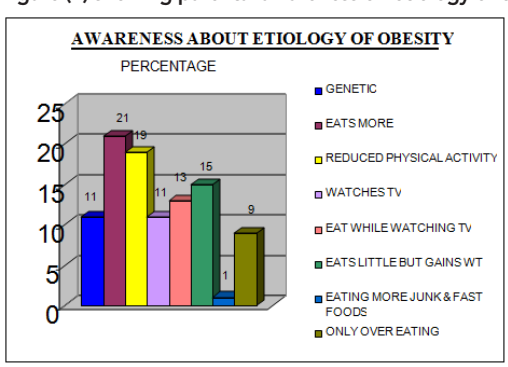

Table (2) showing the BMI results among the study population: (n=60)

S. no	Category	Obese	Overweight
1.	BMI of the children who are perceived correctly by their parents (78%)	68%	10%
2.	BMI of the children who are not perceived correctly by their parents (22%)	22%	0%

Knowledge about etiology

We studied about parent's/care givers knowledge about etiological factors for obesity in children. 10% of the respondents stated that only overeating causes obesity in children. Remaining was aware that more than one risk factor for causing obesity. 11% of the participants attributed obesity to genetic factors.

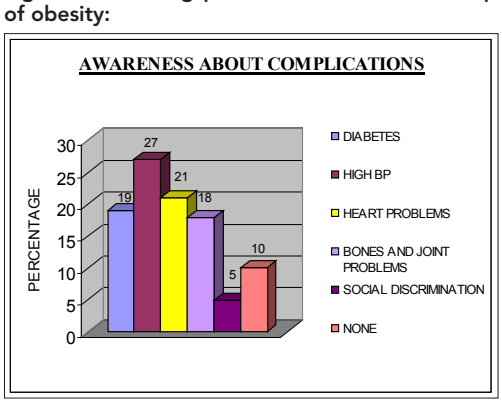

Figure (1) showing parental awareness on etiology of obesity:

Complications of obesity

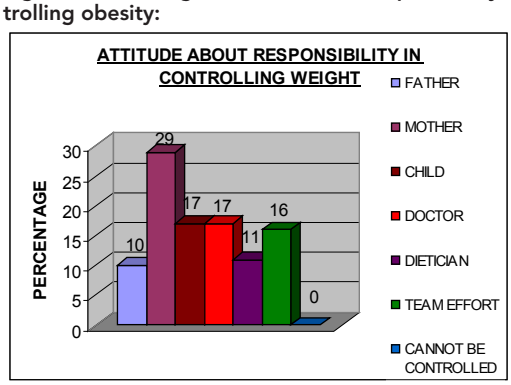
When enquired about the complications of obesity in children, many were aware the common complication such as diabetes (19%), hypertension (27%), cardiac problems (18%). 10 % of the participants said that there was no major complications related to obesity (figure-2). Only 20% of parents were aware that their child can become obese adult in future.

Figure -2, showing parental awareness on complications of obesity:

Measures taken to reduce obesity

We evaluated the participant's attitude towards preventing obesity. None said that child's weight cannot be controlled and most of them thinks that it is mother's (29%) responsibility to control weight (figure-3). 16 % of participants felt that it is a team effort. While attempting to reduce their ward's weight 74% of participants encountered some difficulties. Consistently controlling the diet (39%) was the most difficult task, followed by restriction of television watching(32%) and increasing physical activity(25%). 10 % of parents felt that even after following physicians recommendations there was no significant improvement in weight reduction. 17% felt that child itself also has responsibility in weight reduction. However, 55% of the parents think that it gives good results if they follow the lifestyle changes recommended for children.

Figure -3, showing the attitude on responsibility in controlling obesity:



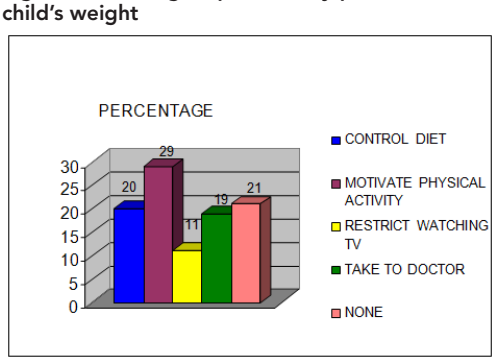


Figure -4 showing steps taken by parents to reduce their child's weight

Discussion

Obesity in children and adolescents is a serious issue with many health and social consequences that often continue into adulthood. Implementing prevention programs and getting a better understanding of treatment for children is important to controlling the obesity epidemic. Many parents are rightly concerned about their child's weight and how it affects them. They look for specific answers for prevention and treatment options. Unfortunately, the state of the science is a lot less precise than we would like. The first and foremost step in preventing obesity is early recognition of it among parents. The parents should acknowledge obesity in their wards for optimal control measures.

In children, the normal range for BMI changes with age and gender. We used the Centers for Disease Control (CDC)[10] definition; a child whose BMI is between the 85th and 95th percentile for age as being "at risk" for obesity. A child who has a BMI at or above the 95th percentile for age is considered obese.

In our study, about 78% of the parents were aware their child was overweight and mothers perceived better than others. 74% are taking steps to control weight. These results are in

Volume : 4 | Issue : 3 | Mar 2014 | ISSN - 2249-555X

contrary with earlier studies [6,7,8] where about only 1/4th of obese children were perceived correctly. The high level of correct perception may be due to the sample selection as samples taken from a territory care teaching hospital. Routine nutritional assessment could have sensitized the parents. Among 22% parents those who have not perceived correctly, all children were obese. The inability to recognize it clearly reflects their reluctant to acknowledge concern for their obese children.. This is because overweight children are identified as healthier and better nourished and perceived as "better eaters. It also carries the risk of perceiving overweight child as normal and normal weight child as underweight child. BMI results showed obese children are perceived more correctly than overweight children. Our study findings also showed parents are aware of eating behavior and reduced physical activity. But they fail to recognize junk food and fast foods as a factor which also contributes to obesity.

Complications are well known to them mainly as hypertension and cardiac problems than other problems. Unfortunately 10% were not aware of complications. Most of them think its mothers responsibility to control weight and only 15% have understood it is a team effort of all involving parents, children, doctor and dietician. The parents are taking measures like motivating physical activity, control diet and restrict watching television to reduce their child's weight. Parents are the most important role models for children. Half of the parents are ready to adapt the life style changes recommended for their children as they think it will give better results. 25% of the parents are not facing any problem in reducing weight whereas 40% of them are encountering inconsistency in maintaining diet as the major problem.

Teaching healthy behaviors at a young age is important since change becomes more difficult with age. Behaviors involving physical activity and nutrition are the cornerstone of preventing obesity in children and adolescents[11]. Families and schools are the two most critical links in providing the foundation for those behaviors.

An important part of treating obesity among children and adolescents is for parents and healthcare professionals. Health care professionals' lack of attention to weight related concerns in childhood may be contributing to parental misperceptions of children's weight status. Involvement of the entire family is also a motivating factor. Weight control programs that involve both parents and the child have shown improvement in long-term effectiveness compared to directing the program only to the child [11]. This study has following limitations;1. Small sample size, 2. Not a community based study, 3.parents educational status were taken for analysis

Conflicts of interest: none
Data collection was sponsored by ICMR(STS –study).

ABSTRACT

Background: An association between rotavirus vaccination and intussusception has been documented in post-licensure studies in some countries. We evaluated the risk of intussusception associated with monovalent rotavirus vaccine (Rotavac) administered at 6, 10 and 14 weeks of age in India.

Methods: Active prospective surveillance for intussusception was conducted at 22 hospitals across 16 states from April 2016 through September 2017. Data on demography, clinical features and vaccination were documented. Age-adjusted relative incidence for 1–7, 8–21, and 1–21 days after rotavirus vaccination in children aged 28–364 days at intussusception onset was estimated using the self-controlled case-series (SCCS) method. Only Brighton Collaboration level 1 cases were included.

Results: Out of 670 children aged 2–23 months with intussusception, 311 (46.4%) children were aged 28–364 days with confirmed vaccination status. Out of these, 52 intussusception cases with confirmed receipt of RVV were included in the SCCS analysis. No intussusception case was observed within 21 days of dose 1. Only one case occurred during 8–21 days after the dose 2. Post-dose 3, two cases in 1–7 days and 7 cases during 8–21 days period were observed. There was no increased risk of intussusception during 1–7 days after the doses 1 and 2 (zero cases observed) or dose 3 (relative incidence [RI], 1.71 [95% confidence interval {CI} 0.0–5.11]). Similarly, no increased risk during 8–21 days after the dose 1 (zero cases observed), dose 2 (RI, 0.71 [95% CI, 0.0–3.28]) or dose 3 (RI, 2.52 [95% CI, 0.78–5.61]). The results were similar for 1–21 day periods after the doses separately or pooled.

Conclusions: The risk of intussusception during the first 21 days after any dose of rotavirus vaccine (Rotavac) was not higher among the Indian infants than the background risk, based on limited SCCS analysis of 52 children.

1. Introduction

To prevent diarrhoea related deaths, 107 countries (103 nationally and 4 sub-nationally) have introduced rotavirus vaccine (RVV) into their national immunization program (NIP) as of April 2020 [1]. The impact of RVV on the illness episodes, hospitalisations and deaths due to rotavirus and all-cause diarrhoeas has been documented from post-licensure studies from various countries [2–5].

Following the increased risk of intussusception documented with the first licensed rotavirus vaccine (RotaShield™, Wyeth-Lederle Laboratories) [6] and its withdrawal, all the clinical trials of RVV captured intussusception as an adverse event. No increased risk of intussusception was observed in large scale multicountry clinical trials of two RVVs (Rotarix™, RV1; GlaxoSmithKline Biologicals and RotaTeq™, RV5; Merck & Co, Inc) [7,8]. However, several postlicensure studies have identified some increased risk of intussusception during 1–7 days after the first (relative risk, RR: 5.3–9.9) and second (RR: 1.3–2.8) doses of these two RVVs in different countries (Mexico, Brazil, Australia, the United Kingdom, and the United States) [9–11,13,14]. Notably, the impact of RVV on morbidity and mortality outweigh the risk of intussusception and associated mortality [15].

Intussusception incidence varies widely across the countries [16]. In India, information on incidence of intussusception is lim-

Please cite this article as: , Risk of intussusception after monovalent rotavirus vaccine (Rotavac) in Indian infants: A self-controlled case series analysis, Vaccine, https://doi.org/10.1016/j.vaccine.2020.09.019

ited and it varies from 17.7 (Delhi, North India) to 254 (Vellore, South India) cases per 100,000 child-years [17]. Although the exact causes of the variation in intussusception rate remain unknown, ethnicity, dietary pattern, breastfeeding practices, gut microbial environment, and vertical transmission of rotavirus antibodies have been proposed as the possible risk factors [16].

Out of the four RVVs licensed in India, two Indian (Rotavac™, RV1-116E; Bharat Biotech and Rotasill™, RV5; Serum. Institute of India) have undergone efficacy trials in India and remaining two (Rotarix™ and RotaTeq™) were licensed based on evidence from other countries. Clinical trials of the Indian-manufactured rotavirus vaccines enrolled 6799–7500 infants each and had inadequate sample size for documenting the risk of intussusception [18,19]. Under the NIP, India introduced Rotavac™ in March 2016 and Rotasill™ in April 2018 in different states in a phased manner [20]. All four licensed vaccines are being used in private sector. In view of the variable risks of intussusception after RVV doses across the countries, it is necessary to generate evidence from the Indian context to sustain confidence of the professionals and public on the vaccine and program.

As part of the vaccine safety surveillance linked to RVV introduction in India, a nationally representative sentinel surveillance network was established. We used the self-controlled case series (SCCS) method to evaluate the risk of intussusception following Rotavac vaccination in Indian infants.

2. Methods

2.1. Study area and participating hospitals

This active prospective surveillance was conducted during April 2016 to September 2017 at 23 tertiary care hospitals across 20 cities and 17 states in India representing different regions. The list and location of these hospitals are given in Supplementary Figure SF1. These hospitals were selected through a systematic process and the study protocol has been published earlier [21].

2.2. Case recruitment and data collection

Children aged >1 month and <24 months admitted to these hospitals were screened to identify the suspected cases (any of these diagnoses: intussusception, intestinal obstruction- acute or subacute, acute abdomen, pain abdomen, abdominal distension, and blood in stool with vomiting). These suspected cases tracked for final diagnosis and confirmed intussusception cases meeting the Brighton collaboration level 1 criteria for diagnostic certainty were recruited. The cases were recruited irrespective of the immunization exposure and data availability. For the recruited cases, data on clinical features, investigations, treatment, outcome, and socio-demography were obtained from the hospital records and parent interview. Immunization data were collected from the immunization cards and a copy of which was obtained, whenever possible. An independent Case Adjudication Committee (CAC), with a paediatrician, paediatric surgeon, and radiologist as members, reviewed the documents to assign the diagnostic certainty levels, according to Brighton Collaboration criteria [22]. Independently the suspected and intussusception cases were verified from the medical records using diagnoses and/or International Classification of Diseases (ICD) codes (ICD-9/10, codes listed in Supplementary Table ST1), to identify any missed cases.

2.3. Statistical analysis

We used the SCCS method to estimate the age-adjusted relative incidence of intussusception for the periods 1–7, 8–21 and 1–21 days after each dose of the RVV among the children aged 28–364 days at onset of symptoms (primary analysis). In the SCCS method, each case acts as its own control and the frequency of the outcome (intussusception) that occurred in the exposure periods after vaccination is compared with the frequency in the unexposed period [23,24]. As no external controls are used, this method automatically controls for time-invariant confounding [25]. The SCCS has been used in several studies investigating the risk of intussusception with RVV vaccine [9–11,14,23,26–29] with the pseudo-likelihood method [30]. We limited the analysis to the first occurrences of intussusception that met the level-1 Brighton collaboration criteria and children aged 28–364 days at the onset of symptoms, considering the minimum and maximum ages at which RVV could be given in India. Days 22 days after the RVV dose till 364 days of age were considered as the control period. Onset of first compatible symptom was considered the date of intussusception onset. Cases with confirmed vaccine exposure information were included in analysis and those without vaccination card were excluded. The relative incidence (RI) for each case was calculated comparing the incidence of intussusception within the risk window with the incidence in all other observation widows using conditional Poisson regression. Because the background incidence of intussusception varies substantially by age in the first year of life, age was controlled using 14-day intervals in the model and confidence intervals (CIs) were derived by bootstrapping with 1000 iterations and all cases were included. Sensitivity analysis was done considering the admission date as the date of intussusception onset. P values < 0.05 were considered to be statistically significant and all reported P values are two-sided. Statistical analysis was performed using STATA version 15.0 (StataCorp LLC, Texas, USA).

2.4. Sample size

To detect a relative incidence of 1.75 within 1–7 days of after any of the 3 RVV doses with 80% power and 95% confidence level, the sample size needed was 220 using the signed root likelihood ratio [31].

2.5. Ethical issues

Informed written consent was obtained for all the eligible cases from parent or legal guardian before recruitment and data collection. Confidentiality in data handling was maintained. The study protocol was reviewed and approved by all the institute ethics committees of participating institutes.

3. Results

A total of 670 children aged >1 month and <24 months with intussusception were recruited at these study sites. Among these, 420 (62.7%) children were aged 28–364 days. Out of the infants, 86.4% (364/420) had vaccine exposure information and 80.5% (338/420) had the first episode of intussusception. The 27 (4%) children who resolved with conservative management (i.e. no radiologic or surgical intervention) were excluded. The 19 (2.8%) children who received either Rotarix™ or Rotateq™ were also excluded. Thus data for 311 children (52 with and 259 without RVV) were analysed. The Fig. 1 shows the selection of cases for SCCS analysis.

There were no significant differences in the age at onset of symptoms, gender and interval between the onset and hospitalisation between the cases included in analysis and excluded (Supplementary Table ST2). The median age of cases was 28 weeks (interquartile range [IQR], 22–35 weeks) and 68.2% were boys (Supplementary Table ST2). Vomiting (78.8%), blood in stool (71.1%), excessive crying (62.4%) and abdominal pain (49.8%) were

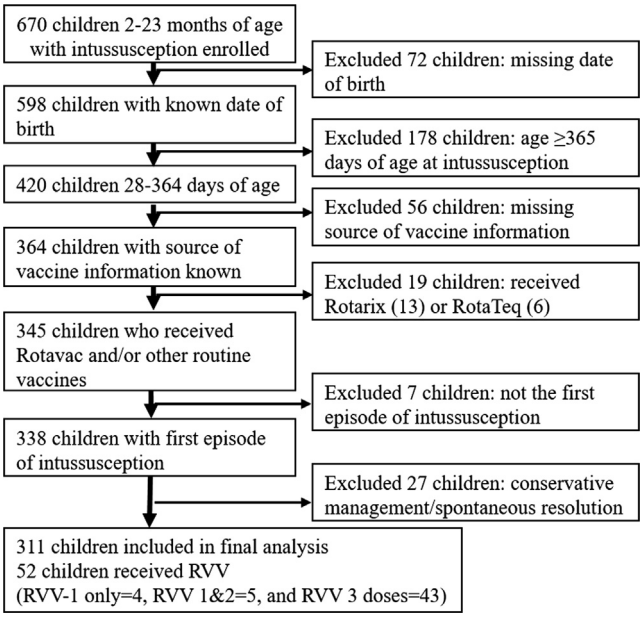

Fig. 1. Flow of case selection for the self-controlled case series analysis. *Note: RVV: Rotavirus vaccine.*

the commonest presenting features (Supplementary Table ST3). The median interval between onset of symptoms and hospitalization was 3-days (IQR, 2–6 days). Overall, RVV was received by 52 (16.7%) cases including three doses by 43, two doses by 5 and one dose by 4 cases. Among the 53 cases recruited from the five sites from states in Phase-1 RVV national introduction, 34 (64.1%) received RVV-1. Out of the 258 children recruited from the 15 sites in the states without RVV in the NIP, 18 (7%) received RVV-1. The median ages at intussusception were comparable for the children who received RVV (26.5 weeks; IQR 19.5–32.5 weeks) and who did not receive (28 weeks; IQR 22–36 weeks) (Supplementary Table ST5). The median ages of vaccination in children with and without RVV were comparable; dose 1 (with RVV: median age 7.1 weeks, IQR 6.6–8.8 weeks and without RVV: median age 7 weeks, IQR 6.6–8.4 weeks), dose 2 (with RVV: median age 12 weeks, IQR 11.3–13.8 weeks and without RVV: median age 12.3 weeks, IQR 11.3–14.1 weeks) and dose 3 (with RVV: median age 16.6 weeks, IQR 15.7–18.3 weeks and without RVV: median age 17.1 weeks, IQR 16–19.1 weeks). The Fig. 2 shows the ages at vaccination for the children with RVV and the ages of vaccination for children without RVV is given as Supplementary Figure SF2. There was no significant difference in the characteristics between the children who did or didn't receive RVV (Supplementary Table ST5).

After the first RVV dose, no case of intussusception was observed during the 1–7 days and 8–21 days risk periods (Fig. 3A). After the second RVV dose, no case of intussusception during the 1–7 days and one case during 8–21 days risk periods were observed (Fig. 3B). After the third RVV dose, two cases of intussusception during the 1–7 days and seven cases during 8–21 days risk periods were observed (Fig. 3C). One case occurred on day zero after RVV dose 3.

Table 1 shows the RI estimates using the date of symptom onset (primary analysis) and date of admission (sensitivity analysis) for intussusception in different risk periods (1–7 days or 8–21 days or 1–21 days) after the RVV doses compared to the background risk. There was no increased risk of intussusception during 1–7 days after the first and second doses (no cases observed) or third dose (relative incidence, RI, 1.03; 95% CI 0–5.11) of RVV. Similarly, no increased risk of intussusception was observed during 8–21 risk period after the first dose (no case observed), second dose (RI 0.71; 95% CI 0–3.28) and third dose (RI 2.52; 95% CI 0.78–5.61) of RVV. There was no increased risk of intussusception observed for any RVV dose at pooled level for 1–7, 8–21 and 1–21 days risk periods.

4. Discussion

This study was conducted at 20 sites as part of the vaccine safety surveillance linked to rotavirus vaccine introduction. Out of the 20 sites, five sites were in the states where the RVV was introduced in Phase-1 of the national introduction. According to the WHO and UNICEF estimates of immunization coverage using the administrative report for 2017, the RVV (Rotavac™) coverage in these Phase-1 states was 69% [32]. The RVV coverage (64.1%) among the study subjects from the study sites in Phase-1 states was comparable to the administrative coverage data. Out of the

Notes: Among children aged 28–364 days; Risk period is number of days prior to the reference date; IS: Intussusception; RI: Relative Incidence.
* Using the symptom onset date for calculating the risk periods.
** Using the admission date as onset of intussusception for calculating the risk periods.
@ 95% confidence intervals bootstrapped with 1000 iterations.

258 children recruited from other 15 sites (from the states without RVV in the NIP), 18 (7%) children received RVV. We did not observe an increased risk of intussusception after any of the doses of the monovalent 116E RVV (Rotavac™) in Indian infants. No clustering of the intussusception cases in either 1–7 days or 8–21 days or 1–21 days risk windows after any RVV doses was observed. However, the study was under powered due to the low number of intussusception cases having received RVV (n = 52).

Our results are comparable to the reports of intussusception after RV1 (Rotarix™) vaccination in several African countries (Ethiopia, Ghana, Kenya, Malawi, Tanzania, Zambia, Zimbabwe and South Africa), where no increased risk of intussusception after any dose of RV1 were observed [23,28]. However, increased risks of intussusception were documented in the 1–7 days following dose 2 of RV1 in Brazil (IR 2.6; 95% CI 1.3–5.2; OR 1.9; 95% CI 1.1–3.4) and after dose 2 (IR 5.3; 95% CI 3.0–9.3 and OR 5.8; 95% CI 2.6–13) and dose 1 (IR 6.49; 95% CI 4.17–10.09) in Mexico [9,10]. Similarly, increased risks of intussusception were documented in high income countries, United States (first dose, RR 7–8.8; second dose, RR 1.8–8.1), United Kingdom (first dose, RR 13.8; second dose, RR 2.2), and Australia (first dose, RR 6.8; second dose, RR 2.8) in the 1–7 day period with RV1 vaccine [11-14]. Increased risks of intus-

susception were documented in high income countries in United States (first dose, RR 2.6–9.1; second dose, RR 1.8; third dose, RR 1.2–2.2), Finland (first dose, IRR 2) and Australia (first dose, RR 9.9; second dose, RR 2.8) in the 1–7 day period with RV5 vaccine (Rotateq™) [11–13,29]. In Singapore (first dose, RR 8.3; second dose, RR 3.0)and Spain (first dose, RR 4.7; second dose, RR 1.6) also the intussusception risk was higher where both RV1 and RV5 were used [26,27]. The RV1 doses are administered at 2 and 3 or 4 months schedule. The RV5 doses are administered at 2, 4 and 5 or 6 months schedule.

Although the exact reasons of increased risk of intussusception with RVV in some countries but not in others are not clear, some possible factors like age at vaccination, coadministration of oral polio vaccine (OPV), gut replication of RVV virus, intestinal microbiota environment, breastfeeding and dietary patterns, maternal antibody transfer and ethnicity may be considered [33]. In this study, the median age of the intussusception cases is 28 weeks (IQR, 22–35 weeks), which is comparable to the reports for Indian infants without RVV exposure [34–36]. In this study no case was observed before 6 weeks, one case before 10 weeks and 11 cases before 14 weeks of ages. This observation is similar to that from African countries [23,28]. The median or peak ages of intussusception in children from the countries with increased risk were also comparable to the Indian and African children. It was interesting to note that the countries following 6 and 10 weeks (African countries) and 6, 10 and 14 weeks (India) schedules have no or lower risk of intussusception [23,28]. But the countries following 2 and 3 months or 2 and 4 months schedules for RV1 and 2, 3 and 5 months or 2, 4 and 6 months schedules for RV5 had higher risk of intussusception [9–14,26–29]. Risk of intussusception was highest in 1–7 days after the first dose or either RV1 or RV5. In this study, we observed one case on day-zero of RVV dose-3. Apart from the schedule, while no increased risk of intussusception was observed in the low and middle income countries (LMICs) from Africa and India, the middle income countries (MICs) from Latin America and developed countries from North America, Europe and Australia had increased risks of intussusception. So, the earlier age of administration of first RVV dose may have lower risk of intussusception, when the background occurrence is low. The RVV administered at 10–14 weeks schedule was observed to have higher seroconverion compared to 6–10 weeks schedule [37]. In India and the African countries OPV is coadministered with RVV. In this study, 47 children received RVV and OPV simultaneously. The co-administration of RVV and OPV was observed to have lower rotavirus seroconversion in South Africa, Bangladesh and Chile infants [37–39]. The lower seroconversion may be due to suboptimal RVV virus replication in the intestine.

Lower efficacy (49.7–64.5%) in clinical trials and effectiveness (18–69%) of the RVVs have been observed in LMICs from Africa, Latin America and Asia compared to the middle and high income countries [5,40]. The lower immune responses to the RVVs may be due to lower replication of the RVV viruses in the intestine of infants in LMICs, which is reflected in lower fecal shedding [33]. The lower replication of RVV viruses may be dependent on the intestinal microbiota and other competing microbes of the infants in these LMICs [33,41]. The intestinal replication of virus may be influenced by the breastfeeding pattern, immunoglobulin and non-specific antibodies content in the breastmilk, dietary pattern, environmental sanitation and nutritional status of the infants [33,41]. Apart from these the maternal infection with rotavirus and vertical transfer to infants may also affect the vaccine virus replication, and thereby the immunogenicity and risk of intussusception [33,41]. The variation in the intussusception rates across the different regions globally may also be due to genetic and/or ethnic risk factors [16,41]. With these possible factors influencing the intussusception risk after RVV, the subnational variations of the risks in India should also be explored, considering the wide variation in the dietary, sociocultural practices, sanitation and environmental risk factors.

Our study had some limitations. First, the number of children who received RVV was small and is underpowered to observe significant risk of intussusception. However, we did not observe any case of intussusception during 1–7 days after the first and second doses of RVV, which was reassuring. There were two cases of intussusception (ages 18.2 and 25.3 weeks) during 1–7 days after third dose of RVV, which overlaps with the age of natural occurrence of intussusception in infants, even without RVV. The observations are similar to a recent report from India on intussusception after Rotavac, where out of 104 intussusception cases, none occurred during 1–7 days after RVV1 and RVV2 while one case occurred during 1–7 days after RVV3. The relative incidences of intussusception during 1–21 days after RVV1 and RVV2 (RI: 1.56; 95% CI: 0.0–5.28) and any RVV dose (RI: 1.51; 95% CI: 0.58–3.23). The findings from our study are comparable to observations from this report [41,42]. Second, only cases from selected hospitals were included and no definite catchment area or population base could be ascertained to derive the incidence rate. Third, all the children with intussusception were recruited at the sites irrespective of the immunization exposure status. Several of the infants were from outside the city and their parents were not carrying the vaccine cards with them. We surveillance team tried to collect the vaccination information to their best. The vaccine exposure information was available for 78.4% of infants, which corroborates with the immunization coverage status of infants in India and there was no significant difference in the age distribution between the infants who were included in analysis and those who were not. The key parameters for the vaccinated and unvaccinated infants appeared similar. We had study sites across 17 states of India and had mix of public and private hospitals and we believe that the findings are generalizable to other areas of India.

In conclusion, this SCCS analysis did not observe any increased risk of intussusception in the 1–7 and 8–21 days periods after the any dose of the oral monovalent 116E RVV (Rotavac™) among Indian infants compared to the background risk. This observation is similar to the risks observed among African infants following oral RV1 administration from post-licensure studies [23,28]. Although no increased risk of intussusception with the RVV in Indian infants is encouraging, continued documentation over longer period and sub-national risk assessment should also be considered. Such evidence will also be useful for other counties in the region and globally considering use of these RVVs for preventing diarrhoea morbidity and deaths.

5. Consent for publication

Not applicable.

6. Availability of data and materials

All data is available with the investigators and can be provided by the corresponding author upon reasonable request.

7. Disclosure statement

None. There is no financial interest or benefit for the authors arisen from this project or its direct application.

8. Funding xxx

This project was supported by the Bill and Melinda Gates Foundation, USA to The INCLEN Trust International (grant number

OPP1116433). The funder or its representative had no role in the design of the study and collection, analysis, and interpretation of data and writing the manuscript.

9. Authors' contributions xxx

MKD and NKA conceptualised the framework for the study protocol, training, data analysis and interpretation. All TAG members provided input for finalisation of the study protocol and provided quality assurance oversight. All site investigators supervised the data collection at respective study site institutes. BG and AS coordinated the data collection and collation. MKD, RR, JET and BG analysed the data. MKD and RR wrote the first draft of the manuscript. JET and UP reviewed and revised the manuscript. All authors reviewed, provided critical input and approved the final version.

10. Disclaimer

The content represents the views of the authors alone and do not necessarily represent the official positions of their organizations, World Health Organization or Ministry of Health and Family Welfare, Government of India or the US Centers for Disease Control and Prevention or Bill and Melinda Gates Foundation.

India

ABSTRACT

Objective: Intussusception has been linked with rotavirus vaccine (RVV) as a rare adverse reaction. In view of limited background data on intussusception in India and in preparation for RVV introduction, a surveillance network was established to document the epidemiology of intussusception cases in Indian children.

Methods: Intussusception in children 2–23 months were documented at 19 nationally representative sentinel hospitals through a retrospective surveillance for 69 months (July 2010 to March 2016). For each case clinical, hospital course, treatment and outcome data were collected.

Results: Among the 1588 intussusception cases, 54.5% were from South India and 66.3% were boys. The median age was 8 months (IQR 6, 12) with 34.6% aged 2–6 months. Seasonal variation with higher cases were documented during March-June period. The most common symptoms and signs were vomiting (63.4%), bloody stool (49.1%), abdominal pain (46.9%) and excessive crying (42.8%). The classical triad (vomiting, abdominal pain, and blood in stools) was observed in 25.6% cases. 96.4% cases were diagnosed by ultrasound with ileocolic location as the commonest (85.3%). Management was done by reduction (50.8%) and surgery (41.1%) and only 1% of the patients' died. 91.1% cases met Brighton criteria level 1 and 3.3% Level 2. Between 2010 and 2015, the case load and case ratio increased across all regions.

Conclusion: Intussusception cases have occurred in children across all parts of the country, with low case fatality in the settings studied. The progressive rise cases could indicate an increasing awareness and availability of diagnostic facilities.

1. Introduction

Intussusception is the most common bowel obstruction in young children, usually occurring between 4 and 10 months of age [1,2]. Some of these may be transient and resolve spontaneously. If the intussusception is not relieved early, it may lead to bowel ischemia and perforation and may be fatal [2]. Ileocecal region is the most common site documented. Some anatomical lead points may trigger in 10–15% cases [2]. Intussusception has been linked as an adverse reaction with rotavirus vaccine (RVV). An increased rate of intussusception (1 additional case per 10000 vaccinated children) following introduction of RVV, Rotashield™ (Wyeth Lederle, Marietta, PA, USA) in 1999 forced its withdrawal from the market [3–5]. Recognising the intussusception risk, subsequent two candidate RVVs underwent clinical trials with over 60,000 participants documented no significant increased risk [6,7]. The post-licensure surveillance with two RVVs (Rotarix™, GlaxoSmithKline Biologicals, Rixensart, Belgium and Rotateq™, Merck & Co. Inc., Kenilworth, USA) reported variable risks of intussusception across countries; ranging from no increased risk [USA [8] and Brazil [9] to a low risk of 1–2 additional cases per 100,000 vaccinated infants [Mexico [9] and Australia [10]. Introduction of RVV in national immunization programmes (NIPs) has been recommended by World Health Organization (WHO) to reduce the rotavirus diarrhoea related deaths. Also, WHO has recommended documentation of baseline rates of intussusception to allow for estimation of potential attributable risks associated with vaccine, to enable a quantitative assessment of the potential risks and benefits of a vaccine programme [11].

According to WHO, 96 countries have introduced RVV in their NIP till August 2018. India has introduced the RVV in NIP since April 2016 in a phased manner. Monitoring the risk of intussusception related to RVV requires reliable surveillance systems. Currently available studies from India have assessed the risk of intussusception from single or few medical centres. The studies use different case definitions and age groups, reference periods, methodology and case management protocols [12–14]. Measured intussusception incidence in children from published reports varied between 17.7 (95% CI 5.9, 41.4) to 254 (95%CI 5.9, 41.4) cases per 100,000 child-years [15,16].

Wide variations in incidence and case load exist across sites in India and globally [17] although reasons for those variations are not known. There is limited information about regional differences in intussusception incidence among children from India. In view of the limited background data, we established a network of tertiary care hospitals to monitor trends of intussusception over time to identify any vaccine associated risk [18,19]. In this study we report on the epidemiology of intussusception in under-two children prior to RVV introduction in India.

2. Methods

2.1. Study area and participating hospitals

This retrospective study of hospital-based sentinel surveillance for intussusception in under-two children was conducted at 19 Indian major tertiary care hospitals. Data were collected for a 69-months period (July 2010 to March 2016) at all these sites. The sites were selected from four regions (north, south, east, and west) of the country with three to six hospitals per region with a mix of medical colleges and private-sector hospitals (North region- 5 sites, 3 public and 2 private; South region- 5 sites, 2 public and 3 private; East region- 6 sites, 5 public and 1 private; West region- 3, public 2, and private 1). The data was collected during January 2016- September 2017. The method of selection of the sites are described in the protocol published [20].

2.2. Case definition, case selection and data collection

Children aged >1 month and <24 months (2–23 months) admitted to these hospitals with intussusception were reviewed. At the institutions using international classification of diseases (ICD), cases with one of the clinical conditions as per ICD-10 (K56.1, K56.2, K56.3, K56.4, K56.5, K56.6, K56.7 and K56.0) or ICD 9 (560.0, 560.2, 560.31, 560.30, 560.81, 560.9 and 560.1) were identified. At the institutes not using ICD classification, cases with exit diagnoses including intussusception, acute intestinal obstruction, subacute intestinal obstruction, acute abdomen, and blood in stool with vomiting were identified. Additionally, all the registers from clinical (pediatrics, pediatric surgery and emergency) wards, operation theatres, radiol-

Please cite this article as: M. K. Das, N. K. Arora, B. Gupta et al., Intussusception in children aged under two years in India: Retrospective surveillance at nineteen tertiary care hospitals, Vaccine, https://doi.org/10.1016/j.vaccine.2020.04.059

ogy (ultrasound, barium studies and CT scan) and pathology departments were screened to identify any cases. The case records of these suspected patients were extracted and reviewed to identify intussusception cases. For confirmed cases, data including demography, clinical features, management, and final outcome were abstracted using case record form (CRF). The data including symptoms, signs and other relevant information as documented in the case records were captured. A record of cases screened, identified as suspected and confirmed cases was maintained. For the suspected and confirmed cases with incomplete information from case records, the other sources of information were searched and supplemented. The modes of treatment cases as documented in case record were recorded (surgical- laparotomy with or without resection, reduction- hydrostatic or barium enema under ultrasound guidance or conservatively- managed for intestinal obstruction without reduction or surgery). The cases with documented findings compatible with intussusception on ultrasound, CT scan, barium enema or surgery were considered as confirmed cases. An independent case adjudication committee (CAC), including paediatrician, paediatric surgeon and radiologist, reviewed and assigned diagnostic certainty level using Brighton Collaboration criteria [1].

2.3. Quality assurance

To ascertain protocol adherence, rigor and completion of surveillance, multilevel quality assurance processes were implemented. Technical Advisory Group (TAG) members visited sites to assess the suspected cases identification, record retrieval and data abstraction for confirmed cases. Data team members visited all the sites on a second occasion, repeated the case identification process for 2014, 2015, and 2016 using the protocol to assess the completeness of data collection and identify any missed cases. The data abstracted for confirmed intussusception cases were verified from case records. Any additional data query was clarified with reference to the source documents.

2.4. Data management and analysis

Double data entry was done for the CRFs using a customised data entry platform with inbuilt data matching feature. The verified data were stored in a server with authorised access and daily backup. The descriptive analysis was included proportions for categorical; means and standard deviations for normally distributed continuous variables, and median with IQR for continuous variables with skewed distributions. The values between groups were compared for statistical significance using Student's *t* test or Mann–Whitney *U* test depending on the skewness. Statistical significance was considered if $p < 0.05$. Statistical analysis was performed using STATA version 15.0 (Stata Corp LLC, Texas, USA). Due to the lack of well-defined population catchment area for the hospitals, the estimation of intussusception incidence was not feasible. Instead, we estimated intussusception case ratio per 1000 paediatric hospitalisations at each hospital for comparing the case volumes by sites and years. On review, it was observed that the paediatric surgery admission numbers were relatively stable compared to the medicine department and the intussusception cases were primarily admitted to the paediatric surgery wards. Thus the intussusception case ratio was estimated per 1000 paediatric surgery admissions at the hospitals for comparison and trend analysis. The detailed methodology can be referred from the published protocol [20].

2.5. Ethical issues

The study protocol was reviewed and approved by all the ethics review committees of each participating institute. Confidentiality in data handling was maintained.

3. Results

A total of 1588 children aged under two years (2–23 months) with intussusception were admitted to these hospitals between July 2010 and March 2016. Out of these 96 (6%) (North region, n = 13; South region, n = 68; East region, n = 10 and West region, n = 5) cases had past history of intussusception documented in the case records. Over half of the cases (n = 865, 54.5%) were documented from the hospitals in Southern region. Figures for other regions were: Eastern (n = 381, 24%), Northern (n = 254, 16%) and Western (n = 88, 5.5%). Demographic and clinical characteristics of the intussusception patients are summarised in Table 1. A consistent male predominance was observed across all regions

Table 1
Demographic and clinical characteristics of children aged 2-23 months with intussusception in India (region wise and pooled).

Notes:
PR: Per-rectal
The p values for some parameters could not be estimated due to no value in at least two groups.
[*] The patient presented to the study hospital as the first institute.
[**] The patient referred to the study hospital from another hospital.
[¥] Vomiting includes bilious vomiting.
[¥¥] Includes only bilious vomiting.
[#] Classical triad include abdominal pain, vomiting and blood in stools
[##] Triad include abdominal pain, vomiting and rectal bleeding (detected either as blood in stool or blood on per-rectal examination)
[$] None, as the patient(s) were referred or died before any definite treatment.
[£] The denominators used for percentage estimation are patients undergone surgery only.
[^] LAMA: Left against medical advice.
[@] The residence of the patient is in other district in the state where the study hospital is based.
[€] The location of intussusception is at more than one site; such as Ileo-colic + Colo-colic, Ileo-olic + Ileo-colo-colic, Ileo-colic + Ileo-ileo-colic, Ileo-colic+ Ileo-ileal.
[&] Others including cyst, Meckel's diverticulum, incisional hernia, intraluminal growth and malrotation.

(male: female ratios: pooled 1.96; north 3.0; south 1.65, east 2.2; and west 2.1). The majority of cases were aged <12 months, with 34.6% in the 2–6 months and 41% in the 7–12 months age bands. Nearly half (48.1%) of the patients were aged 4–8 months. Over one-third (34.7%) children were aged >1–6 months, the age for administration of routine RVV doses. The overall median age at presentation was 8 months (Inter Quartile Range, IQR 6, 12) with 8 months (IQR 6, 12) for boys and 8 months (IQR 6, 15) for girls (p = 0.09). The median age was higher for Western (11 months, IQR 7, 17) and Southern (9 months, IQR 6, 14) regions compared to Northern (7 months, IQR 5, 12) and Eastern (7 months, IQR 6, 10) regions (p = 0.00) (Table 1 and Fig. 1). Additional peaks in case load was observed around the 12th and 23rd months of age across all regions.

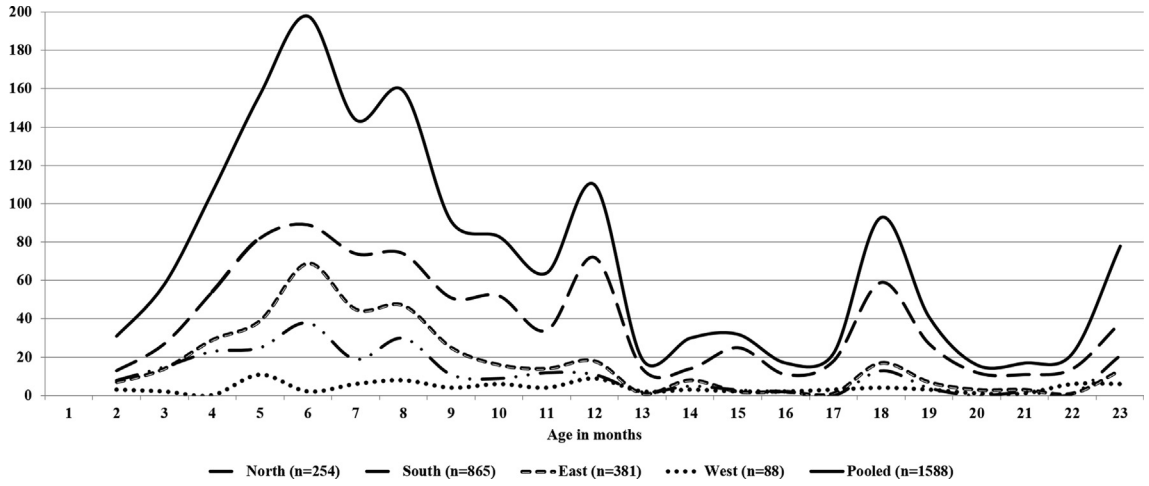

Fig. 1. Age distribution of children aged 2–23 months with intussusception in India (region wise and pooled).

Seasonal variation was observed with higher number of intussusception cases and case ratio during March to June months over each individual year studied (Fig. 2).

While the pooled intussusception case ratio was 15.5 (IQR 14.8, 16.3) per 1000 paediatric surgery admissions, the case ratio for Northern, Southern, Eastern and Western regions were observed to be 8.8 (IQR 7.8, 9.9), 36.2 (IQR 33.9, 38.6), 9.9 (IQR 8.9, 10.9) and 8 (IQR 6.5, 9.9) respectively. Between 2010 and 2015, rises in both absolute number of intussusception cases and case ratio (per 1000 paediatric surgery admissions) was observed across all the regions, but the rise was relatively higher for Eastern and Northern than the Southern and Western regions (see Fig. 3 and 4).

While 51.9% of hospitalized patients resided outside the hospital district, 44% were from the same district and 4.1% came from other states. Overall 76.8% cases presented directly to hospitals and 23.2% patients were referred from other hospitals. The median duration of symptoms to admission was 3 days (IQR 1, 5 days), but a shorter interval was observed in Southern (median 1 day, IQR 1, 5 days) and Western (median 2 days, IQR 1, 6 days) than in Northern and Eastern (median 3 days, IQR 1, 10 days) ($p = 0.04$) regions.

The most common symptoms were vomiting (63.4%), passage of blood stained stool (49.1%), abdominal pain (46.9%) and excessive crying (42.8%). Bilious vomiting was documented in 10.5% cases, more frequently Western region (15.9%). Higher proportions of abdominal pain in Western (60.2%) and Northern (56.7%); excessive crying in Southern (62.2%); blood in stool in Northern, Southern and Western (52.7%-54.9%) regions were documented. The intussusception classical symptoms triad (abdominal pain, vomiting and blood in stools) was documented in 25.6% cases, which varies from 25.2% to 29.5% in in Northern, Southern and Eastern regions, but was quite lower (17.1%) in the Western region. There was no variation in the presence of the symptoms triad with the interval between onset of symptoms and presentation to the hospital. On examination children had abdominal mass (28.7%), abdominal distention (17.3%), blood on per-rectal examination (18.5%), and abdominal tenderness (10.2%). The prevalence of findings varied across regions for abdominal distention (Northern 37.8% to Southern 8.6%), abdominal mass (Southern 43.5% to Eastern 6.3%), and blood on per-rectal examination (Western 35.2% to Northern 12.4%). On considering presence of blood on per-rectal examination, presence of triad of intussusception (abdominal pain, vomiting and blood in stools or per-rectal examination) was present in 50.8% and ranged from 57.9% in Northern to 38.9% in Eastern regions.

Most cases were diagnosed by ultrasound (96.4%) and few by laparotomy (3.3%). The most common site of intussusception was

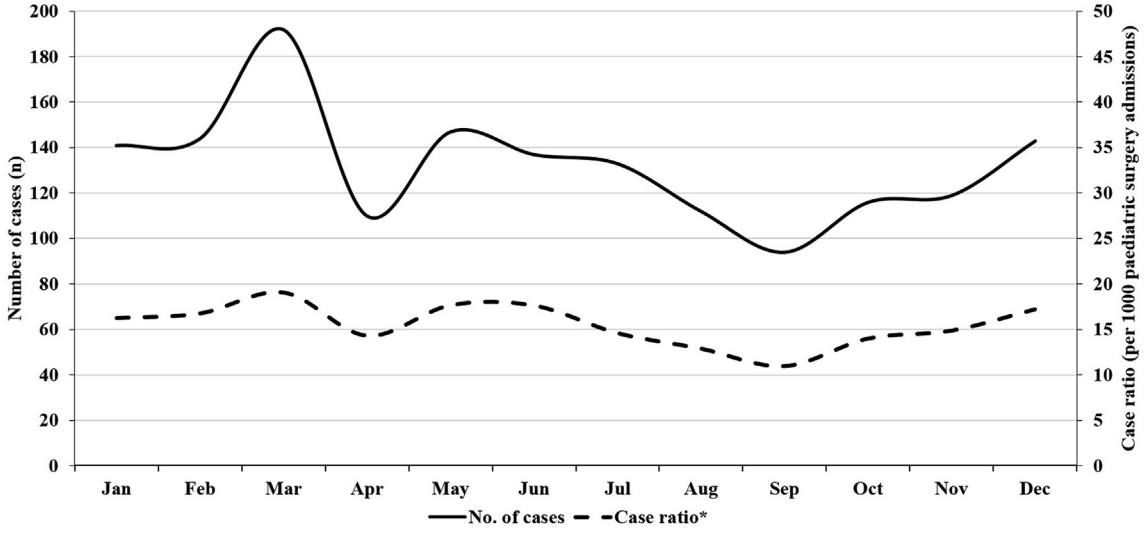

Fig. 2. Calendar monthly distribution of intussusception case load and case ratio in children aged 2–23 months in India (pooled).

Please cite this article as: M. K. Das, N. K. Arora, B. Gupta et al., Intussusception in children aged under two years in India: Retrospective surveillance at nineteen tertiary care hospitals, Vaccine, https://doi.org/10.1016/j.vaccine.2020.04.059

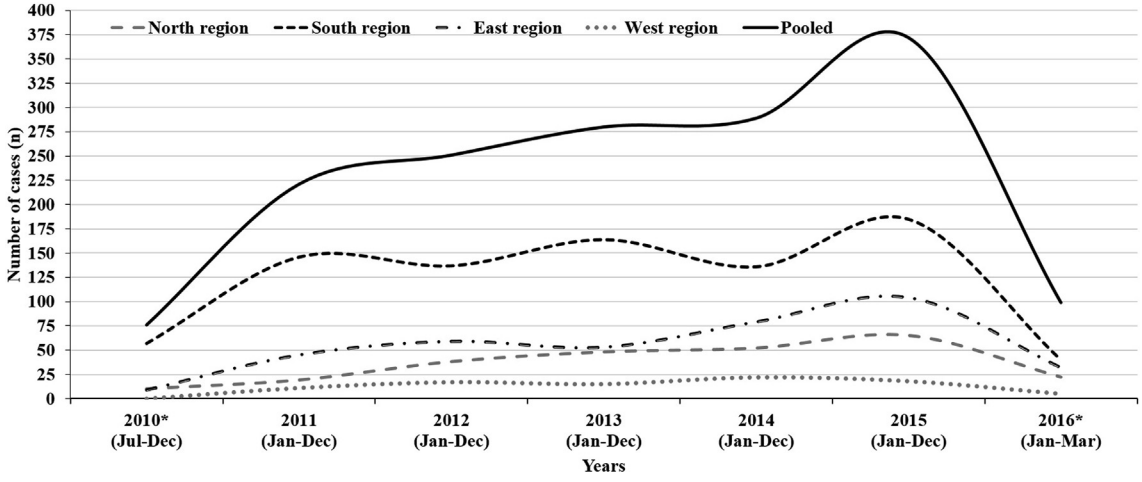

Fig. 3. Trend of intussusception case load in children aged 2–23 months in India during 2010–2016 (region wise and pooled).

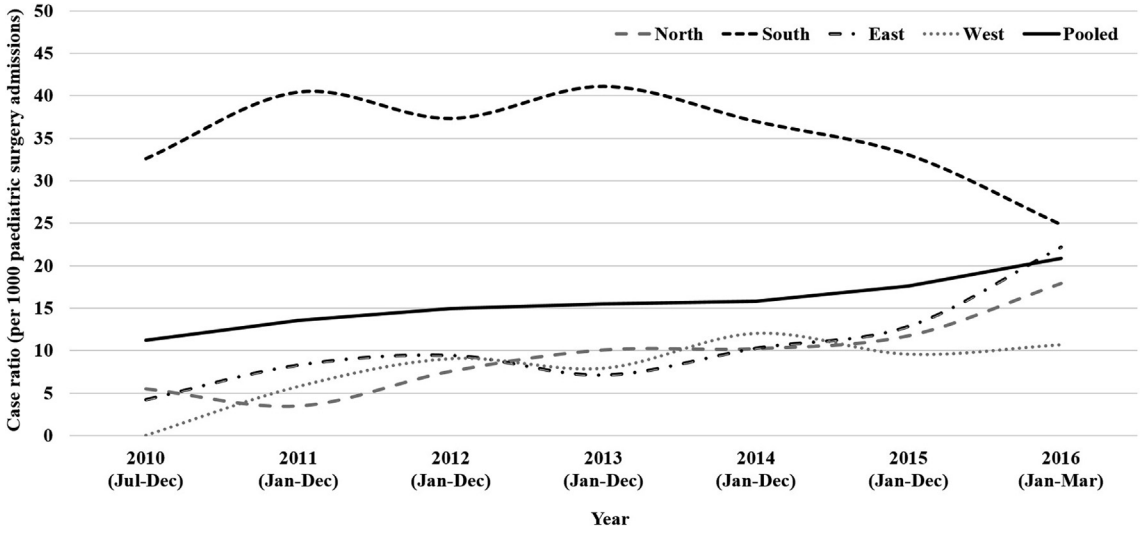

Fig. 4. Trend of intussusception case ratio in children aged 2–23 months in India during 2010–2016 (region wise and pooled).

ileocolic (85.3%) across all regions, age groups and gender. Other intussusception sites included ileo-ileal (north 15.8% and west 11.4%), colo-colic (west 11.4%) and ileo-colo-colic (north 7.1%). Double site intussusception was documented in few (1.5%) cases. Pathological lead point (PLP) was documented in 91 (17.9%) cases with lymph nodes (11.8%) as the most common one and higher proportion in Western region (37.5%) followed by Northern region (26%).

Most patients were treated by reduction (50.8%) and surgery (41.1%), while 7.2% children were managed conservatively. Among children managed by surgery, 14.8% required bowel resection. The median interval to presentation was not associated with different treatment choices: surgery (1 day; IQR 0, 3), reduction (1 day; IQR 1, 2) and conservative treatment (1 day; IQR 0, 3). Higher proportion of patients underwent surgery in Northern (73.6%) and Eastern (71.7%) regions compared to Western (31.8%) and Southern (19.1%) regions. Five hospitals did not use reduction (3 in Eastern, 1 in Northern and 1 in Southern regions) but, instead, use exclusive surgery. At the hospitals with both surgical and reduction facilities for management, surgery was done in 28.3% (341/1205) cases with 18.1% cases reduced under anaesthesia and the remainder required bowel resection. The indications for surgery were failed reduction (33.9%), late presentation (23%) and associated complications (43.1%). Only 1% of the cases died and most of these presented late (median interval 3 days, IQR 1, 6 days). The causes of death were due to complications (sepsis, shock, and gangrene) associated with delayed presentation and after surgery. Thirty three cases left against medical advice before definite treatment. The overall median period of hospitalisation was 3 days (IQR 2, 6 days), which varied from 2 to 6 days; there were important regional variations, from 2 days in the Southern to 6 days in the Northern and Eastern regions. The median hospitalisation periods were 7 days (IQR 5, 9 days), 2 days (IQR 2, 3 days) and 2 days (IQR 2, 4 days) for surgery, reduction and conservative management respectively. Using Brighton diagnostic criteria, 91.1% cases were categorised as Level 1, 3.3% as Level 2 and none in Level 3. No level could be assigned for 4.8% cases.

4. Discussion

In preparation for RVV introduction, assessing the background rate of intussusception helps prepare monitoring vaccine safety [21,22]. The global average rate of intussusception is about 74 (range 9–328) per 100,000 child years based on review of 82 studies [17]. Very high incidences have been measured in South Korea

Please cite this article as: M. K. Das, N. K. Arora, B. Gupta et al., Intussusception in children aged under two years in India: Retrospective surveillance at nineteen tertiary care hospitals, Vaccine, https://doi.org/10.1016/j.vaccine.2020.04.059

[23], Vietnam [24], Israel [25], and Japan [26] with 328, 302, 219, and 185 per 100,000 child years respectively [17]. Reported intussusception rates in India vary from 17.7 to 254 per 100,000 child years, [15,16]. Most reports from India are hospital-based passive surveillance and few are population-based active surveillance. These studies were of limited geographical representation to derive any national interpretation. The RVV pre-licensure studies in India (for Rotavac™ and Rotasiil™) have not shown increased intussusception risk.

This study was undertaken to document the intussusception case load in India through a nationally representative sentinel surveillance network of tertiary care hospitals to assist monitoring the trend following RVV introduction. We observed important regional difference in intussusception case load and case ratio. The Southern region documented higher absolute case number (3–10 times) and case ratio (4–5 times). The higher number of cases and case ratio in southern region sites could be due to better access to diagnostic facilities and timely referral. Additionally presence of pediatric surgeon and management facility could be the other reasons for higher referral to some of these hospitals. Higher case load and case ratio were observed during March to June, as previously reported from India [14,16,27,28].

Actual case incidence could not be estimated due to lack of defined draining population base. Instead, we used the intussusception case ratio per 1000 paediatric surgery admissions which were comparable to absolute case load. This proxy could be useful for comparison across the sites or regions and tracking in future studies. Three-fourth of the diagnosed cases were during the first year of life, with a majority of male patients aged 4–8 months, which was similar to other reports from India [12,14,16,27] and globally [1,12,14,16,17,27,29,30]. The variations in the symptoms and signs may be due to the interval between onset and admission time, longer in north and east regions. In 25.6% cases, the intussusception triad (abdominal pain, vomiting and blood in stools) was documented, which was higher than reports from other parts of India [14,27]. When either symptom (blood in stool) or sign (blood on per-rectum examination) was considered, the prevalence of a triad was 50.8%. There was regional variation in the observation of a triad which also varied with the interval prior to presentation. The most common site for intussusception was ileocolic, which matched with reports from India [12,16,27] and globally [17]. PLPs were documented in 17.9% patients and lymph nodes were the most common (11.8%). Cases that presented early had shorter hospital stay. While in several hospitals reduction was the leading treatment modality, surgery was the only treatment method at some of the hospitals. A high degree of suspicion and early investigation for detection with appropriate referral is crucial for reducing surgical intervention. The proportion of cases with level 1 certainty according to BC criteria was high and similar to other reports from India [5,16,27]. For some cases Level 1 certainty could not be achieved due to non-documentation of reduction. Based on the findings of this study, the available information with the risk of intussusception with the RVVs in market and age pattern from literature, the pattern (age of occurrence, seasonality and sites) should remain similar. The studies after RVV introduction in India shall inform on this.

The study has several limitations. These sentinel surveillance sites were tertiary care hospitals and had no definite draining population territory. Thus estimation of incidence or a case rate was not possible. Several of the institutions used manual and paper record keeping methods and were not practicing the ICD classification system. This study being retrospective in nature, could have missed the cases, if they were not listed or available in the record section. The data collection may have missed the data including symptoms, signs and other information, if not documented in the case records. The number of institutes across the regions, the case load at the hospitals, the methods of case record archival and listing of the diagnoses might have influenced the case yield.

This study documented the intussusception case load, their distribution, clinical features, management and outcome across different sites and regions in India before RVV introduction. This may provide a reasonable background information. More importantly it establishes the methodological basis for active surveillance of intussusception following RVV introduction. The private and public mix of hospitals and regional representation will allow for a more representative evaluation of the vaccines in the whole population. Intussusception is a common condition among children under-two years of age across in India with majority of cases during infancy. There were regional variations in the case load and ratio observed. An increasing secular trend of intussusceptions has been documented among children across all regions prior to the beginning of the rotavirus vaccination program. Case management was dependent on facilities available at the hospitals. Although mortality was low, it can be further prevented by early case detection, referral and timely management. Studies of intussusception following vaccine introduction will require RVV exposure documentation. A periodic monitoring of the intussusception should be undertaken to interpret the trend over time. It may also be useful to further investigate the potential risk factors for the regional variations and increasing trend.

Funding

This project was funded by the Bill and Melinda Gates Foundation, USA (grant number OPP1116433).

Ethics approval

The study protocol was reviewed and approved by INCLEN Ethics Committee (Ref: IIEC 023) and all participating Study Site Institute Ethics Committees.

Data availability

The data can be made available in request from the corresponding author.

Authors' contributions

MKD and NKA conceptualised the framework for the study protocol, training, data analysis and interpretation. All TAG members provided input for finalisation of the study protocol and provided quality assurance oversight. All study site investigators led and supervised the data collection. BG and AS coordinated the data collection and collation. MKD and BG analysed the data. MKD and BG wrote the first draft of the manuscript. All authors reviewed, provided critical input and approved the final version. The content represents the views of the authors alone and do not necessarily represent the official positions of their organizations, World Health Organization or Ministry of Health and Family Welfare, Government of India.

Declaration of Competing Interest

The authors declare that they have no known competing financial interests or personal relationships that could have appeared to influence the work reported in this paper.

ABSTRACT

Isolated osteochondroma presenting as hemothorax is a rare entity. A 7-year-old boy presented with respiratory distress and diagnosed with hemothorax, and computed tomography showed osteochondroma and removal with resection of the rib was curative.

KEYWORDS: *Curative resection, hemothorax, osteochondroma*

INTRODUCTION

Osteochondroma is the most common benign lesion of the bones, commonly arising from the growing end of long bones. It is characterized as bony outgrowths from the surface with a cartilaginous cap. It can be solitary or multiple, with the former most commonly seen in clinical practice. Osteochondromas are benign developmental anomalies, characterized by the separation of epiphysis growth-plate cartilage from the main epiphysis.[1]

It is commonly seen on the long bones. However, the index child had an osteochondroma of rib presenting as hemothorax which is exceedingly rare, and hence, presented as a case report.

CASE REPORT

The index case was a 7-year-old boy admitted with complaints of difficulty in breathing along with left-sided chest pain of 2-day duration. There was no history of trauma or infections or any other respiratory symptomatology. The child had no swelling anywhere else in the body, and the parents were normal.

The clinical examination revealed evidence of left pleural effusion. Complete blood count within normal parameters and Mantoux test was negative, and the patient reported no history of recent contact with tuberculosis patients. Coagulation profile was also normal. Chest X-ray [Figure 1] and ultrasound showed collection of moderate amounts of pleural fluid associated with collapse of the left lower lobe.

Diagnostic aspiration under ultrasound guidance revealed uniformly bloody fluid from the pleural cavity. Computed tomography (CT) of the chest [Figure 2] was done which revealed a speculated tumor mass over the left seventh rib near the anterior end, protruding toward the left lower lobe of the lung which is clearly evident upon three dimensional (3-D) reconstruction. Thus, a diagnosis of bony tumor causing perforative injury to the left lower lobe of the lung causing hemothorax was made.

The child was taken up for the surgery, and thoracoscopy was done initially to identify and localize the lesion and to rule out any complications. The bony spicule over the left seventh rib was resected, which was a 2 cm × 2 cm hard spicule with a smooth surface from the inner surface of the rib injuring the adjacent pleura and lung parenchyma.

The histopathological examination revealed nodular lesion comprising external fibrous tissue, middle cartilaginous tissue, and inner bony trabeculae enclosing the marrow cavity [Figure 3]. There was endochondral ossification with proliferating capillaries, hematopoietic and fatty marrow elements within the lesion. The outer fibrous layer is seen continuous with the periosteum of underlying bony tissue.

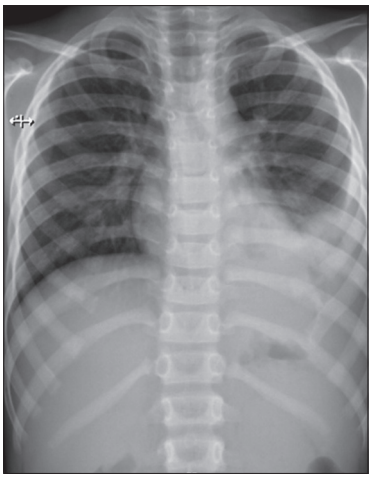

Figure 1: X-ray showing left-sided pleural effusion

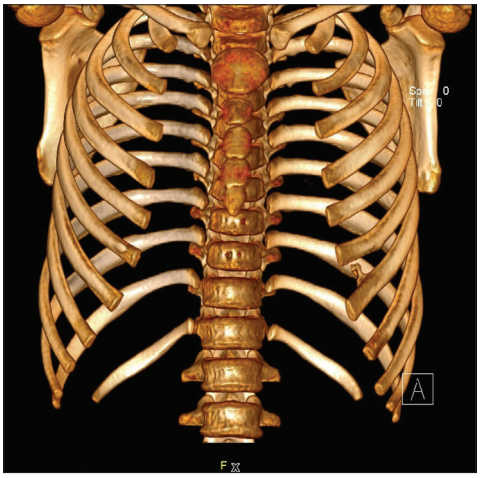

Figure 2: Three-dimensional computed tomography reconstruction showing the osteochondroma involving the anterior portion of the left seventh rib on the inner aspect

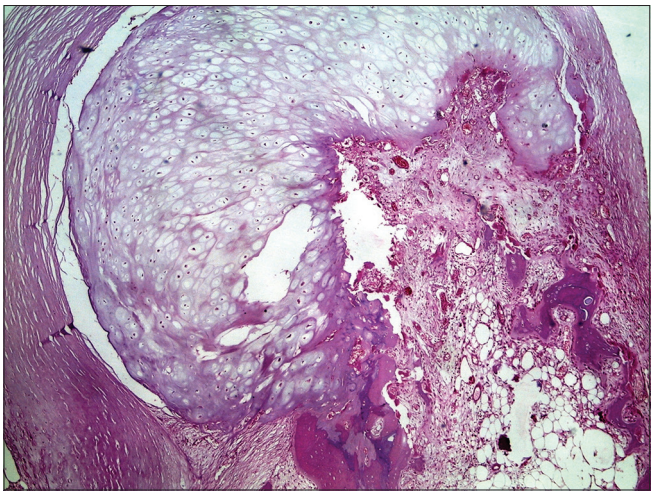

Figure 3: Histopathological examination showing external fibrous tissue, middle cartilaginous tissue, and inner bony trabeculae

These confirmed the diagnosis of osteochondroma of rib, in benign status.

Discussion

Being relatively common tumor of long bones, the incidence of osteochondroma of ribs is exceedingly rare, with an incidence of 1 in 50,000 only.[2] Even rarer is the osteochondroma causing hemothorax in the pediatric age group with only <5 cases reported in previous literature. The rarity of the case was the main reason for reporting it.

Kadu *et al*., have previously reported a similar case of 9-year-old boy with osteochondroma of the right 6th rib. During his follow-up of 3-year period, the tumor did not increase in size or developed any complications and hence was managed conservatively.[3]

Most of the patients are asymptomatic which makes it hard to diagnose. Only very few cases are observed with symptoms such as chest pain.

Osteochondroma starts early in childhood and grows till skeletal maturity is reached. It is asymptomatic when benign and small. The main complications include fracture of rib, vascular injury, osseous deformities, neural compression, and malignant transformation.

Our patient had a rare complication of hemothorax caused by the lesion, possibly due to chronic irritation of the chondroma spicule growing inward into the pleura, causing bleeding from pleural vessels.

The tumor peaks around the age group of 10–30 years with a 3% thoracic origin, which rises to 10% in hereditary multiple exostosis,[4] as evident by the case report submitted by Maeda *et al*., where the children suffering from hereditary multiple exostosis and strong family history, eventually developed osteochondroma in the ribs at latter part of life.[5,6] Hence, it is considered worthwhile to closely follow-up such patients with hereditary multiple exostosis.

Bess *et al*. emphasized the importance of preoperative radiological evaluation to provide optimal data about the lesions such as erosion, internal lytic areas, and destruction of adjacent structures, calcifications, and soft-tissue masses.[6] The size of the cartilaginous cap serves as the best indicator of malignant transformation in osteochondroma.[7]

However, according to Naidu *et al*., like in our index case, CT scan when coupled with reconstruction technique can help to localize the lesion, but the size

is often underestimated because of cartilaginous cap, which can be better visualized by magnetic resonance imaging.[8]

Malignant transformation of osteochondroma is very rare and has been seen only in <1% of solitary and 2% of hereditary multiple exostosis cases.[9]

Few other adult cases of osteochondroma of rib have been reported by Phatak *et al*., but all of them were asymptomatic and were incidentally found, unlike our index child who presented with hemothorax due to osteochondroma.[4]

The presence of complications favored surgical excision as the mainstay of treatment unlike previously reported cases, which were asymptomatic and hence managed conservatively.

This emphasized the importance of osteochondroma as an etiological factor in hemothorax and should be given due consideration while considering a diagnosis in the pediatric age group.

Declaration of patient consent

The authors certify that they have obtained all appropriate patient consent forms. In the form the patient(s) has/have given his/her/their consent for his/her/their images and other clinical information to be reported in the journal. The patients understand that their names and initials will not be published and due efforts will be made to conceal their identity, but anonymity cannot be guaranteed.

Prospective surveillance for intussusception in Indian children aged under two years at nineteen tertiary care hospitals

The INCLEN Intussusception Surveillance Network Study Group

Abstract

Background: India introduced rotavirus vaccines (RVV, monovalent, Rotavac™ and pentavalent, Rotasiil™) in April 2016 with 6, 10 and 14 weeks schedule and expanded countrywide in phases. We describe the epidemiology of intussusception among children aged 2–23 months in India.

Methods: The prospective surveillance at 19 nationally representative sentinel hospitals from four regions recruited children with intussusception from April 2016 to September 2017. Data on sociodemography, immunization, clinical, treatment and outcome were collected. Along with descriptive analysis, key parameters between four regions were compared using Chi-Square/Fisher's exact/Mann–Whitney U/Kruskal-Wallis tests. The pre- and post-RVV periods were compared to estimate the risk ratios.

Results: Six hundred twenty-one children with intussusception from South ($n = 262$), East ($n = 190$), North ($n = 136$) and West ($n = 33$) regions were recruited. Majority ($n = 465$, 74.8%) were infants (40.0% aged 4–7 months) with median age 8 months (IQR 5, 13 months), predominantly males ($n = 408$, 65.7%) and half ($n = 311$, 50.0%) occurred during March–June months. A shorter interval between weaning and intussusception was observed for ragi based food (median 1 month, IQR 0–4.2 months) compared to rice (median 4 months, IQR 1–9 months) and wheat (median 3 months, IQR 1–7 months) based food ($p < 0.01$). Abdominal pain or excessive crying (82.8%), vomiting (72.6%), and bloody stool (58.1%) were the leading symptoms. Classical triad (abdominal pain, vomiting and bloody stool) was observed in 34.8% cases (24.4 to 45.8% across regions). 95.3% of the cases were diagnosed by ultrasound. 49.3% (10.5 to 82.4% across regions) cases were managed by reduction, 39.5% (11.5 to 71.1% across regions) cases underwent surgery and 11.1% spontaneously resolved. Eleven (1.8%) cases died. 89.1% cases met Brighton criteria level 1 and 7.6% met Level 2. RVV was received by 12 cases within 1–21 days prior to intussusception. No increase in case load (RR = 0.44; 95% CI 0.22–1.18) or case ratio (RR = 0.5; 95% CI 0.3–1.2) was observed after RVV introduction in select sites.

Conclusions: Intussusception cases were observed across all sites, although there were variations in cases, presentation and mode of management. The high case load age coincided with age of the RVV third dose. The association with ragi based weaning food in intussusception needs further evaluation.

Background

To reduce the rotavirus diarrhoea related childhood deaths, the World Health Organization (WHO) has recommended introduction of rotavirus vaccine (RVV) in national immunization programmes (NIPs). Some increased risk of intussusception after the first (relative risk, RR: 4.7–13.8) and second (RR: 1.3–5.3) doses of RVVs was reported from several countries (Mexico, Brazil, Australia, United Kingdom, United States, Spain and Singapore) [1–8]. But no increased risk of intussusception after any dose of RVV was observed in some countries (Ethiopia, Ghana, Kenya, Malawi, Tanzania, Zambia, Zimbabwe and South Africa) [9, 10]. The impact of RVV on diarrhoea morbidity and mortality outweigh the risk of intussusception and associated mortality [11]. In view of the concern about intussusception, documentation of baseline and monitoring following RVV introduction have been recommended [12]. India introduced RVV into the NIP in April 2016 and by 2019 expanded countrywide in four phases [13]. Two types of RVV are used in NIP, Rotavac™ (RV1-116E; Bharat Biotech) in 26 states/union territories and Rotasill™ (RV5; Serum. Institute of India) in 11 states/union territories, both follow 6, 10, 14 weeks schedule. Intussusception is an acute severe clinical condition occurring mostly during infancy, which overlaps with the age of primary vaccinations. The nationally representative background epidemiology of intussusception in India is not clear. The reports from India primarily included retrospective data and considerably varied in the epidemiology, presentation and management [14, 15]. Information on population level rate in India is limited and the reported incidences of intussusception requiring hospitalization varied from 17.7 (95% CI 5.9–41.4) in Delhi (North India) to 254 (95% CI 102, 524) cases per 100,000 child-years in Vellore (South India) [16, 17]. The incidence of intussusception vary widely globally, across the different high and low-middle income countries [18]. The reasons for the variations are unknown. There is no information from India regarding the regional variation in intussusception epidemiology. Thus, documentation of the intussusception epidemiology prior to RVV introduction to establish a reliable baseline for monitoring the trend over time and identify potential risk factors was needed to support the vaccine safety surveillance efforts [19, 20]. Under the vaccine safety surveillance effort, we describe the epidemiology, clinical characteristics of intussusception among children aged under-2 years seeking hospital care in India and initial changes with RVV introduction documented through a nationally representative sentinel surveillance network.

Methods

Study area and participating hospitals

This prospective active hospital-based sentinel surveillance was conducted over 18 months, at 19 nationally representative tertiary care hospitals (Supplementary Figure 1). From the four regions, 3–6 hospitals per region including medical colleges and private-sector hospitals (North region- 5 sites, 3 public and 2 private; South region- 5 sites, 2 public and 3 private; East region- 6 sites, 5 public and 1 private; West region- 3 sites, 2 public and 1 private) were selected through a systematic process. Out of these sites, four sites were located in the states where RVV was introduced in April 2017 under phase 1. At all sites the RVVs were available in private market during the study period, even prior to the introduction in NIP.

Case definition, case selection and data collection

The children aged 2–23 months admitted to these hospitals with diagnosis of intussusception were eligible. All the age-eligible patients admitted were screened to identify the suspected cases (any of the diagnoses: intussusception, acute or subacute intestinal obstruction, acute abdomen, abdominal pain, abdominal distension, and blood in stool with vomiting). These suspected cases were tracked till final diagnosis and all confirmed intussusception cases were recruited after written informed consent from parent or legally authorised representative. A log of screened, suspected and confirmed cases was maintained. The data on socio-demography, feeding and immunization (from immunization card), clinical features, investigation findings, hospital course, treatment and outcome were collected using common case record form (CRF). The symptoms were captured as recorded in the case sheets and reported by the parents. An independent Case Adjudication Committee (CAC) comprised of a paediatrician, paediatric surgeon, and radiologist reviewed the CRFs and investigations to assign the diagnostic certainty levels, according to Brighton Collaboration case definition (BCCD) [21].

Quality assurance

Multilevel quality assurance and data quality-checking processes were put in place to ascertain protocol adherence, rigor and completion of surveillance at all sites. A data team reviewed all the CRFs and data-related query was resolved at the earliest. Each site was visited by external experts (Technical Advisory Group, TAG) to assess the case surveillance and tracking, consent, and data extraction quality and completeness in the CRFs. The TAG members checked CRFs completeness and quality for few randomly identified cases with the case records. Subsequently members from the data team visited the study sites and checked the admissions for the study period from the medical records section using diagnoses and International Classification of Diseases (ICD) codes (ICD-9/10, codes listed in Supplementary Table 1), to identify any missed cases.

Data management and analysis

Double data entry was done for the CRFs using a customised data entry platform. The matched and verified data were stored in the server with authorised access

and daily backup. The standard of living index (SLI), representing the socioeconomic status was estimated using the scores for household assets ownership, with reference to the National Family and Health Survey for India [22]. The SLI was categorised into high, medium and low categories. The cases were categorised into levels 1 to 3 based on the BCCD criteria by the CAC [21]. In view of the number of sites, for representation we grouped the sites into four regions, North (5 sites), South (5 sites), East (6 sites) and West (3 sites) regions. The parameters (sociodemographic, feeding, clinical, intervention and outcomes were compared between the regions to detect variations. The intussusception classical triad includes three features; abdominal pain, vomiting and blood in stools. We considered intussusception modified triad with abdominal pain, vomiting and rectal bleeding, detected either as blood in stool or blood on per-rectal examination. The descriptive analysis findings expressed the outputs as proportions, means and standard deviations, or median and interquartile range (IQR), as appropriate. The values between regions and groups were compared for statistical significance using Chi-Square or Fisher's exact tests for the proportions and Mann–Whitney U or Kruskal-Wallis tests for the medians depending on the skewness, sample and number of groups. The missing data were excluded from analysis. The statistical significance was considered if $p < 0.05$. The statistical analysis was performed using STATA version 15.0 (StataCorp LLC, Texas, USA). In the Indian context, there is no definite population catchment area for hospitals and no definite referral chain, which makes estimation of the intussusception incidence difficult. For comparison of the data across sites and intussusception time trend, in addition to case load (absolute number of cases), we attempted deriving the intussusception case rate per 1000 paediatric hospitalisations at the hospitals. On review, while the admission numbers in the paediatric medicine wards varied widely, the admission numbers in the paediatric surgery wards were relatively stable and the intussusception cases were primarily managed in the paediatric surgery wards. Thus we estimated the intussusception case rate per 1000 paediatric surgery admissions at these hospitals for comparison and trend analysis. For the four sites in three states (Odisha, Andhra Pradesh and Haryana), where RVV (monovalent Rotavac™, 3 doses at 6, 10, 14 weeks age) was introduced under NIP (in April 2017), the data for the post-introduction period (April to September 2017, 6 months) was compared with the pre-introduction periods (first: October 2016 to March 2017, immediate 6 months pre-introduction period and second: April 2016 to September 2016, calendar matched 6 months during the previous year) to document the risk ratio (95% confidence interval, CI). The detailed methodology of the site selection and study implementation has been published as protocol [23].

Ethical issues

Informed written consent was obtained for all the eligible cases before recruitment and data collection. Confidentiality in data handling was maintained. The study protocol was reviewed and approved by the ethics committees of all participating institutes.

Results

Between April 2016 and September 2017, out of the 182,824 children (including 32,910 paediatric surgery admissions) admitted to the network hospitals, 1203 suspected intussusception cases were identified and 621 eligible children were recruited (Supplementary Figure 2). More cases were recruited from Southern region (42.2%; 262/621) followed by East (30.6%; 190/621), North (21.9%; 136/621) and West (5.3%; 33/621) regions. Past history of intussusception was present in 24 (3.8%) cases. Table 1 shows the sociodemographic characteristics of children with intussusception. A male predominance (male-female ratio: 1.9:1) was consistent across all regions. The median age at presentation was 8 months (IQR 5, 13 months) (Supplementary Figure 3). Three quarters of the cases were infants with equal share from the age bands of 2–6 months (37.2%) and 7–12 months (37.7%) ($p < 0.01$). Children aged 4–7 months contributed to 40.0% of the total cases. The pooled intussusception case rate per 1000 paediatric surgery admission was 18.4 (IQR 14.7, 23.4). The intussusception case rate per 1000 paediatric surgery admission was highest for South (25.3, IQR 23.4, 32.7) followed by North (14.5, IQR 11, 19.7), East (13.8, IQR 10.5, 22) and West (6.6, IQR 1.2, 19.2) regions respectively. The Fig. 1 shows monthly trends of pooled intussusception case load and case rates per 1000 paediatric surgery admission (Fig. 1a) and the regional case rates per 1000 paediatric surgery admission (Fig. 1b). More cases ($n = 311$, 50.0%) were seen during March to June months, in the summer season (Fig. 1). While 42.8% of the patients were resident of the same district where the hospital was based, 41.9% of the patients presented directly to the hospital. Among the children aged > 6 months, 23.2% were exclusively breastfed for 6 months and the median duration of breastfeeding was 4 months. Mixed feeding was initiated before 6 months of age in 53.9% children. The median weaning age was 6 months and 61.0% received rice based food. Ragi (finger millet) was given to 22.8% children, only in the South region. The interval between weaning and intussusception was significantly shorter for ragi (median 1 month, IQR 0–4.2 months) than rice (median 4 months, IQR 1–9 months) and wheat (median 3 months, IQR 1–7 months) based food (Table 1) ($p < 0.01$). On analysis for the South

	Other food, median (IQR)	4 (1.5–6)	1 (0–3)	0 (0–1)	9.5 (5.2–13)	2.5 (0.7–5.5)	0.09
	Multiple food, median (IQR)	7 (2.5–9)	6 (2.7–12)	6 (3–12)	6 (3–12)	6 (3–12)	0.1
	Any food, median (IQR)	3 (1–7)	3 (1–8)	3.5 (1–8.2)	3 (1–9)	3.5 (1–8.2)	0.1

Notes:
Mixed food: Food used for weaning included at least two of the ingredients- rice, wheat, lentil and vegetables & fruits
[a]SLI: Standard of living index, was estimated using the household assets ownership (22)
[b]The residence of the patient was in other district in the state where the study hospital was based
[c]The patient presented to the study hospital as the first institute
[d]The patient was referred to the study hospital from another hospital
[e]The denominators (N) indicate valid responses received for the parameters
[f]Ragi: finger millet
The p values for some parameters could not be estimated due to small or no value in at least two groups

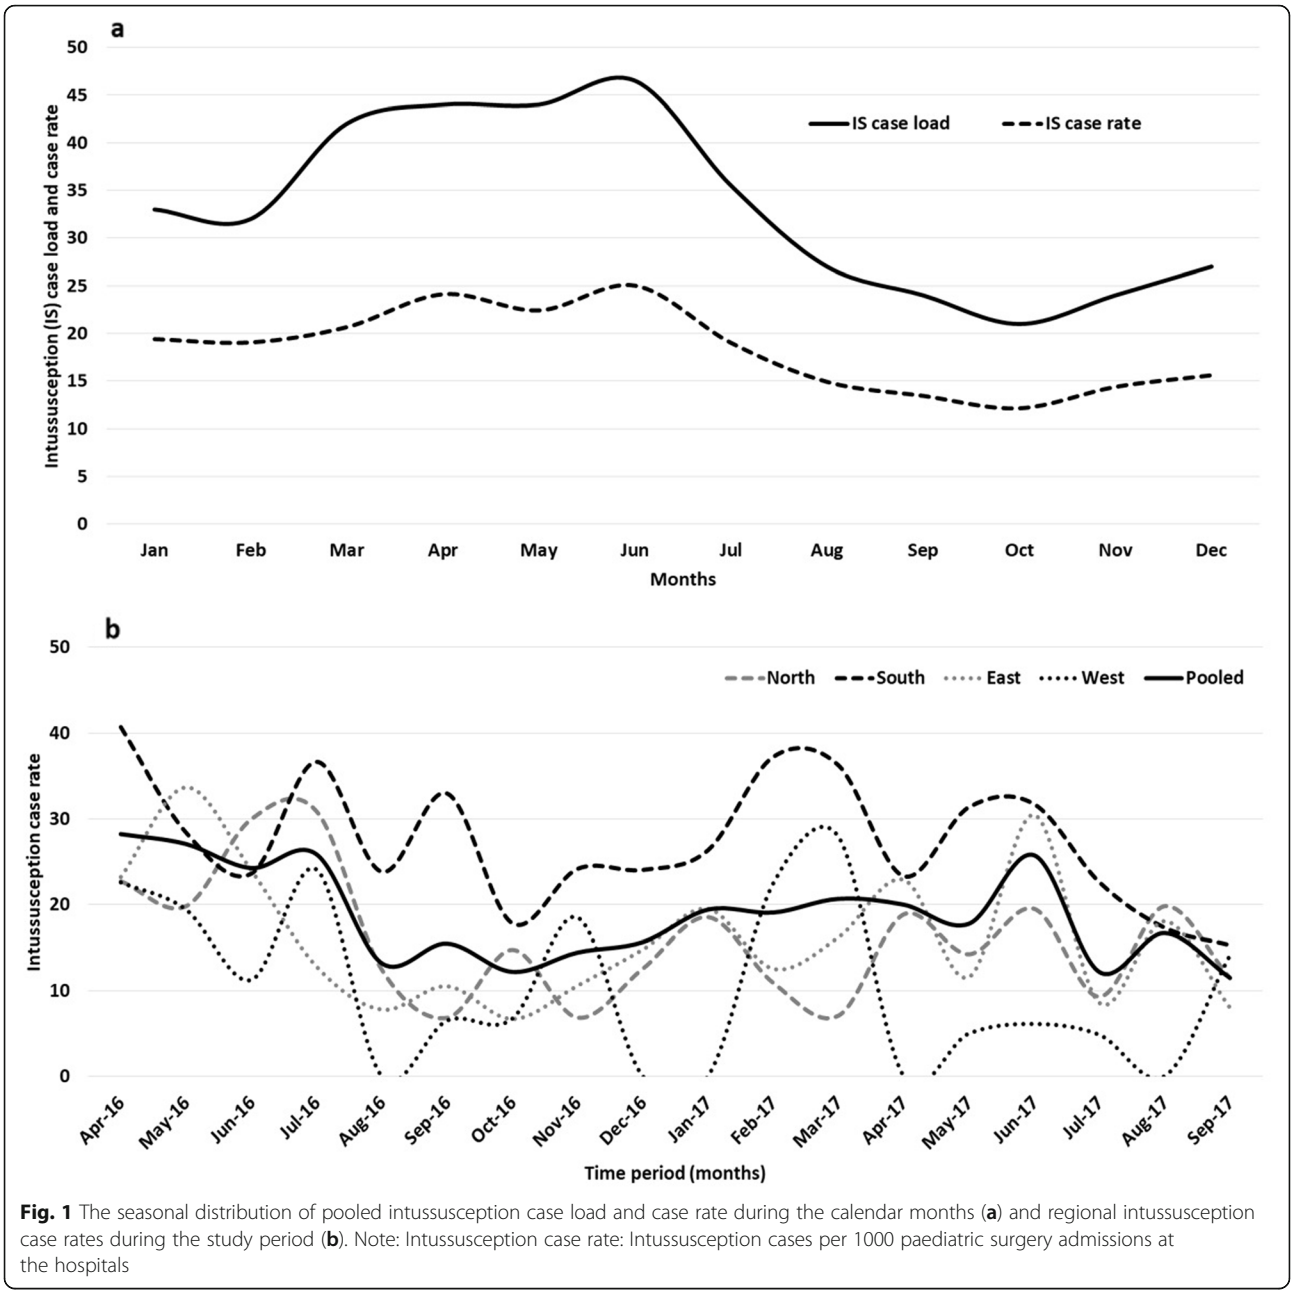

Fig. 1 The seasonal distribution of pooled intussusception case load and case rate during the calendar months (**a**) and regional intussusception case rates during the study period (**b**). Note: Intussusception case rate: Intussusception cases per 1000 paediatric surgery admissions at the hospitals

region only (where ragi based weaning practice was observed), the median interval between weaning and intussusception for ragi based food was significantly shorter (median 1 month, IQR 0–4 months) than rice (median 5 months, IQR 2–9 months) and wheat (median 3 months, IQR 2–8 months) based food ($p < 0.01$).

The pooled median interval between the onset to hospital admission was 2 days (IQR 1, 3), which varied across the regions; North- 2 days (IQR 1, 3), South- 1 day (IQR 1, 3), East- 2 days (IQR 1, 3) and West- 2 days (IQR 1, 2) ($p = 0.07$). Table 2 summarises the clinicopathological parameters and management for the recruited children. Abdominal pain or excessive crying (82.6%) was the most common symptom followed by vomiting (72.6%) and blood in stool (58.1%), as reported by the parents. More children had abdominal pain or excessive crying in North (84.6%) and East (72.6%) regions and blood in stool in the East region (73.2%). The classical triad (abdominal pain, vomiting and blood in stool) was observed in 34.8% cases, with 24.4 and 45.8% in the South and in East regions, respectively ($p < 0.01$). When blood on per-rectal examination was included, the modified intussusception triad (abdominal pain, vomiting and blood in stool or blood on per-rectal examination) was

Notes: *PR* Per-rectal, *ARI* Acute respiratory illnesses
[a]Includes all vomiting including bilious vomiting
[b]Includes only bilious vomiting
[c]Classical triad includes abdominal pain, vomiting and blood in stool
[d]Modified triad includes abdominal pain, vomiting and rectal bleeding (detected either as blood in stool or blood on per-rectal examination)
[e]The location of intussusception at more than one site; such as Ileo-colic + Colo-colic, Ileo-colic + Ileo-colo-colic, Ileo-colic + Ileo-ileo-colic, Ileo-colic + Ileo-ileal
[f]Others include cyst, Meckel's diverticulum, incisional hernia, intraluminal growth and malrotation
[g]Spontaneously resolved: The patient was managed with IV fluids and nil orally, not required any additional intervention
[h] None- No definite treatment could be provided, as the patient(s) was referred or died before any definite treatment
[i] The denominators used for percentage estimation include patients undergone surgery only
[j]LAMA: Left against medical advice
The p values for some parameters could not be estimated due to no value in at least two groups

present in 59.9% cases; 47.7% in South to 75.3% in East regions ($p < 0.01$).

Most of the cases (95.3%) were diagnosed by ultrasound. Ileocolic (84.7%) was the most common site of intussusception. A pathological lead point (PLP) was documented in 91 (14.6%) cases and lymph nodes or Payer's patch were the commonest (13.0%) and few had appendix or polyps (Table 2). While 49.3% cases were reduced, 39.5% underwent surgery and 11.1% resolved spontaneously. More children in East region (71.1%) underwent surgery followed by North region (50.0%) ($p < 0.01$). Among those who underwent surgery, 26.1% children required bowel resection, and 39.5% were from the North region. The onset-admission interval was longer for the cases who underwent surgery (median 2 days; IQR 1, 3) than reduction (median 1 day; IQR 1, 3) ($p < 0.01$) (Supplementary Table 2). Among the children who presented on the day of onset, 62.3% were managed by reduction (28.9% required surgery), which declined to 35.1% when they presented after 3 days (48.3% required surgery) ($p < 0.01$) (Supplementary Table 2). Seven hospitals (East-1, North-1, and South-1) were conducting only surgical management. At the hospitals with both facilities (reduction and surgery), 31.0% (127/404) children underwent surgery for indications: failed reduction (32.2%), late presentation (> 3 days since onset, 28.3%) and associated complications (39.3%) ($p < 0.01$). Most of the cases (97.1%) recovered and were discharged. Eleven cases (North-4 and East-7) died of post-surgery sepsis, shock and multiorgan failure. The median hospitalisation period was 3 days (IQR 2, 6 days) ranging from 2 to 5 days (South: 2 days, IQR 2, 3 days; North: 3 days, IQR 1, 7 days; West: 4 days, IQR 2, 6 days; and East: 5 days, IQR 3, 8 days; $p < 0.01$). The median hospital stay periods for children who underwent surgery, reduction and spontaneously resolved were 7 days (IQR 5, 9 days), 2 days (IQR 1, 2 days) and 3 days (IQR 2, 5 days), respectively ($p < 0.01$) (Supplementary Table 2). CAC assigned 89.1% (553/621) and 7.6% cases as Level 1 and 2 respectively according to the BCCD. Diarrhoea and acute respiratory illnesses (ARIs) within 4 weeks prior to intussusception was reported in 12.9 and 23.7% children respectively. More children from South region had history of diarrhoea (21%) and ARIs (39.7%) than other regions ($p < 0.05$).

Vaccination information was available for 487 (78.4%) children and 391 (80.2%) of those with vaccination information had no RVV exposure. Out of 96 (15.4%) children who received any RVV (RVV-1, $n = 96$; RVV-2, $n = 88$; and RVV-3, $n = 65$), 12 children received RVV in

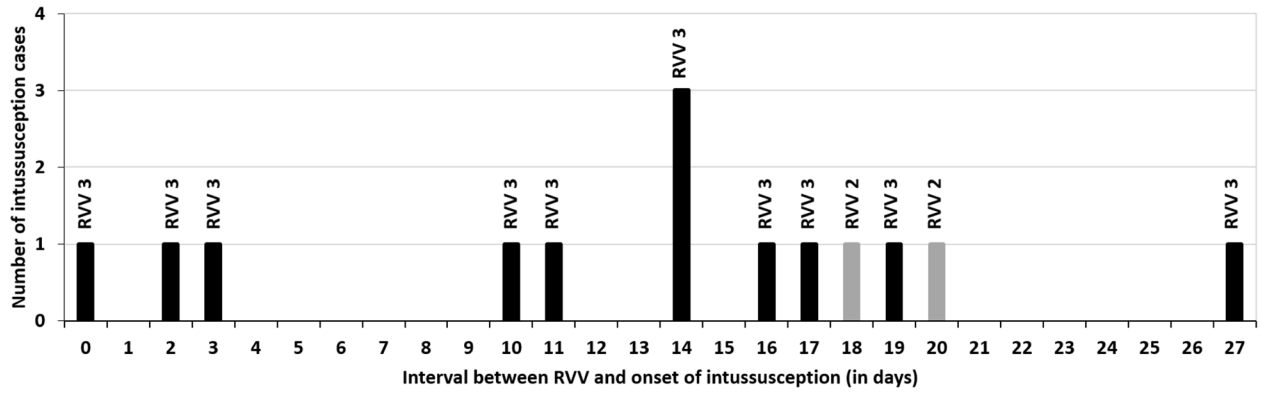

Fig. 2 Interval between last rotavirus vaccination and onset of intussusception within 28 days in the children. Note: RVV: Rotavirus vaccine

the 1–21 days preceding onset of intussusception and most ($n = 10$) after RVV-3 (median age 3.8 months, IQR 3.6, 4.2 months) (Supplementary Table 3). As shown in Fig. 2, only two cases occurred during 1–7 days after the third dose RVV and one case occurred on the vaccination day. At the four sites from three states where RVV (Rotavac™) was introduced, no increase in either intussusception case load (RR = 0.44; 95% CI 0.22, 1.18) or case rate per 1000 paediatric surgery admission (RR = 0.5; 95% CI 0.3, 1.2) during the post-RVV introduction period were observed (Table 3).

Discussion

We observed regional variances in the intussusception case load and case rate per 1000 paediatric surgery admission, high in the South region and low in the West region. Higher number of cases were observed during March to June months, which was comparable to other reports from India [14, 15, 17, 24, 25]. The male predominance (65.7%), median age at 8 months and high case load at 4–7 months of age (40.0%) were similar to other reports from India and globally (proportion of male: 63.0–77.2%; median age: 5–8 months and high case load age: 4–9 months) [14, 15, 17, 18, 21, 24, 26, 27]. About 37.0% of cases occurred during 2nd to 6th month of age, the usual age for administration of RVV. The children came from all socioeconomic categories and in all the regions. The proportion of exclusively breastfed children (< 6 months) was lower than national average (52.1%, 2015–16) [22]. The children weaned with ragi food (only in South region) had intussusception earlier (median 1 month) than those weaned with wheat (median 3 months) and rice (median 4 months) based food. A shorter exclusive breastfeeding duration with mixed feeding and some weaning foods may have some role in intussusception occurrence. Exposure to foreign proteins and enteric infections are potential risk factors for intussusception, but we couldn't find any report on association with any specific diet. There were significant variations for several sociodemographic and dietary practice parameters across the regions (Table 1). The classical triad was documented in 34.8% cases, which was higher than reports

Table 3 The intussusception cases and case ratios during post-rotavirus vaccine introduction period compared to pre-introduction periods

	Post-RVV period (Apr- Sep 2017)		Pre-RVV period (Oct 2016 - Mar 2017)				Pre-RVV period (Apr- Sep 2016)			
Region (number of sites)[a]	No of cases	IS case rate	No of cases	IS case ratio	RR (95% CI) for cases	RR (95% CI) for IS case rate	No of cases	IS ratio	RR (95% CI) for cases	RR (95% CI) for IS case rate

Pooled ($n = 4$)[a]	26	16.3	39	27.2	0.67 (0.34–1.19)	0.6 (0.3–1.18)	59	32.8	0.44 (0.22–1.18)	0.5 (0.3–1.2)

Note: *IS* Intussusception, *Intussusception (IS) case rate* Intussusception cases per 1000 paediatric surgery admission, *RVV* Rotavirus vaccine, *RR* risk ratio with 95% confidence interval (CI), *RVV*: Rotavirus vaccine

The comparison includes the data from four study sites in three states

[a]Numbers in the bracket with the regions indicate the numbers of study sites per region where RVV was introduced

Post-RVV period: April 2017 to September 2017 (6 months)

Pre-RVV period: Comparison has been done for two pre-intervention periods of 6 months each; October 2016 to March 2017- the immediate pre-RVV introduction period and April 2016 to September 2016- the calendar months comparable period during the previous year

from India (19.0%) and South Korea (7.6%), but lower than Tanzania (42.5%) [15, 24, 28]. The regional variation in the classical triad appeared to parallel with the interval between illness onset and hospitalization. Ultrasound was the commonest (95.3%) mode of diagnosis, as reported (72.0–100%) from India and other countries [15, 18, 28–30]. Ileocolic was the most common location, similar to reports (68.0–79.0%) from India and globally [3, 7, 8, 14]. PLPs observed in this study was higher than reported in studies (8.0–9.0%) from India and Tanzania with appendix and lymph nodes as the common [31, 32]. The cases who presented early were more frequently managed non-surgically with shorter stay (2–3 days) compared to those with surgical intervention (7 days). There were significant variations in the clinical features among the children across the regions, which may be due to the interval for presentation or clinical practices followed at the hospitals (Table 2). Death was observed in 1.7% cases, which was comparable to reports from India (1.0%) and other countries from Asia (0.25–6.0%), Latin America (1.0–5.0%), but lower than the African countries (2.0–25.0%) [17, 18, 24, 28, 29, 31–33]. Level 1 BCCD was met by 89.1% of the cases, similar to other reports from India [5, 7, 14]. Failed documentation of reduction prevented some cases meeting the BCCD level 1 certainty.

From the limited period of post-RVV (Rotavac™) introduction at four sites (from three states), no increase in the intussusception case load and case rate per 1000 paediatric surgery admission were observed. Intussusception within 1–21 days was observed mostly after the third RVV dose, which also overlaps with the age of natural occurrence. Under the NIP, RVV is given at 6, 10, 14 weeks of age and allowed before 12 months of age [34]. A delay in RVV administration may coincide with the high case load age of natural intussusception (4–7 months age), which may make the interpretation of association with the vaccine difficult. In routine practice, documentation of vaccine exposure should improve and appropriate guidance to parents be given regarding the subsequent RVV vaccination. Monitoring of intussusception risk is recommended for countries as part of the RVV introduction program [35, 36]. In the absence of any specific population denominator for tertiary care hospitals, estimation of incidence in Indian context is difficult. The intussusception case rate per 1000 paediatric surgery admissions may be a proxy indicator for monitoring and comparison across the sites and regions with RVV introduction.

Early suspicion, case detection and referral to appropriate hospital are critical for minimizing the surgical interventions and favourable outcomes. Efforts are needed to equip and enable the public health facilities for non-surgical management in children, though this depends on the timing of the presentation to hospital.

The epidemiology, clinical presentation and management of intussusception in children across the regions may serve as baseline for future studies. The regional representation and mix of private- and public-sector hospitals were the advantages for this surveillance.

This study had some limitations. In absence of definite catchment population and referral pattern, population-based incidence or case rate estimation was not possible. The etiologies and risk factors for intussusception were not studied.

Conclusion

To conclude, the intussusception cases were seen all across the country and the majority of the cases occurred during the first year of life. The high case load age (4–7 months) for intussusception in children coincided with the age of RVV third dose. Some variations in case loads across the different regions and seasonality were observed. The potential role of diet exposure, weaning practices and food like ragi in intussusception needs further evaluation. No increased occurrence of intussusception cases was observed during the limited RVV post-introduction period. Early case detection, prompt referral and appropriate management are needed to avoid surgical intervention and complications. Immunization exposure must be documented to assess the vaccine associated risk. In absence of population-based incidence or case rate, the intussusception case rate per 1000 paediatric surgery admission may be used for inter-regional comparison and trend monitoring.

Acknowledgments

We acknowledge the support from Ministry of Health and Family Welfare, Government of India for undertaking the study. We are thankful to the hospital administrations and the clinicians at the study site institutes, who supported and facilitated conduct of the study.

We highly value the technical guidance and inputs provided by the members of Technical Advisory Group: Satinder Aneja, Anju Seth and Archana Puri, Lady Hardinge Medical College, New Delhi; Ashok Patwari, Hamdard Institute of Medical Sciences & Research, New Delhi; Yogesh Kumar Sarin, Maulana Azad Medical College, New Delhi; Rakesh Aggarwal, Anshu Srivastava and Ujjal Poddar, Sanjay Gandhi Postgraduate Institute of Medical Sciences, Lucknow; Malathi Satyasekharan, Kanchi Kamakoti Childs Trust Hospital, Chennai; Raju Sharma and Nirupam Madan, All India Institute of Medical Sciences, New Delhi; Jyoti Joshi and Deepak Polpakara, Immunization Technical Support Unit; Ministry of Health & Family Welfare, New Delhi; Umesh D. Parashar; Centers of Disease Control and Prevention, Atlanta, USA; Naveen Thacker, Child Health Foundation, Gandhigram; and Rashmi Arora, Indian Council of Medical Research, Ansari Nagar, New Delhi.
We acknowledge the contribution of the research staffs at The INCLEN Trust International:
Harshpreet Kaur, Janvi Chaubey, Mrinmaya Das, Shweta Sharma and Vaibhav Jain.
We highly appreciate the efforts made by the research staffs at the study sites: Aarezo Bashir and Rafia; Sher-I-Kashmir Institute of Medical Sciences, Srinagar, Jammu & Kashmir; Prabha Shankar, Medanta-The Medicity Hospital, Gurgaon, Haryana; Anju Sharma; Maulana Azad Medical College, New Delhi; Anita Singh and Shubhranshu Srivastava, King George Medical University, Lucknow, Uttar Pradesh; Hemant Meena, Choithram Hospital, Indore, Madhya Pradesh; Pankaj Kumar and Shashi Kant; Indira Gandhi Institute of Medical Sciences, Patna, Bihar; Goutam Benia, IMS & SUM Medical College & Hospital, Bhubaneshwar, Odisha; Prasantajyoti Mohanty, SVP Post Graduate Institute of Paediatrics and SCB Medical College, Cuttack, Odisha; Angshuman Chatterjee, Institute of Postgraduate Medical Education and Research & SSKM Hospital, Kolkata, West Bengal; S. Yamuna, Andhra Medical College, Vishakhapatnam, Andhra Pradesh; Srinidhi Sudam, Apollo Hospitals, Hyderabad, Telengana; Rajesh Francis, Apollo Hospitals, Chennai, Tamil Nadu; T. Easter Chandru, PSG Institute of Medical Sciences, Coimbatore, Tamil Nadu; Deepthy R, Julie and Anju Shivakumar, Government Medical College & SAT Hospital, Thiruvananthapuram, Kerala; Archit Vaidya, Grant Medical College & JJ Hospital, Mumbai, Maharashtra; Nimesh Chouksey, MP Shah Government Medical College, Jamnagar, Gujarat; Nidhi Singh, Fortis Escorts Hospital, Jaipur, Rajasthan; Mrinmoy Gohain, Gauhati Medical College, Guwahati, Assam; Arpita Bhattachrjee, Saugat Ghosh and Tanusmita Debnath, Agartala Government Medical College, Agartala, Tripura.

ABSTRACT

Objectives To document and share the process of establishing the nationally representative multisite surveillance network for intussusception in India, coordination, data management and lessons learnt from the implementation.

Design This study combined both retrospective and prospective surveillance approaches.

Setting 19 tertiary care institutions were selected in India considering the geographic representation and public and private mix

Participants All children under-2 years of age with intussusception

Primary and secondary outcome measures The experience of site selection, regulatory approvals, data collection, quality assurance and network coordination were documented.

Results The site selection process involved systematic and objective four steps including shortlisting of potential institutions, information seeking and telephonic interaction, site visits and site selection using objective criteria. Out of over 400 hospitals screened across India, 40 potential institutions were shortlisted and information was sought by questionnaire and interaction with investigators. Out of these, 25 institutes were visited and 19 sites were finally selected to participate in the study. The multistep selection process allowed filtering and identification of sites with adequate capacity and motivated investigators. The retrospective surveillance documented 1588 cases (range: 14–652 cases/site) and prospective surveillance recruited 621 cases (range: 5–191 cases/site). The multilayer quality assurance measures monitored and ensured protocol adherence, complete record retrieval and data completeness. The key challenges experienced included time taken for obtaining regulatory and ethical approvals, which delayed completion of the study. Ten sites continued with another multisite vaccine safety surveillance study.

Conclusion The experience and results of this systematic and objective site selection method in India are promising. The systematic multistep site selection and data quality assurance methods presented here are feasible and practical. The lessons from the establishment and coordination of this surveillance network can be useful in planning, selecting the sites and conducting multisite and surveillance studies in India and developing countries.

Strengths and limitations of this study

- ► Provides a systematic study site selection process using objective methodology.
- ► Documents the experience with prospective and retrospective surveillance data collection with multilayered data quality assurance process.
- ► The study site selection and quality assurance measures may serve as reference for suitable adaptation in different research topics and contexts.
- ► The lessons are applicable only to the multisite studies.
- ► The documentation of contractual and financial management challenges may be limited.

INTRODUCTION

Intussusception is an acute emergency in children and most commonly occurs in infants aged 4–10 months.[1 2] Although some are transient and resolve spontaneously, if not intervened timely, it may lead to bowel ischaemia and perforation and may even be fatal.[1] Intussusception has been reported as an adverse reaction with rotavirus vaccines (RVV) with variable risks ranging from no increased risk to low risk (1–2 additional cases per 100 000 vaccinated infants) across different countries with different RVVs.[3–12] The intussusception background rate varies widely across different countries, 9 (Bangladesh) to 328 (South Korea) per 100 000 infants.[13] Limited information from India reported its incidence between 17.7 and 254 cases per 100 000 child years.[14 15] Several other studies were single or few centre studies and varied in case definitions, age groups, reference periods and methodology.[12–14]

In view of the vaccine safety concern and limited information on intussusception in India, the National Technical Advisory Group (TAG) on Immunisation recommended

BMJ Open: first published as 10.1136/bmjopen-2020-046827 on 28 May 2021. Downloaded from http://bmjopen.bmj.com/ on May 28, 2021 at India:BMJ-PG Sponsored. Protected by copyright.

vaccine safety surveillance along with RVV introduction.[16] This surveillance network aimed to generate background information on intussusception epidemiology Indian children to inform the policy and programme related to RVV introduction and serve as baseline for future surveillance to identify any change after vaccine introduction and address the vaccine safety concerns. The objectives were to: (1) establish a surveillance network of public and private hospitals ensuring regional representation and data capturing system; (2) undertake retrospective surveillance to document the intussusception epidemiology over past 5 years; (3) undertake prospective surveillance to document the intussusception epidemiology over 18 months and potential linkage with RVVs and (4) build capacity of the investigators and institutions.

Multicentre studies face several challenges related to design, site selection, regulatory approvals, study conduct, coordination, data management and dissemination.[17–20] The lessons from multisite studies in India are limited. The intussusception surveillance study has been successfully completed and the network has evolved over time to undertake more vaccine safety studies. The purpose of this paper is to share the process of network establishment, coordination, data management and lessons learnt from such nationwide network research.

METHODS

Study design

This study combined both retrospective and prospective surveillance. The experiences and lessons presented here are based on the concurrent documentation of processes and retrospective review of the study documents.

Study governance

The Central Coordinating Unit (CCU) constituted investigators, research staffs and administrative and finance team. For technical integrity and implementation monitoring, a TAG was constituted with 17 Indian and international experts in vaccine safety, surveillance, immunisation programme, public health, child health, paediatric surgery, radiology and medical record system, representation from Ministry of Health and Indian Council of Medical Research.

Site selection

We followed a four-step systematic study site selection process (figure 1). *Step 1 (Shortlisting):* We categorised the states into four regions (north, south, east and west) and screened the tertiary care hospitals (medical colleges and private hospitals) in these regions from the websites. *Step 2 (Screening):* We solicited information about the case load, clinical and diagnostic capacities (paediatrics, paediatric surgery and radiology), medical record system, ethical and administrative approvals from the shortlisted institutions using questionnaire and telephonic interactions (online supplemental document 1). *Step 3 (Evaluation):* A TAG member visited the institutions to assess the institution capacity (clinical facility, case documentation, research support system and medical record-keeping system) and interacted with the potential investigator(s), department and institution leaderships to assess the commitment, institution support and research environment (online supplemental document 2). *Step 4 (Site finalisation):* Based on the questionnaire, interaction with investigators and TAG member feedback, the study sites were finalised.

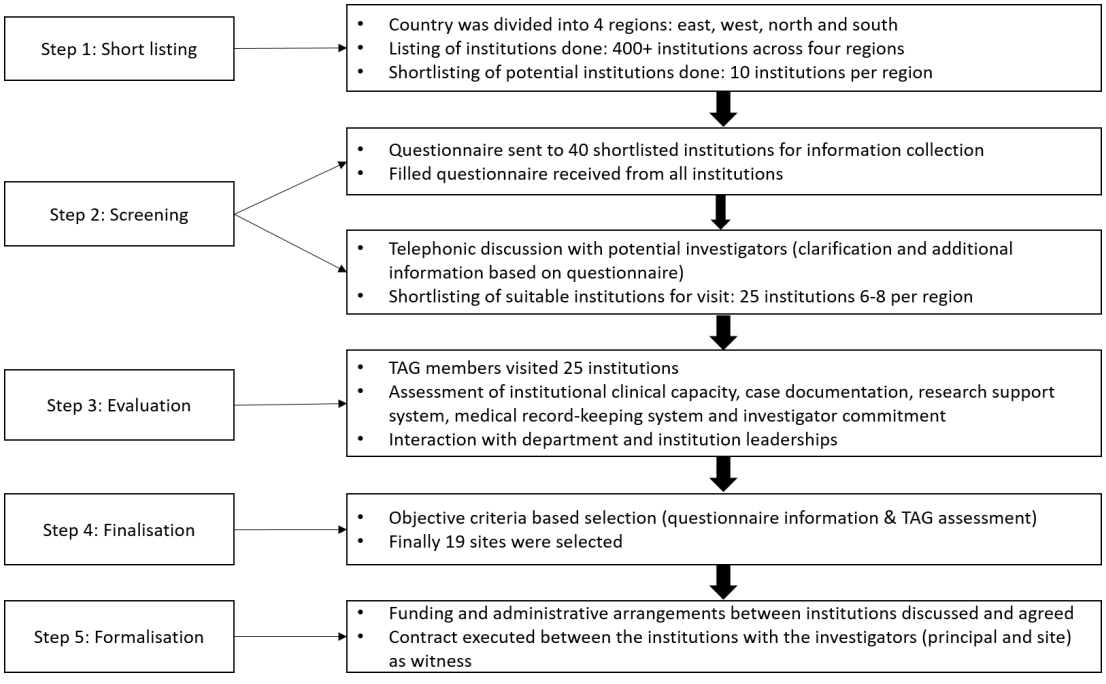

Figure 1 The steps of the site selection process. TAG, Technical Advisory Group.

Protocol finalisation and study tool development

In multisite research projects, consensus building among the investigators on the study protocol, case record forms (CRFs), data management and monitoring are critical. The study protocol and CRFs were shared and piloted at the study sites. The protocol, study tools, implementation, data management and monitoring were discussed in detail during protocol finalisation workshop involving lead investigators from all sites and TAG members.

Regulatory procedures

As this study involved international funding, the approval from Health Ministry Screening Committee (HMSC) was obtained. The study protocol documents were submitted to the participating institutes for ethical approvals. Following the ethical approval, the study was implemented at the sites.

Study implementation process

Before implementation of the study at the sites, the following four items had to be completed: (1) institute administrative approval; (2) ethical approval; (3) agreement executed with the institution and (4) research staff selected and trained.

Data collection, management and monitoring

Separate CRFs and log sheets were prepared for the retrospective and prospective data collection. The retrospective data collection involved multiple sources; case records, registers from different departments and operation theatres and medical records section. For case record retrieval, the sites following International Classification of Diseases (ICD, ICD-9 or ICD-10) system, the ICD codes for intussusception or acute abdomen conditions were used (online supplemental document 3) (published in methodology paper).[21] At the other sites, cases were identified as per the diagnoses. For the prospective data collection, all admitted children were screened to identify the suspected cases, who were followed till final diagnosis. The children with intussusception were recruited and data collected. A weekly reporting from the sites was solicited for tracking progress. Initially, a weekly call with the study teams and later fortnightly to monthly calls were done to monitor the progress and address challenges. Based on the data collection progress reports, a monthly bulletin was prepared indicating the progresses and data quality. The completed study tools were sent periodically to CCU. The data received at CCU were reviewed for completeness, correctness and queries were resolved with reference to the source documents. Double data entry was done using customised data entry platform with inbuilt data matching programme. The data were archived in the server with authorised access and regular backup. Data analysis was done by under guidance of TAG. The data collection, flow and management followed for prospective and retrospective surveillance are shown in figures 2 and 3.

Quality assurance measures

Multiple quality assurance measures focused on protocol adherence and data quality. After initiation of data collection, TAG members visited each study site during the retrospective surveillance to verify: (a) protocol adherence; (b) identification of suitable cases and (c) data abstraction. The corrections/clarifications and repeat training was imparted as per TAG observations. After 6 months, during the prospective surveillance, TAG member again visited to review the: (a) patient screening; (b) tracking and eligible patients identification; (c) obtaining consent; and (d) data abstraction.

Patient and public involvement

No patients or the public were involved in the design, conduct, reporting and dissemination of research.

RESULTS

Study timelines

The study was sanctioned in November 2014. The HMSC application was submitted in December 2014 and approved in May 2015. The formal study site selection initiated after the HMSC approval and was completed by August 2015. The protocol finalisation workshop was held in October 2015. Following the ethical approvals, the retrospective surveillance was initiated at majority of the sites in February 2016. The prospective surveillance was initiated in April 2016 and continued through September 2017. The data entry, cleaning and analysis and report drafting were completed by June 2018.

Study site selection

Out of over 400 hospitals screened across regions, 40 potential hospitals/institutions (10 per region) were shortlisted. While preparing the database, many institutions did not have adequate information on their websites about the facilities and faculty members or specialists. The potential investigators from these 40 shortlisted institutions were invited to submit desired information using a questionnaire via email and all responded. Telephonic discussions was held with the potential investigator(s) from these institutions (45–60 min) for additional information or clarifications. Based on the criteria and consultation with TAG, 25 institutes were visited. Based on the questionnaire, interactions and TAG member assessment, 19 institutions (north region: 5 sites, 3 public and 2 private; south region: 5 sites, 2 public and 3 private; east region: 6 sites, 5 public and 1 private; west region: 3 sites, 2 public and 1 private) were selected (figure 4). The study originally planned for 17 sites. Two more sites from the states where RVV was scheduled for introduction were added later. Several potential investigators requested the CCU team to discuss with their institute leadership for permission and allow him/her to lead the project. The CCU team succeeded in all expect two institutions, which could not be included. The site selection process was delayed by 7 months due to the delay in HMSC approval.

Regulatory approvals

The ethics approvals from the sites needed average 4 months (range: 1–8 months). No protocol amendment was needed.

Data collection

During July 2010 and March 2016 (retrospective surveillance period), out of 42 866 admitted under-2 years children, 2092 suspected cases were identified and 1588 confirmed intussusception cases were recruited.[22] The cases recruited at study sites ranged from 14 to 652. While five sites documented <20 cases each, two sites contributed >100 cases each. During April 2016 and September 2017 (prospective surveillance period), out of 6300 hospitalised under-2 years children, 1203 suspected cases were identified and 621 confirmed intussusception cases were recruited.[23] The cases recruited at the study sites ranged from 5 to 191 cases. While seven sites recruited <10 cases each, three sites contributed >50 cases each. At one study site, very few cases were retrieved from the retrospective and prospective surveillance, contrary to the anticipation. The descriptive data analysis was done at pooled and regional levels to document the epidemiology of intussusception. The variables and data parameters between the regions were compared with identify the similarities and differences.

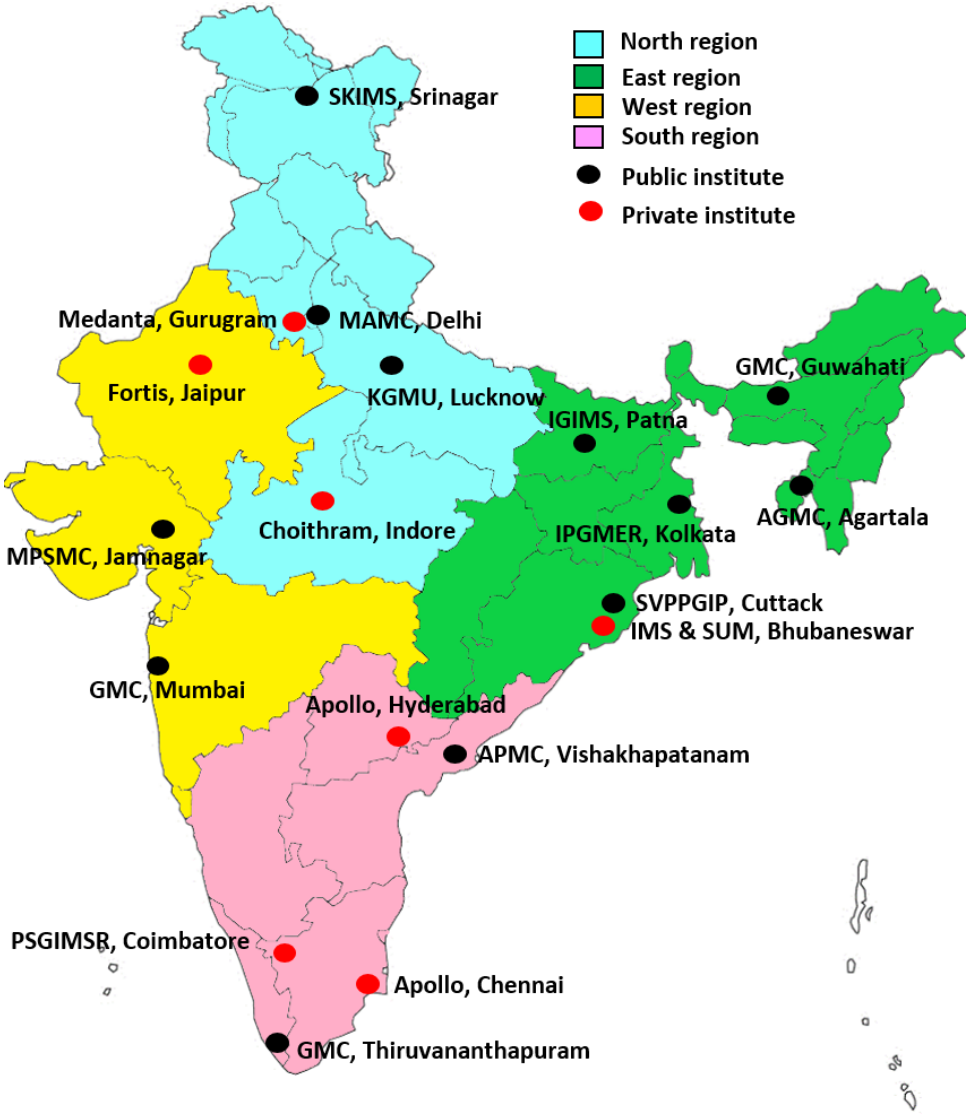

Figure 4 The geographic distribution of the network study sites. Note: The image was created for the research project by the investigators.

Medical record retrieval

Twelve (seven private and five public) institutions had electronic medical record (EMR) system. The ICD system was used at all sites except the two private hospitals, where the diagnosis was used for listing and archival. The medical records were accessible at all study sites except one site, where the research staff faced challenge in timely and adequate access to the medical records. The medical records required organisation at this site and thus the retrospective data collection took longer. The record retrieval was quicker at institutions with EMR system and retrospective data collection was completed in 2–4 months. At two sites, the retrospective data collection took longer 6 and 10 months, due to higher case load and challenge in record retrieval, respectively.

Radiology documentation

The ultrasound digital images and report were available for all prospectively recruited cases. There were variations in the ultrasound finding documentations and details in the reports, which required clarification from the radiologist for data capturing. Ultrasound reports were available at all but one hospital, where the findings were recorded in the case sheet. Digital records of ultrasounds were stored for minimum 3 months to 5 years. These ultrasound reports, digital films and clinical records were reviewed by independent TAG members for confirmation and classification according to Brighton Collaboration Criteria.[1]

Vaccination information

Majority of the parents were not carrying the vaccination card at the time of hospitalisation and about half of them came from outside the city. The research staffs pursued to obtain the vaccination card during hospitalisation and after discharge. The vaccination card after discharge was obtained through email, mobile message and also self-addressed and stamped envelopes handed over to the parents. The vaccination information was available for 78.4% of the prospective cases.

BMJ Open: first published as 10.1136/bmjopen-2020-046827 on 28 May 2021. Downloaded from http://bmjopen.bmj.com/ on May 28, 2021 at India:BMJ-PG Sponsored. Protected by copyright.

Clinical case management

At five sites only surgery was done. At two sites, reduction was available during daytime only and surgery during other period and at 12 sites, both methods were available always.

Data quality assurance

TAG members made two quality assurance visits, first during the retrospective surveillance period, second during the prospective surveillance period and provided written feedback. The retrospective surveillance was at risk of missing cases. As it was difficult to compare the absolute case numbers across the centres and periods, we derived intussusception case rate per 1000 paediatric surgery admissions. After completion of 1 year of prospective surveillance, third quality assurance visit was made by the data management team to 11 sites with >30% differences in the case rates between retrospective and prospective periods. The team targeted verifying the confirmed cases, suspected cases and total admissions during 2015, 2016 and 2017 (until visit). The team identified three missed cases (one each at three sites).

Investigators commitment and transition

Despite the systematic selection process, the involvement of the investigators in the day-to-day operations and data verification was lesser than expected at three sites. At three sites, the lead investigators transitioned without any impact on the study activities.

Research staff issues

Although one research staff per site was planned, at seven sites, two research staffs were engaged considering the efforts needed for data retrieval and case load. These research staffs were trained through regional training workshops followed by hands-on training. At eight sites, the research staffs changed during the study period, once at six sites and twice at two sites. All the new staffs were trained by the CCU team member through site visit followed by virtual support. The investigators swiftly ensured replacements and no loss of cases. At CCU, there were three rounds of research staff transition.

Intradepartment and interdepartment coordination

At all institutions the nurses, residents and faculty members supported the surveillance. The nurse and residents at most places informed the research staff about any confirmed case, even on holidays. If the patient was discharged on any holiday, the research staffs attended and collected the data. Intradepartmental and interdepartmental coordination for data collection were smooth at all sites except two sites, where the participation from paediatric department was limited. As most of the intussusception cases were directly admitted to or transferred to paediatric surgery department on diagnosis, it did not affect the case screening and recruitment.

Financial management

In view of the foreign funding source and Foreign Contribution Regulation Act (FCRA) regulation, the funds could not be transferred to most institutes without FCRA approval. Thus, the fund was managed by the CCU for most of the institutes. Despite no fund transferred to the institutes, agreements were executed between the institutes with the investigators as the witnesses. We experienced challenges with some institutes in explaining the FCRA obligations prior to agreement execution.

Study tenure

Although planned for 30 months, the study was completed in 43 months. The delays in HMSC and ethics approval at sites were the key reasons for the delay.

Dissemination

Five peer-reviewed manuscripts have been published and seven manuscripts are under review or in preparation. The manuscripts have all the site investigators as authors, either individually or as group. The findings have been shared with the Ministry of Health and Family Welfare, WHO and other key partners. Over 22 oral presentations had been made at national, regional and international meetings.

Capacity building and transition

After this study, several sites were included in other studies coordinated by the CCU, 10 sites in one study and four sites in another study. Four site investigators collaborated in other research projects. Several of the research staffs at these sites continued with the new studies.

DISCUSSION

This multicentre sentinel surveillance successfully generated clinical and sociodemographic epidemiology information on intussusception in children including the regional the variations. The network adopted a systematic site selection process. A common understanding among the investigators was ensured and transmitted to the research staffs for appropriate implementation. The effective coordination, data management and quality assurance measures ensured high-quality data. Despite the efforts, there were challenges related to the regulatory and administrative challenges, which affected the implementation timelines. The continuation of several sites and investigators in other studied demonstrated the strong collaboration and confidence coupled with capacity building.

Poor site selection can lead to delay in completion, rise in cost, protocol amendment, implementation variations or study failure.[24] Studies have used different site selection processes: active hunting, peer referrals, inviting expression of interests, engaging research organisations, etc.[25–27] Our organisation has been conducting multisite network studies (ranging from 5 to 84 partner institutions) over last 15 years. We have adopted variable combination of

BMJ Open: first published as 10.1136/bmjopen-2020-046827 on 28 May 2021. Downloaded from http://bmjopen.bmj.com/ on May 28, 2021 at India:BMJ-PG Sponsored. Protected by copyright.

processes for the study site and investigators selection, which have evolved over time. For this study, we adopted a systematic site selection process, which appeared lengthy and required several rounds of interactions. The four-step process assisted in identifying the highly motivated investigators and study sites with desired capacity. The potential investigators who failed to return the questionnaire with desired information or participate in the interaction are unlikely to devote time for study conduct and supervision. The systematic selection process allowed reducing the potential sites to a manageable number of suitable sites that were further assessed through visit. While the process was lengthy, it allowed also to build common understanding and commitment for the study. These experiences were similar to some multicounty studies.[25 27 28] The experiences from longer tenure clinical trial network (CTN) suggest that adoption of objective, standardised and systematic approach of site selection has better performance than an informal process. A CTN experimenting interventions for substance abuse moved from informal site selection process initially to five-step process including identification of potential sites, site selection surveys, pilot simulation data abstraction, blinded review, site selection interviews or site visits.[27] A CTN experimenting surgical interventions adopted five-step site selection process including open call, site capacity survey and pilot simulation data abstraction, criteria-based evaluation, telephonic interview and final assessment for selection.[25] The steps adopted were comparable to the steps adopted in our study.

The procedural efforts and time taken for ethical approval from the site institutes are well known. A review observed that the study site ethics approval took from 5 to 798 days and the review process and contents varied widely.[29] The ethics review process consumed sizeable staff hours and budget, forcing timeline extension and budget shortfall.[29–31] In our study also, the documentation and formats used for submission varied widely, apart from the study protocol, CRFs and consent forms. Some of the committees asked the investigators to present their protocol, while others did not.

Although the investigators were responsible for the conduct of the study, the agreements with institutions assisted in implementation of the study. The involvement of external experts TAG as in study site selection and monitoring facilitated standardisation and quality assurance. The additional data retrieval and verification effort at the sites documented the protocol adherence and robustness of data collection.

This is the first documentation of systematic site selection process for a multisite network in India. The positive experience from this study encouraged adoption of similar systematic site selection and data quality assurance mechanism for subsequent two vaccine network studies in India.

There are some limitations in the current study and documentation. While many of the lessons may be generic and have relevance for most of the multisite studies, some of them may be relevant for India and the developing countries. The documentation of contractual and financial management challenges may be limited. The study was not a clinical trial and did not involve any laboratory procedures. This was a descriptive study and had no comparison or control arm to compare the experience.

CONCLUSIONS

In conclusion, our experience with this systematic study site selection process was positive and satisfying. It used a four-step selection process using questionnaire, objective criteria for assessment and interactions with the investigators and institution stakeholders with site visits to identify suitable sites with adequate capacity. The participation of motivated instigators, agreement with the institutions and contributory protocol and tool development facilitated successful completion. Difficulties and delays in site initiation were primarily due to the regulatory and administrative approvals. The multistep site selection adopted is feasible and practical even in Indian context. The quality assurance processes also assisted in high-quality data collection. We hope that the site selection and quality assurance processes would be informative for multisite studies in India and developing countries and appropriate adaptation or modifications may be needed as per the objectives and implementation protocol of the network studies.

Acknowledgements We acknowledge the support from Ministry of Health and Family Welfare, Government of India for undertaking the study. We are thankful to the hospital administrations and the clinicians at the study site institutes, who supported and facilitated undertaking of the study. We highly value the technical guidance and inputs provided by the members of Technical Advisory Group: Satinder Aneja, Anju Seth and Archana Puri, Female Hardinge Medical College, New Delhi; Ashok Patwari, Hamdard Institute of Medical Sciences & Research, New Delhi; Yogesh Kumar Sarin, Maulana Azad Medical College, New Delhi; Rakesh Aggarwal, Anshu Srivastava and Ujjal Poddar, Sanjay Gandhi Postgraduate Institute of Medical Sciences, Lucknow; Malathi Satyasekharan, Kanchi Kamakoti Chailds Trust Hospital, Chennai; Raju Sharma and Nirupam Madan, All India Institute of Medical Sciences, New Delhi; Jyoti Joshi and Deepak Polpakara, Immunisation Technical Support Unit; Ministry of Health & Family Welfare, New Delhi; Umesh D Parashar; Centres of Disease Control and Prevention, Atlanta, USA; Naveen Thacker, Child Health Foundation, Gandhigram; and Rashmi Arora, Indian Council of Medical Research, Ansari Nagar, New Delhi. We acknowledge the contribution of the research staffs at The INCLEN Trust International:Harshpreet Kaur, Janvi Chaubey, Mrimmaya Das, Shweta Sharma and Vaibhav Jain. We highly appreciate the efforts made by the research staffs at the study sites: Aarezo Bashir and Rafia; Sher-e-Kashmir Institute of Medical Sciences, Srinagar, Jammu & Kashmir; Prabha Shankar, Medanta-The Medicity Hospital, Gurgaon, Haryana; Anju Sharma; Maulana Azad Medical College, New Delhi; Anita Singh and Shubhranshu Srivastava, King George Medical University, Lucknow, Uttar Pradesh; Hemant Meena, Choithram Hospital, Indore, Madhya Pradesh; Pankaj Kumar and Shashi Kant; Indira Gandhi Institute of Medical Sciences, Patna, Bihar; Goutam Benia, IMS & SUM Medical College & Hospital, Bhubaneshwar, Odisha; Prasntajyoti Mohanty, SVP Post Graduate Institute of Paediatrics, Cuttack, Odisha; Angshuman Chatterjee, Institute of Postgraduate Medical Education and Research & SSKM Hospital, Kolkata, West Bengal; S Yamuna, Andhra Medical College, Vishakhapatnam, Andhra Pradesh; Srinidhi Sudan, Apollo Hospitals, Hyderabad, Telengana; Rajesh Francis, Apollo Hospitals, Chennai, Tamil Nadu; T Easter Chandru, PSG Institute of Medical Sciences, Coimbatore, Tamil Nadu; Deepthy R, Julie and Anju Shivkumar, Government Medical College & SAT Hospital, Thiruvananthapuram, Kerala; Archit Vaidya, Grant Medical College & JJ Hospital, Mumbai, Maharashtra; Nimesh Chouksey, MP Shah Government Medical College, Jamnagar, Gujarat; Nidhi Singh, Fortis Escorts Hospital, Jaipur, Rajasthan; Mrinmoy Gohain, Gauhati Medical College,

ABSTRACT

Objectives The study aimed to document the association between intussusception in Indian children and meteorological parameters and examine regional variations.

Design A bidirectional (retrospective and prospective) surveillance between July 2010 and September 2017.

Setting At 20 hospitals in India, retrospective case record review during July 2010 and March 2016 and prospective surveillance during April 2016 and September 2017 were performed.

Participants 2161 children aged 2–24 months with first intussusception episode were included.

Interventions The monthly mean meteorological parameters (temperature, sunshine, rainfall, humidity and wind speed) for the study sites were collected.

Methods The association between monthly intussusception cases and meteorological parameters was examined at pooled, regional and site levels using Pearson (r) and Spearman's rank-order (ρ) correlation, factorial analysis of variance, and Poisson regression or negative binomial regression analyses.

Results The intussusception cases were highest in summer and lowest in autumn seasons. Pearson correlation analysis showed that temperature (r=0.056; p<0.05), wind speed (r=0.134; p<0.01) and humidity (r=0.075; p<0.01) were associated with monthly intussusception cases. Spearman's rank-order correlation analysis found that temperature (ρ=0.049; p<0.05), wind speed (ρ=0.096; p<0.01) and sunshine (ρ=0.051; p<0.05) were associated with monthly intussusception cases. Poisson regression analysis resulted that monthly intussusception case was associated with rising temperature (North region, p<0.01 and East region, p<0.05), sunshine (North region, p<0.01), humidity (East region, p<0.01) and wind speed (East region, p<0.01). Factorial analysis of variance revealed a significant seasonal difference in intussusception cases for pooled level (p<0.05), 2–6 months age group (p<0.05) and North region (p<0.01). Significant differences in intussusception cases between summer and autumn seasons were observed for pooled (p<0.01), children aged 2–6 months (p<0.05) and 7–12 months (p<0.05).

Conclusions Significant correlations between intussusception cases and temperature, humidity, and wind speed were observed at pooled and regional level in India. A peak in summer months was noted, which may be used for prediction, early detection and referral for appropriate management of intussusception.

Strengths and limitations of this study

- ► This study included intussusception cases in children from 20 sites in India representing different geographical and climate regions.
- ► A relatively large number of intussusception cases in children over 7 years were analysed at pooled, regional and site levels using multiple statistical tests for consistency and triangulation.
- ► Consistency in the correlation between meteorological parameters and intussusception using multiple statistical tests was reassuring.
- ► Data for over 5 years, collected by retrospective surveillance, may be a limitation.

INTRODUCTION

Intussusception is the most common acute abdomen with intestinal obstruction in children, mostly occurring in infants.[1 2] The incidence of intussusception varies widely with a mean of 74 per 100 000 (range: 9–328) among infants with the peak during 5–7 months of age.[3] The available reports from India suggest that intussusception incidence varies from 17.7 to 254 per 100 000 child-years.[4 5] These children usually present with abdominal pain or excessive crying, vomiting, bloody stools and may have abdominal mass. Ultrasound is the leading diagnostic tool. The majority of the patients can be managed by reduction method and some may need surgery. The aetiology of intussusception remains unknown in the majority of cases.[6]

Intussusception has attracted attention due to its association with the rotavirus vaccine (RVV).

BMJ Open: first published as 10.1136/bmjopen-2020-043687 on 25 May 2021. Downloaded from http://bmjopen.bmj.com/ on May 25, 2021 at India:BMJ-PG Sponsored. Protected by copyright.

India introduced RVV under the universal immunisation programme in 2016 and it expanded country-wide by 2019. A recent publication by our group reported regional variation in intussusception cases among Indian children under 2 years of age.[7] More number of cases were observed during March–June (summer months), suggesting seasonal variation. Other studies from India also reported seasonal variations.[5 8–11] There is variation in the seasonality of intussusception occurrence globally. A higher number of intussusception cases have been reported during warmer months from some countries,[12–16] while no seasonal variation was reported from other countries.[17–23] Reports from China found the intussusception caseload to be associated with meteorological parameters like temperature, sunshine and humidity.[12 24] In several reports from different countries, the association between meteorological factors and intussusception remains unclear, due to various reasons, including shorter study duration, smaller sample size and no definite statistical methods to explore the association. Although seasonal variations have been observed, no association between intussusception and meteorological parameters has been reported from India.

Multisite surveillance in India documented the epidemiology and trend of intussusception in children as part of the vaccine safety surveillance linked to the RVV introduction. Using the data collected by the Indian surveillance network, this study investigated the possible association between intussusception cases and various meteorological parameters and seasonality at the site, regional and national levels.

METHODS

Study area and participating hospitals

This hospital-based sentinel surveillance for intussusception in under 2-year-old children at 20 tertiary care hospitals in India included both prospective and retrospective periods. This bidirectional surveillance was comprised of retrospective (1 July 2010–31 March 2016) and prospective (1 April 2016–30 September 2017) periods of data collection. The study sites were selected from four regions (North, South, East and West) of the country, ensuring a mix of public and private tertiary care hospitals (North: three public and two private; South: two public and three private; East: five public and one private; West: two public and one private) (online supplemental figure 1). The study sites represented different climate zones in India. The method of study site selection has been detailed in the protocol published.[25]

Case definition, case selection and data collection

Children aged 2–24 months admitted to these hospitals with intussusception were eligible. For the retrospective surveillance period, the potential cases were identified using the International Classification of Diseases 9/10 or the diagnoses in the medical record section (online supplemental table 1). These case records were reviewed to identify the intussusception cases and all identified cases were recruited. For the prospective surveillance period, all age-eligible children were screened and tracked until final diagnosis, and all intussusception cases were recruited after written informed consent. Only the first intussusception cases were included in the analysis. The cases with the first episode of intussusception were identified from the history and/or from parents. For the confirmed cases, data including demography, clinical features, management and outcome were abstracted using case record forms. External experts visited the study sites to assess the protocol adherence for case selection, record retrieval and data abstraction. Data team members visited the sites and repeated the case retrieval process for the years 2014, 2015 and 2016 to assess the retrieval completeness. The data queries were clarified referring to the source documents.

Meteorological data collection

For the study sites, monthly mean meteorological data including temperature (°C), sunshine (total hours), rainfall (mm), humidity (%) and wind speed (km/hour) were collected from the website, World Weather Online (https://www.worldweatheronline.com/). These meteorological data collected for the period July 2010 through September 2017 were available in the public domain.

Data management and analysis

The descriptive analysis included proportions, means (with SDs) and median (with IQR). There was no definite population catchment area for the hospitals and the estimation of intussusception incidence was not possible. The calendar months were grouped into seasons (summer, rainy, autumn, winter and spring) for the individual sites and regions (online supplemental table 2). Chi-squared goodness-of-fit test was used to examine the periodicity of intussusception and monthly differences. Kruskal-Wallis H test (χ^2) was performed to document the differences between >3 groups (years, months/seasons and temperature ranges: <20°C, 21°C–25°C, 26°C–30°C and >30°C). Pearson correlation (r) analysis explored the association between monthly intussusception cases (dependent variable) and monthly mean meteorological parameters separately (independent variables). Spearman's rank-order correlation (ρ) analysis was also conducted to explore whether the monthly intussusception and monthly mean meteorological parameters covary. Factorial analysis of variance (F) was used to analyse the variations in the intussusception cases during the different seasons (dependent variable: seasonal intussusception cases and independent variables: season and year). Poisson regression or negative binomial regression (β) (for parameters with wide dispersion) analyses were performed to evaluate the relationships between the monthly intussusception cases (dependent variable) and the monthly mean meteorological parameters (independent variables). The association between intussusception and meteorological parameters was examined at pooled, regional and site levels with 95%

*The period of data collection was 6 months (July–December).
†The period of data collection was 9 months (January–September).

CI estimation. Statistical significance was considered if p<0.05. Statistical analysis was performed using STATA V.15.0 (Stata Corp, Texas, USA).

Patient and public involvement

The study participants or the public were not involved in the design, or conduct, or reporting, or dissemination plans of our research. The findings would be relevant for care-seeking and case management for intussusception in children. The results published shall be disseminated to the public through social media and healthcare providers.

RESULTS

Demography data

From July 2010 through September 2017, 2279 children aged 2–24 months with intussusception were recruited. Out of these, 118 children with a history of intussusception were excluded. Thus, 2161 children with the first intussusception were analysed. The demography and regional distribution of the intussusception cases across the years are shown in table 1. There were 1431 (66.2%) boys and 730 (33.8%) girls (male–female ratio, 1.96). Majority (n=1653, 76.5%) were infants. The number of cases increased across the years with the highest (31%) jump between 2014 and 2015. During 2010–2014, children aged 7–12 months had a higher share, which changed during 2015–2017. The South region contributed the highest (50%), followed by East (27.4%), North (17.1%) and West (5.4%) regions, which were consistent across the years.

Meteorological data

The monthly meteorological parameters for the regions are shown in online supplemental table 3. The monthly meteorological parameters for each site are given in online supplemental table 4. Across the regions, April–June and December–February had the highest and lowest temperatures, respectively. The pattern of meteorological parameters across the regions is shown in online supplemental figure 2.

Monthly and seasonal cycles of intussusception

The Chi-squared goodness-of-fit test revealed obvious monthly (χ^2-statistic=71.36; p<0.01) and seasonal differences (χ^2-statistic=382.28; p<0.01) in the intussusception caseload. Also, the Kruskal-Wallis H test revealed significant differences in the intussusception cases for months (p<0.01) and seasons (p<0.01). As shown in figure 1, more intussusception cases were observed during March in the South region, June in North and East regions, all during the summer season. Not much variation in cases was observed in the West region. The intussusception cases were lowest in September and October during these years. The peak and lowest seasons were summer (March–June; n=661, 30.6% cases) and autumn (September–October; 14.5% cases), respectively (online supplemental figure 3).

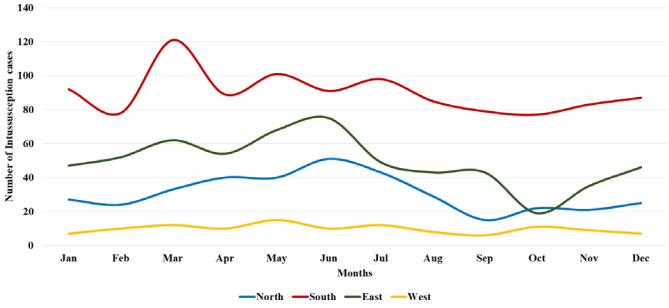

Figure 1 Monthly distribution of intussusception cases in children during 2010–2017.

Correlation between intussusception and meteorological factors

Table 2 shows Pearson correlation analysis for pooled, regions and age groups. For pooled data, the temperature (r=0.056; p<0.05), wind speed (r=0.134; p<0.01) and humidity (r=0.075; p<0.01) had significant association with intussusception. At regional level, intussusception cases had association with temperature for East region (r=0.052; p<0.05); with rainfall for North (r=−0.103; p<0.01) and East regions (r=0.073; p<0.01); with wind speed for all regions (r=-0.084–0.21; p<0.01); with humidity for three regions except West region (r=-0.373–0.161; p<0.01); and with sunshine for North region (r=0.163; p<0.01). For the age groups, intussusception cases had association with temperature for 7–12 months (r=0.068; p<0.01), with wind speed for all age groups (r=-0.092–0.125; p<0.01), with humidity for 7–12 months (r=0.069; p<0.01) and 13–24 months (r=0.076; p<0.01) age groups. The Pearson correlation analysis for intussusception cases with the meteorological parameters for the study sites is given in online supplemental table 5. Significant correlations for intussusception cases with temperature were observed for three sites, with rainfall for two sites, with wind speed and humidity for five sites each, and with sunshine for three sites.

Table 3 shows Spearman's rank-order correlation analysis for pooled, regions and age groups. For pooled data, the temperature (ρ=0.049; p<0.05), wind speed (ρ=0.096; p<0.01) and sunshine (ρ=0.051; p<0.05) were associated with intussusception. At regional level, intussusception

cases had association with temperature for North region (ρ=0.110; p<0.05); with wind speed for North (ρ=0.183; p<0.01) and East (ρ=0.109; p<0.01) regions; with humidity for North (ρ=−0.114; p<0.05) and East (ρ=−0.102; p<0.05) regions; and with sunshine for North region (ρ=0.119; p<0.05). For the age groups, intussusception cases had association with temperature for 7–12 months (ρ=0.064; p<0.01), with wind speed for all age groups (ρ=0.063–0.106; p<0.01), with humidity (ρ=0.049; p<0.05) and sunshine (ρ=0.048; p<0.05) for 7–12 months age group. The Spearman's rank correlation analysis for intussusception cases with the meteorological parameters for the study sites is given in online supplemental table 6. Significant correlations for intussusception cases with temperature were observed for one site, with rainfall for two sites, with wind speed for three sites, with humidity for five sites and with sunshine for two sites.

Regression analyses (Poisson regression and negative binomial regression) revealed significant association between intussusception cases and temperature for pooled level (β=0.026; 95% CI 0.011 to 0.041; p<0.01), North (β=0.027; 95% CI 0.007 to 0.047; p<0.01) and East (β=0.029; 95% CI 0.001 to 0.057; p<0.05) regions; wind speed for pooled level (β=0.082; 95% CI 0.061 to 0.103; p<0.01), North (β=0.208; 95% CI 0.101 to 0.315; p<0.01) and East (β=0.091; 95% CI 0.042 to 0.141; p<0.01) regions; humidity for pooled level (β=0.011; 95% CI 0.007 to 0.016; p<0.01) and East (β=−0.021; 95% CI −0.035 to −0.007; p<0.01) region; and sunshine for pooled level (β=0.002; 95% CI 0 to 0.003; p<0.01) and North (β=0.004; 95% CI 0.002 to 0.007; p<0.01) region (table 4). Associations between intussusception cases and temperature and humidity were evident across different age groups (p<0.01). The association was also significant at study sites level for temperature (three sites), humidity (six sites) and sunshine (five sites) (online supplemental table 7).

The monthly average temperatures at the sites and regions varied widely: 14°C–35°C in North, 23°C–31°C in South, 20°C–32°C in East and 22°C–31°C in West regions. χ^2 goodness-of-fit test showed significant difference at 20°C–30°C for pooled, North and South regions (p<0.01), indicating that intussusception cases occurred more during this temperature (online supplemental table 8/13). Kruskal-Wallis H test found significant variation in intussusception cases between different temperature categories for pooled (χ^2=15.933; p<0.01), North (χ^2=21.054; p<0.01) and South (χ^2=50.625; p<0.01) regions (online supplemental table 9/14). The number of intussusception cases increased when the mean daily temperature and the wind speed increased and mean daily humidity decreased at the pooled level and for North and East regions (online supplemental figures 4–8).

Correlation between intussusception, seasons and age groups

Factorial analysis of variance revealed significant difference in seasonal intussusception cases at pooled level (F=1.442; p<0.05), for 2–6 months age group (F=1.579; p<0.05) and for North region (F=1.809; p<0.01) (online supplemental tables 8 and 10 & 9 and 11). Multiple comparisons revealed significant difference in intussusception cases between summer and autumn seasons (mean difference=0.569; 95% CI 0.11 to 1.03; p<0.01) at the pooled level (online supplemental table 10 and 12). Significant differences in intussusception cases between summer and monsoon (mean difference=0.165; 95% CI 0.04 to 0.29, p<0.01), summer and autumn (mean difference=0.179; 95% CI 0.03 to 0.32, p<0.01), spring and monsoon (mean difference=0.276; 95% CI 0.09 to 0.46, p<0.01), and spring and autumn (mean difference=0.290; 95% CI 0.09 to 0.49, p<0.01) were observed for North region (online supplemental table 11 and 13). Significant differences in intussusception cases were observed between summer and autumn for children aged 2–6 months (mean difference=0.195; 95% CI 0.01 to 0.38, p<0.05) and for children aged 7–12 months (mean difference=0.231; 95% CI 0.01 to 0.45, p<0.05) (online supplemental table 12 and 14).

DISCUSSION

The seasonal influence on intussusception cases has been proposed, but with inconsistent findings from different countries and different parts of India. This study is the first to explore the association between intussusception and monthly mean meteorological parameters (temperature, rainfall, wind speed, humidity and sunshine) in India. This study, comprising 2161 children with the first intussusception from 20 sites in India, documented monthly and seasonal variations. Intussusception case peaks were observed during summer months (March–June) and troughs during autumn months (September–October). There was a positive correlation between intussusception cases and meteorological parameters like temperature, humidity, wind speed, and sunshine at pooled and regional levels and among children aged 7–12 months. The associations were consistent across analysis tests used (Pearson correlation, Spearman's rank correlation tests, Poisson regression or negative binomial regression). The association was more pronounced for North and East regions, where the meteorological parameter fluctuation across months, were widest. Further analysis using factorial analysis of variance also demonstrated seasonal inclination, peaking in the summer season (March–June) in India and significant difference from the autumn season (with lowest cases) (p<0.01). A significant difference in the number of intussusception cases between the temperature ranges (<20°C, 21°C–25°C, 26°C–30°C and >30°C) was observed at pooled and regional (North and South regions) levels, which indicated a rise in intussusception cases with the rise in monthly mean temperature. The intussusception cases increased with the rise in daily temperature and wind speed and fall in humidity.

The findings are consistent with the report from China in 5994 children (aged 0–12 years) with intussusception, where more cases were documented in summer months with a significant positive association with mean monthly meteorological parameters (temperature, sunshine and

*Tests used for regression analysis: negative binomial regression.
†Tests used for regression analysis: Poisson regression.

precipitation).[12] Modelling using the data from 13 887 Chinese children with intussusception and applying the meteorological variation assumptions achieved a considerable agreement with the data collected.[24] These reports from China did not include humidity as a variable.

Studies on intussusception in children from India have reported higher cases during summer (March–July) and lowest during autumn (September–November) seasons. In three studies from South India, the highest and lowest intussusception cases were observed during March–June and September–October, respectively.[5 9 10] A multisite study from India reported the highest and lowest cases during March and September, respectively.[8] A study from North India observed the highest and lowest cases during June and September.[11] A report from our group on the retrospective surveillance observed a higher number of intussusception cases during the summer months (March–June) over the year.[7]

Seasonal patterns of intussusception occurrence have been observed from different countries. A higher number of intussusception cases were observed during the warmer months (May–October) than cooler months (November–April) in Taiwan.[14] Among Hong Kong children with intussusception, higher cases were observed during the summer months (May–July).[26] Seasonality in intussusception case occurrence was observed in Korean children with highest during warmer months (July–August) and lowest during cooler months (February).[27] Among Ethiopian children, higher intussusception cases were observed during June and lower during November.[13] Higher intussusception cases were observed during summer months and lower during winter months among South African children.[15] Among Israeli children, more intussusception cases were observed during the summer months and lower during winter.[16] No seasonal variation was also observed in some studies from different countries. Studies from Latin American countries and North America did not observe visible seasonal variation in cases.[17 23] Studies from Switzerland, France, New Zealand, Singapore and China also had no sizeable seasonal variations.[18–22]

The inconsistencies in the seasonal variations may be due to the sample size, age groups included and stratification in the analysis. Three studies that observed definite seasonal variation[12 14 24] and two that observed a statistically significant association between meteorological parameters and intussusception have a larger sample size (>5000 participants). The association observed in our study may be also due to the higher sample size. The reasons for the higher intussusception cases during summer are not known and the seasonality does not match with the rotavirus infection seasonality in India.[28] According to the reports from some developed countries (the USA and Australia), the intussusception incidence has declined over decades, and also the prevalence of prodrome infection symptoms (gastrointestinal and respiratory infections) in these children over the same period.[29–31] Further studies are needed to confirm the seasonality, association with meteorological parameters and variations in seasonality across the regions in India, along with the influences of the preventive healthcare services coverage, care-seeking practices, access to sanitation and hygiene, and changes in dietary practices.

A seasonal variation in another acute intestinal condition, acute appendicitis in children, has been reported. More acute appendicitis cases in children during summer months and lower during spring/autumn seasons have been reported from India, Pakistan, Iraq, China, Taiwan, Italy, Germany, Canada and the USA.[32–39] Among Chinese children, associations between acute appendicitis and temperature (p<0.01), humidity (p<0.01) and sunshine (p<0.01) were documented to support the seasonal variation.[35] Similar to intussusception, the appendicitis incidence has also declined in developed countries over decades, possibly due to changes in hygiene, sanitation, dietary practices, access to healthcare and reduction in infectious diseases.[40] Intussusception and acute appendicitis are intestinal problems and some of intussusceptions have associated appendicitis.[41–43] The climate factors are unlikely to directly cause intussusception or intussusception in children. But the linkage between seasonality and meteorological parameters and acute intestinal conditions appears to be plausible, which may be mediated by intestinal and non-intestinal infections (including activation of latent viral infections), mucosal inflammatory changes, lymphoid hyperplasia, or motility alterations and dietary intake changes. Although no direct relationship with the rotavirus infection could be established, higher gastrointestinal infection during summer and early rainy

BMJ Open: first published as 10.1136/bmjopen-2020-043687 on 25 May 2021. Downloaded from http://bmjopen.bmj.com/ on May 25, 2021 at India:BMJ-PG Sponsored. Protected by copyright.

seasons may be triggers for higher intussusception in the Indian context. The changes in intussusception and appendicitis incidence over time in parallel with industrialisation, economic improvement, improved access to vaccination, healthcare, and sanitation and hygiene practices suggest a possible association. Such information in the Indian and developing country context is not available. Thus, the seasonal variation in these conditions and association between meteorological parameters appear epidemiologically and biologically plausible, which needs further evaluation. We used Pearson correlation coefficient as the primary analysis to document the strength and direction of the relationship between meteorological parameters and intussusception. As a secondary analysis and checking for consistency in the findings, we used Spearman's rank-order correlation analysis to identify the strength of the association between ranked parameters and intussusception variables.

The Pearson correlation coefficient (r) and Spearman's correlation coefficient (ρ) values for different meteorological parameters were similar, although the r values for temperature, rainfall, wind speed, and humidity were higher than the ρ values, but had r value lower for sunshine than the ρ value at the pooled level. The differences between the r and ρ values were relatively small, which supports the consistent association between the variables. The consistency in findings from factorial analysis of variance and regression analysis with the correlation coefficients further confirms the association between meteorological parameters and intussusception.

The study had several strengths. It included a relatively large number of intussusception cases over a 7-year period recruited from 20 sites representing different regions. This study explored the association between intussusception cases and meteorological parameters at site, regional and pooled national levels. There was consistency in the correlation between intussusception cases and meteorological parameters across multiple statistical methods used, which was convincing. There are several limitations in the study. A major part of this study was retrospective. The sites belong to different climate zones and had variations in the meteorological parameters. The lack of a definite catchment population and referral pattern made it difficult to estimate the intussusception incidence rate.

In conclusion, this study documented higher intussusception cases during the summer months with a positive association between the number of cases with temperature and sunshine. Also, a significant positive correlation with humidity and wind speed was observed. The association was significant for the North and East regions with wider variations in the meteorological parameters across seasons. A higher degree of suspicion for infants with compatible clinical presentation for intussusception during the summer months may improve diagnosis and clinical care to prevent complications. The study provides evidence for predicting the intussusception pattern in children and sensitising the healthcare providers at community and peripheral facilities for early detection and quick referral of patients to minimise the surgical interventions and avoid fatalities. Further studies are needed to confirm the observation and improve the evidence base on the potential risk factors for the season variations and the aetiologies of intussusception.

Acknowledgements We acknowledge the support from the Ministry of Health and Family Welfare, Government of India for undertaking the study. We are thankful to the hospital administrators and the clinicians at the study site institutes, who supported and facilitated the undertaking of the study. We highly value the technical guidance and inputs provided by the members of the Technical Advisory Group: Mahesh K Agarwal and Pradeep Haldar, Ministry of Health and Family Welfare, Government of India; Satinder Aneja, Anju Seth and Archana Puri, Lady Hardinge Medical College, New Delhi; Ashok Patwari, Hamdard Institute of Medical Sciences and Research, New Delhi; Yogesh Kumar Sarin, Maulana Azad Medical College, New Delhi; Rakesh Aggarwal, Anshu Srivastava and Ujjal Poddar, Sanjay Gandhi Post Graduate Institute of Medical Sciences, Lucknow; Malathi Satyasekharan, Kanchi Kamakoti Childs Trust Hospital, Chennai; Raju Sharma and Nirupam Madan, All India Institute of Medical Sciences, New Delhi; Jyoti Joshi and Deepak Polpakara, Immunization Technical Support Unit, Ministry of Health and Family Welfare, New Delhi; Umesh D Parashar; Centers of Disease Control and Prevention, Atlanta, USA; Jan Bonhoeffer, University Children's Hospital, Basel, Switzerland and Brighton Collaboration; Naveen Thacker, Child Health Foundation, Gandhigram; Rashmi Arora, Indian Council of Medical Research, Ansari Nagar, New Delhi; and Patrick L F Zuber and Christine G Maure, WHO, Geneva, Switzerland. Abstract

Objective To report background intussusception epidemiology in children under-two years in Coimbatore district of Tamil Nadu state, India, prior to rotavirus vaccine (RVV) introduction.

Methods Prospective sentinel surveillance was done at four hospitals in Coimbatore during April 2016 to September 2017. The children aged >1 mo and < 24 mo with diagnosed intussusception were recruited and data on clinical, treatment, diet, immunization, and sociodemography were collected.

Results Sixty-eight children with intussusception were recruited. Among them 76.5% were infants with male predominance (57.4%) and 48.5% were 4–8 mo old. Vomiting (83.8%), pain in abdomen (including excessive crying) (72.1%), and bloody stools (45.6%) were the main symptoms. Reduction was tried in 92.6% cases with success in 83.8%. Surgery was needed by 16.2% children. No child died. Any RVV dose was received by 24.1% children and 2 children received RVV in 8–21 d and none within 1–7 d window. The incidence of intussusception requiring hospitalization was estimated to be 36.4 and 11.7 cases/100,000 children/y for the first and second years, respectively.

Conclusion Intussusception occurred in infants even without RVV exposure. Continued surveillance is needed to document the changes in intussusception epidemiology after RVV introduction.

Keywords Intussusception · Prospective surveillance · Incidence · Children · Coimbatore · South India

Introduction

Intussusception was documented as an adverse event associated with rotavirus vaccine (RVV) in 1999, following Rotashield® (Wyeth Lederle, Marietta, PA, USA) introduction in the United States, forcing withdrawal of the vaccine [1]. Subsequently, large RVV efficacy trials for Rotarix® (GlaxoSmithKline Biologicals, Rixensart, Belgium) and Rotateq® (Merck & Co. Inc., Kenilworth, USA) across multiple countries attempted documentation of intussusception risk following RVV [2, 3]. There have been also continued efforts for post-marketing surveillance to document the association and risk of intussusception in different countries. Studies have observed no additional risk in United States and Brazil to 1–2 additional intussusception cases in Mexico and Australia per 100,000 vaccinated infants [4–6].

Intussusception commonly presents as acute abdomen and intestinal obstruction. Available literature suggests that majority of these cases are infants and between 4 and 10 mo. Although some cases resolve spontaneously (transient intussusception), most require early diagnosis and reduction, since obstruction and edema can lead to ischemia and intestinal perforation, which may be fatal. Ileocecal type is the most common [7]. There are several hypothesis postulated

regarding the etiology and risk factors, which include neuromuscular incoordination, intestinal edema, mechanical lead points, as well as intestinal and extraintestinal viral and bacterial infections [7–9].

To reduce child mortality and morbidity, World Health Organization (WHO) has recommended introduction of RVV into the national immunization programmes. In view of the associated risk, WHO recommends surveillance for intussusception as part of the vaccine safety monitoring linked to the vaccine introduction. RVV was inducted into India's Universal Immunization Program in April 2016 and scaled up countrywide in four phases by 2019. Two RVVs, Rotavac® (Bharat Biotech, Hyderabad, India) and Rotasiil® (Serum Institute of India, Pune, India) are being used at 6, 10, 14 wk in different states.

The intussusception incidence and case load vary widely, globally, from 9 (Bangladesh) to 328 (Korea) per 10,000 infants [10–12]. According to the population-based and sentinel hospital based-surveillance studies, the intussusception incidence among Indian infants vary from 17.7–20 (95% CI 5.9–41.4) in North India to 254 (95% CI 102–514) in South India per 100,000 children per year [13–15]. The information on intussusception incidence from many parts of India are not available. Retrospective and prospective surveillances have highlighted regional variations in intussusception case load across India [16–18]. There is a need for information on intussusception epidemiology and characteristics from different states of India to support the vaccine safety monitoring and associated risk factors identification. With this background, the authors present the epidemiology, incidence, clinical features of intussusception in children aged under-two years through sentinel hospital surveillance in Coimbatore district, Tamil Nadu, India.

Material and Methods

This prospective hospital-based sentinel surveillance was conducted at four tertiary care hospitals (three from private sector and one government medical college) in Coimbatore district, Tamil Nadu, India. All these four hospitals were located in Coimbatore city, the district headquarter. These were the leading hospitals in the city and district with functional pediatric surgery facility. Most of the patients from the district attended one of these hospitals. The district has a population of 3,654,026 with over 25% of the population living in the Coimbatore city. RVV was introduced in Tamil Nadu under immunization program in September 2017. These four hospitals were part of a nationally representative sentinel surveillance for intussusception involving prospective and retrospective components conducted to support the vaccine safety surveillance effort in India. The pooled results for the retrospective and prospective surveillance components from the larger intussusception surveillance network have been published [16, 17].

Prospective surveillance system was conducted at these hospitals during April 2016 to September 2017.

All the children aged >1 mo and < 24 mo admitted to these hospitals under pediatrics or pediatric surgery units were screened daily. These age-eligible children were actively tracked till the final diagnosis. All children with intussusception were recruited with written informed consent taken from their parent or legally authorized representative. The data including sociodemography, dietary practices, immunization exposure (from immunization card or register), clinical features, treatment, and final outcome were collected. A dedicated research staff screened the cases and collected the data. Based on the information, an independent expert group including pediatrician, pediatric surgeon, and radiologist assigned diagnostic certainty level according to the Brighton Collaboration case definition (BCCD) [19].

The research staff was trained on the study protocol and data collection. The data collected were sent to the central coordinating unit, where the data were reviewed and queries were resolved with reference to the source documents. Site visits by the Central Coordinating Unit team were made to check protocol adherence and data quality. Site visit was made by the data team, which cross-checked the cases with the medical records to identify missing case.

Double data entry was done at the central unit and the data entered were matched with the hard copies to ensure correctness. The entered data were stored in the server with authorized access and daily backup was taken. The authors conducted descriptive data analysis and expressed the findings as proportions, means (with standard deviations), or medians [with interquartile range, (IQR)] as appropriate. The socioeconomic status was represented as standard of living index (SLI), as used in the National Family and Health Survey for India, using the scores for household assets ownership. SLI was categorized as high, medium, and low categories. The intussusception diagnostic certainty levels were categorized into levels 1 to 3 using the BCCD criteria [19]. The missing data were excluded from analysis. For incidence calculation, the census (2011) population data for Coimbatore district was used as the base population and growth rate (1.85%) as per the Sample Registration System (SRS) data was applied to estimate the population for 2016–2017. For estimating the number of children in the corresponding years, the live birth rate and infant mortality data from the state notification were used (Supplementary Table 1). The incidence of hospitalized intussusception was estimated as number of hospitalized cases among infants or under-two-children per 100,000 infants or under-two-children per year in Coimbatore district. The statistical analysis was performed using STATA version 15.0 (StataCorp LLC, Texas, USA).

The ethics committees of all participating institutes reviewed and approved the study protocol. Prior to recruitment of the

participants, written informed consent was obtained. Confidentiality in data handling was maintained at all levels.

Results

Between April 2016 and September 2017, 68 children with intussusception admitted to these hospitals were recruited. The sociodemographic characteristics and dietary practices for the children with intussusception are summarized in Table 1.

Over three-fourth (76.5%) of these children were infants (ages 2–6 mo: 39.7% and 7–12 mo: 36.8%) with median age of 8 mo (IQR 5–12 mo). The children aged 4–8 mo contributed to 48.5% of the cases (Fig. 1). A male predominance with male-female ratio of 1:3:1 was observed. No definite

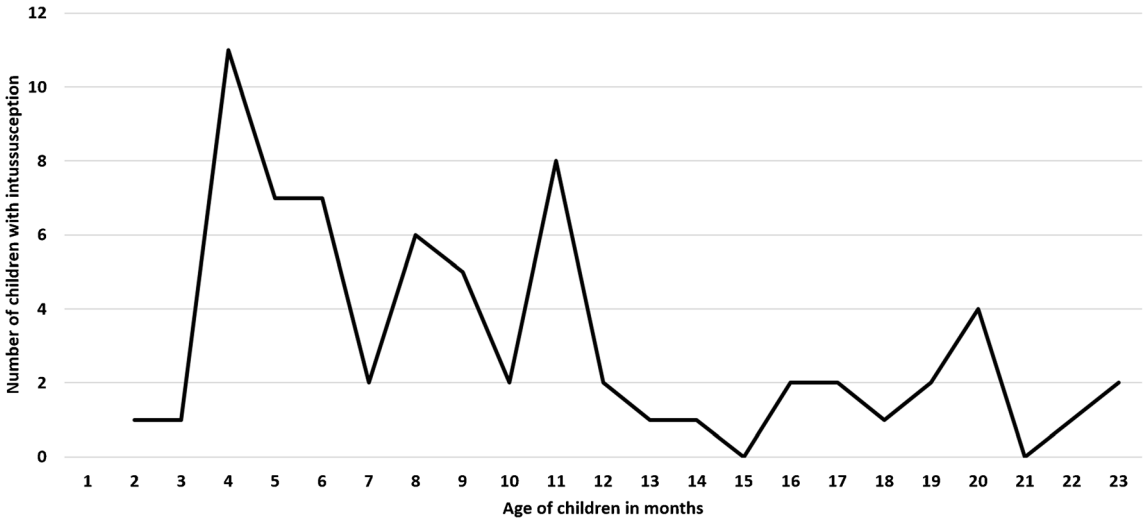

Fig. 1 Age distribution of the children with intussusception in Coimbatore district

seasonal variation was observed (Fig. 2). The patients belonged to all socioeconomic classes. About half (52.9%) of the patients were from the Coimbatore district. Overall, all children were initiated on breast-feeding, but only 29.3% of the children received exclusive breast-feeding for minimum 5 mo. Mixed feeding (animal milk and other feed) was initiated before 6 mo in 40.7% children. The median age of weaning was 6 (IQR 6–7) mo. Over two-third (67.3%) of the children received rice as main weaning food, while 23.1% received fruits or vegetables for weaning. The onset of weaning and intussusception intervals were comparable for the different types of weaning food.

Table 2 presents the clinical findings and management of these cases. Vomiting (83.8%), pain in abdomen (including excessive crying) (72.1%), and bloody stools (45.6%) were the leading symptoms. Classical intussusception triad (pain in abdomen, vomiting, and bloody stools) was observed in 26.5% patients. Abdominal mass was documented in 27.9% children. The diagnosis was made by ultrasonography in all cases with 79.4% had intussusception at ileocolic site. Only 1.5% had lymph nodes as pathological lead points (PLPs). Hydrostatic reduction was attempted in 63 (92.6%) cases and failed in 6 cases. Surgery was needed for 11 (16.2%) patients with bowel resection in 4 cases. No death was observed.

The intussusception onset-to-hospitalization interval was marginally shorter for children managed by reduction compared to those underwent surgery. The period of hospitalization was shorter with reduction (median 2, IQR 2–3 d) than surgery (median 6, IQR 4–7 d). Few children had history of diarrhea (7.3%) and respiratory illnesses (8.8%) within 4 wk of intussusception. All cases were labelled as level-1 using the BCCD criteria.

Immunization exposure information was documented for 85.3% (58/68) of the cases from a definite source. Out of the

[a] Includes all vomiting including bilious vomiting

[b] Includes only bilious vomiting

[c] Includes excessive crying also

[d] Classical triad includes abdominal pain, vomiting and blood in stools

[e] The denominators used for percentage estimation include patients who underwent surgery only

children with known immunization exposure, 24.1% (14/58) received any RVV (Roravac®, Rotateq®, and Rorarix®) and all of them received it from the private hospitals. The median ages of primary doses of vaccination were 48 (IQR 44–57 d), 84 (IQR 77–99 d) and 119.5 (IQR 111–136 d) for first, second, and third doses, respectively (Fig. 3). Only 2 children received RVV (second dose-1 and third dose-1) within 8–21 d of last dose and none within the 1–7 d window (Supplementary Fig. 1).

The incidence of intussusception requiring hospitalization among children during first and second year of life in Coimbatore was estimated to be 36.4 (range 28.3–44.5) and 11.7 cases (range 5.2–18.3) per 100,000 children per year. The pooled incidence of intussusception requiring hospitalization in children under-two years was 23.4 (15.5–31.4) per 100,000 children per year (Supplementary Table 1).

Discussion

This multihospital sentinel study documented the epidemiology, case load, and incidence of intussusception among children under-two years in Coimbatore, Tamil Nadu prior to introduction of RVV in the immunization program. More

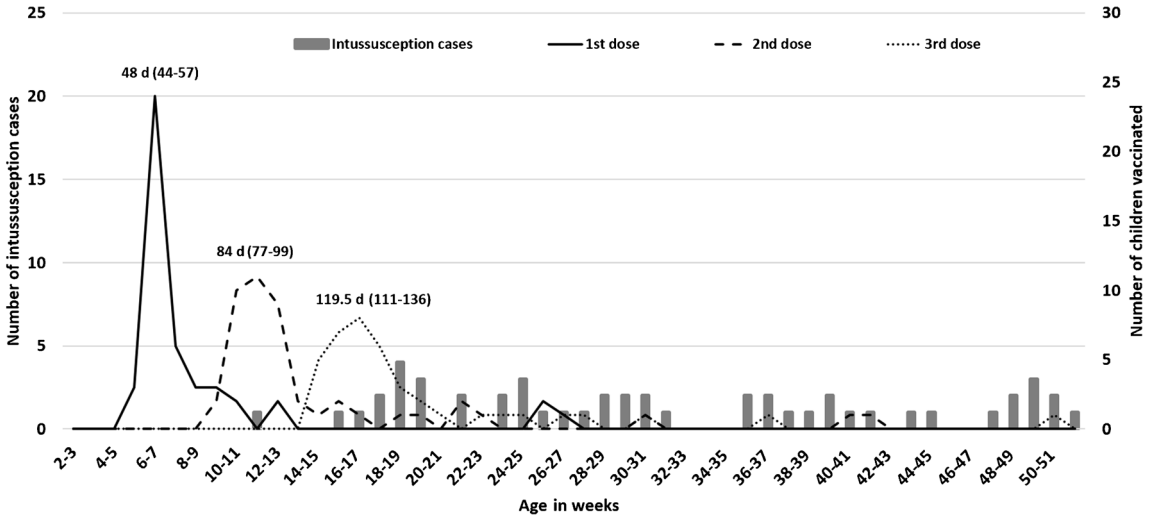

Fig. 3 Ages at vaccination and occurrence of intussusception in infants from Coimbatore. Note: The ages at vaccination are given in days as median [interquartile range (IQR)]

cases were observed among infants (76.5%) with median age of 8 mo (IQR 5–12 mo) and children aged 4–8 mo contributed nearly half of the cases. These observations were comparable to the earlier reports from other parts of India including Tamil Nadu and globally [12, 14–22]. Although males contributed more (57.4%), the male:female ratio was lesser than other reports [12, 14–22].

The children had vomiting, pain in abdomen, and bloody stools as the three top symptoms. These were similar to the reports from India and globally [12, 14–22]. The symptom triad was observed in 26.5% cases, which was comparable to some reports from India (19%–34.8%) [16–18]. Majority (79.4%) had ileocolic type Intussusception, similar (68–85.3%) to observations from India and globally [12, 14–22]. The proportion of children with PLP was comparable to some (2.1%–3.7%) [14, 21] and lesser (14.6%–41%) [16, 17, 23] than other reports from India. All cases met level-1 BCCD criteria indicating better documentation, especially post-reduction.

Majority (83.8%) of the cases were treated by hydrostatic reduction and the success rate of reduction (90.5%) was comparable to other reports from India [21, 24] and globally (67.7%–91.1%) [25]. The lower proportion of patients with triad, surgical intervention, and no mortality indicate early case detection, referral, and response for management.

As three hospitals were from private sector, the socioeconomic class of the patients were more from middle and high category, which is also reflected with the RVV receipt prior to introduction in the public health system. The exclusive breast-feeding rate (29.3%) was lower than the State average (47.8%, 2015–16) and 40.7% children received mixed feeding prior to 6 mo of age. Higher proportion of cases during 4–8 mo, which overlaps with mixed (top) feeding and early weaning suggest possible role of dietary practices in intussusception. Studies have shown increased risk and shorter interval for intussusception following oral vaccines [1]. Feeding cow's milk, weaning with some types of food, and allergy from external food have also been postulated to trigger intussusception in infants [16, 26, 27]. There is limited information regarding association of feeding and intussusception. In a study from Kerala, 78.8% of the children with intussusception were given complementary feeding during 2–4 mo of age [28].

The estimated incidence of intussusception requiring hospitalization was 35.1 per 100,000 infants and 11.7 per 100,000 children in the second year, which was lower than the report from Vellore district, Tamil Nadu (254 per 100,000 children) as part of a Phase-III trial for rotavirus vaccine [15]. The report from Vellore district included all intussusception cases, hospitalized and transient ones (those who did not require any intervention), detected on ultrasonography, which can explain the higher incidence rate [15]. The observed incidence in Coimbatore was a little higher than the reported intussusception incidence rates from North India (17.7–20) [13, 14], but was lower than another report (62, 95% CI 39.8–112.9) from Kerala (neighboring state) [29]; all of these included the hospitalized cases. The estimated intussusception incidence was comparable to the observations from Asian (Thailand - 36), Latin American (Panama - 30, Venezuela - 35) and North American (United States - 33-34) countries [12].

The ages at intussusception overlapped with the third dose of routine vaccination, when the RVV was also expected as part of the immunization schedule. Although among the children who received RVV, none had intussusception within 1–7 d after vaccination, 2 cases had it within 8–21 d window. Such overlap of ages of background intussusception in infants and RVV administration, especially third dose, is expected to make causality assessment difficult. The clinical trials conducted for the RVVs in use under the immunization program

in India were underpowered to detect any risk for intussusception [30, 31]. A recent study did not observe any increased risk of intussusception with Rotavac™ among Indian children [32]. To confirm the intussusception-RVV association in Indian context, longer surveillance and comparison with background incidence rates and analysis using the special methodologies shall be needed. Additionally, there is also need for better documentation of clinical features, reduction outcome, and vaccine exposure in routine clinical practice. In view of the diversities in dietary and sociocultural practices and geographic variations in the intussusception cases, there is a need for documentation of the epidemiology and trends from different parts of the country.

Involvement of multiple hospitals (both from private and public sector) from the district, data collection by separate research staffs following common protocol and standard case definition, and quality assurance measures are the strengths of this study. For immunization exposure, only definite source documents were accepted. There were several limitations also. This was a hospital-based surveillance. Usually hospital attendance and patient referral do not follow any definite catchment area norm. Thus, the observed incidence might be an underestimation, as some cases might have been managed at other facilities in the state. We did not explore any etiological or associated risk factors (including rotavirus vaccine) for intussusception. The clinical feature like abdominal pain has been captured based on the history and assessment of the treating doctors, which could have been under-or overrepresented.

Conclusion

This study documented the clinical features and incidence of intussusception among children aged under-two years prior to RVV introduction in Tamil Nadu, a southern state in India. The intussusception occurred in children, especially infants even without rotavirus vaccination. The intussusception incidence needs to be compared with the post-RVV introduction to document any change. For examining the association with the RVV, especially following the third dose, background rates of intussusception in the age group must be considered. There is a need for better documentation of immunization exposures and other possible risk factors for intussusception, including dietary practices, intestinal and extraintestinal infections and age-related gut motility functions.

Supplementary Information The online version contains supplementary material available at https://doi.org/10.1007/s12098-021-03776-8.

Acknowledgments The authors acknowledge the support from Ministry of Health and Family Welfare, Government of India for undertaking the study. They are thankful to the institute and hospital administration and the clinicians who supported and facilitated undertaking the study. They also acknowledge the contribution of the research staffs at The INCLEN Trust International: Apoorva Sharan, Harshpreet Kaur, Janvi Chaubey, Mrimmaya Das, Shweta Sharma, and Vaibhav Jain. The authors highly appreciate the efforts made by late T. Easter Chandru for data collection at the study site institutes.

Availability of Data and Materials All data are available with the investigators and can be provided by the corresponding author upon reasonable request.

Authors' Contributions MKD and NKA conceptualized the framework for the study protocol, training, data analysis, and interpretation. All the site investigators contributed to the protocol development and finalization. JM, CJS, RG, KR, JK, and PA supervised and coordinated the data collection at study site institutes. MKD and BG coordinated data quality assurance, data cleaning and analysis of the data. MKD wrote the first draft of the manuscript and will act as guarantor for this paper. All authors reviewed, provided critical input, and approved the final version.

Declarations

Ethics Committee Approval The study protocol was reviewed and approved by INCLEN Ethics Committee (Ref: IIEC 23), Institutional Human Ethics Committee, PSG Institute of Medical Sciences and Research, Coimbatore (Ref: 15/295); Ethics Committee, Coimbatore Medical College, Coimbatore (Ref: 5/7/2016); Institutional Ethics Committee, Masonic Medical Centre for Children, Coimbatore (Ref: 28/4/2016) and Institutional Ethics Committee, GKNM Hospital, Coimbatore (Ref: 25/2016). The information about the children were collected after obtaining written informed consent.

Conflict of Interest None.

Source of Funding The surveillance at one hospital was supported by the Bill and Melinda Gates Foundation, USA to The INCLEN Trust International (grant number OPP1116433). The funder or its representative had no role in the study design, data collection, analysis, interpretation and writing of the manuscript.

Clinical spectrum and short-term outcomes of multisystem inflammatory syndrome in children in a south Indian hospital

Muruganantham Balagurunathan, MD*, Thrilok Natarajan, MD, MRCPCH (UK)*, Jothilakshmi Karthikeyan, DNB, Venkateshwaran Palanisamy, MD

Department of Pediatrics, PSG Institute of Medical Sciences and Research, Tamilnadu, India

Background: Multisystem inflammatory syndrome in children (MIS-C) is a new hyperinflammatory variant that evolved during the coronavirus disease 2019 pandemic. Although the precise pathophysiology of MIS-C is uncertain, it is thought to be due to immune dysregulation occurring after recovery from acute infection.

Purpose: Our study aimed to analyze the clinical spectrum, laboratory parameters, imaging characteristics, treatment strategies, and short-term outcomes of children with a diagnosis of MIS-C.

Methods: This retrospective and prospective observational study included children less than 16 years of age who were admitted to the pediatric unit of a tertiary care teaching hospital in south India between August 2020 to January 2021 with a diagnosis of MIS-C according to World Health Organization criteria.

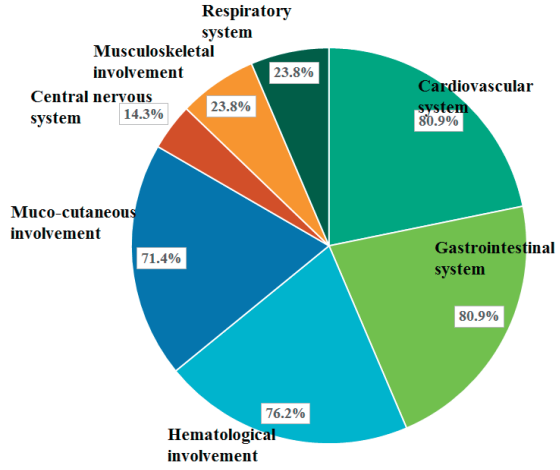
Results: Twenty-one children were included in the analysis; all had fever with variable combinations of other symptoms. The mean age was 6.9 years; 71.4% were male. Gastrointestinal (80.9%) and cardiovascular (80.9%) systems were the most commonly affected. The majority of children had elevated inflammatory markers, and 16 (76.2%) had echocardiographic abnormalities mimicking Kawasaki disease. Eleven children (52.4%) required intensive care admission, 3 (14.3%) required supplemental oxygen, and 4 (19%) required inotropes. Nine (42.9%) were treated with intravenous immunoglobulin alone, 6 (28.6%) with steroids alone, and 3 (14.3%) with steroids and immunoglobulin. The median hospital stay was 6 days; there were no fatalities. Overweight/obesity, elevated ferritin, and mucocutaneous involvement were significantly associated with a prolonged hospital stay (≥7 days). Sixteen children (76.2%) were followed up till now and all of them had no clinical concerns.

Conclusion: MIS-C is an emerging disease with variable presentation. A high index of suspicion is necessary for its early identification and appropriate management. Further research is essential for developing optimal treatment strategies.

Key words: Clinical spectrum, Coronavirus disease 2019, Kawasaki disease, Multisystem inflammatory syndrome in children

Key message

- **Question:** What are the clinical spectrum, course, and short-term outcomes of multisystem inflammatory syndrome in children (MIS-C)?
- **Finding:** MIS-C can have variable clinical manifestations. Fever is most common, followed by gastrointestinal and cardiovascular symptoms. Early identification and appropriate management lead to favorable outcomes.
- **Meaning:** MIS-C can present in a myriad of ways and severities. High suspicion is necessary to ensure its early identification and appropriate management and favorable patient outcomes.



Introduction

The coronavirus disease 2019 (COVID-19) pandemic in India is a part of the global pandemic caused by severe acute respiratory syndrome corona virus-2 (SARS-CoV-2). India is one of the countries with the highest burden of confirmed COVID-19 cases in the world and ranks second in the list of countries with a maximum number of cases.[1] Earlier reports suggested that children infected with COVID-19 were highly resilient and could present with only a mild upper respiratory illness.[2-4] But in April 2020, clinicians in the United Kingdom reported a cluster of previously healthy children presenting with shock, fever, and hyper inflammation.[5] The Royal College of Paediatrics and Child Health referred to this acute condition as pediatric inflammatory multisystem syndrome temporally associated with SARS-CoV-2.[6] As the pandemic progressed and the number of such cases increased globally the illness was labelled as multisystem inflammatory syndrome in children (MIS-C) by the Centers for Disease Control and Prevention and

Clinical Spectrum of Multisystem Inflammatory Syndrome in Children

- Intensive care admission – 52.4 %
- Supplemental oxygen requirement – 14.3%
- Inotrope requirement – 19 %
- Abnormal ECHO – 76.2%
- Mortality - 0%
- Follow-up – 76.2%

Graphical abstract

the World Health Organization (WHO).[7,8] Although the exact pathophysiology of MIS-C is uncertain, it is thought to be due to immune dysregulation occurring after recovery from acute infection. As the burden of COVID-19 infection is increasing in India, more children are being recognized with this condition. Although many articles are reported from western countries there is a dearth of published reports from Asian countries.

Our study aimed at analyzing the clinical spectrum, laboratory parameters, and imaging characteristics of children less than 16 years admitted with a diagnosis of MIS-C. In addition, this study aimed to analyze the treatment strategies and short-term outcomes.

Methods

1. Study design and setting

This study was a partly retrospective and partly prospective observational study done in children admitted with a diagnosis of MIS-C in a tertiary care teaching hospital in south India from August 2020 to January 2021. The hospital is one of the largest COVID-19 care centers in south India and receives referrals from a radius of 200 kilometers. The study was approved by the Institutional Human Ethics Committee of PSGIMS&R (project No. 20/262 dated 27th November, 2020). Informed written consent was obtained from parents prior to the inclusion of children in the prospective part of the study. Waiver of consent was obtained for the retrospective collection of data.

2. Participants

Children less than 16 years of age diagnosed with MIS-C as per WHO criteria were included in the study. The following parameters were considered for diagnosis: (1) fever ≥3 days, (2) 2 of the following: a) rash or bilateral nonpurulent conjunctivitis or mucocutaneous inflammation signs (oral mucosa, hands, or feet), b) hypotension or shock, c) features of myocardial dysfunction, pericarditis, valvulitis, or coronary abnormalities (including echocardiography findings or elevated troponin/N-terminal pro-B-type natriuretic peptide [NT-proBNP]), d) evidence of coagulopathy (by prothrombin time, partial thromboplastin time, elevated D-dimers), e) Acute gastrointestinal problems [diarrhea, vomiting, or abdominal pain], (3) elevated markers of inflammation such as erythrocyte sedimentation rate, C-reactive protein, or procalcitonin, (4) no other obvious microbial cause of inflammation, including bacterial sepsis, staphylococcal or streptococcal toxic shock syndromes, (5) evidence of COVID-19 (real-time reverse transcription polymerase chain reaction [RT-PCR], antigen test or serology positive), or likely contact with patients with COVID-19.

3. Data collection

Data on demographics, clinical features, laboratory results, imaging studies, treatment details, outcomes, and follow-up were collected. All the investigations and treatment were carried out as per institutional protocol and treating physician's discretion.

COVID-19 infection was confirmed by testing for SARS-CoV-2 antibody by chemiluminescence immunoassay (VITROS 3600 immunodiagnostic system, Ortho Clinical Diagnostics, Raritan, NJ, USA) and/or RT-PCR as recommended by Indian Council of Medical Research. The laboratory values were interpreted as either increased or decreased based on the age-specific normal reference ranges. Organ system involvement was described based on clinical features, laboratory reports, and imaging studies. Echocardiography was performed in all children by the pediatric cardiologist to identify the following abnormalities; (a) left ventricular dysfunction (ejection fraction

less than 55%), (b) pericarditis or pericardial effusion, (c) coronary artery abnormalities (dilatation, aneurysm, or irregular nontapering coronary arteries), or (d) valvular regurgitation. The dimension of the coronary artery was measured as per standard criteria and a coronary z score above 2 was reported as dilated. Other imaging studies were done as clinically indicated.

4. Statistical analysis

Data analysis was done using Microsoft Excel 2019 (Microsoft Corp., Redmond, WA, USA). Descriptive statistics were used to summarize population characteristics. Categorical variables were expressed as frequency or percentage and continuous variables were expressed as mean with standard deviation or median with interquartile range. IBM SPSS Statistics ver. 26.0 (IBM Co., Armonk, NY, USA) was used to perform univariate analysis and a *P* value of <0.05 was considered significant.

Results

From August 2020 to January 2021, twenty-one children met the WHO MIS-C criteria and were included in the analysis. Among them, only 2 children were admitted with active coronavirus-2 infection and were subsequently diagnosed as MIS-C. The demographic and clinical characteristics of the study population are mentioned in Table 1. The mean age of the study population was 6.9 years and 71.4% were male. All children were previously healthy and 9.5% were either obese or overweight.

All patients had fever with a variable combination of other symptoms. Gastrointestinal symptoms like abdominal pain, diarrhea, and vomiting were the most common presenting symptoms. The mean duration of symptoms prior to admission was 4.8 days and the mean total duration of fever was 7.9 days. The majority of children in this series had multiorgan involvement. Gastrointestinal (80.9%) and cardiovascular (80.9 %) systems were the most commonly affected organ systems. This was followed by hematological (76.2%), mucocutaneous (71.4%), and central nervous system (14.2%) involvement. None of the children had acute kidney injury in this series. Two children in this series had been treated for COVID-19 3 weeks prior to the diagnosis of MIS-C, and 5 children had history of confirmed exposure to COVID-19 patients in the preceding 3 to 4 weeks. In other children, no history associated with COVID-19 was revealed.

In the study population, 19 children (90.4%) had positive COVID-19 antibody tests, 1 (4.8%) had positive COVID-19 RT-PCR test, and another (4.8%) had both positive COVID-19 RT-PCR and antibody tests. The results of laboratory tests and imaging studies are summarized in Tables 2 and 3. Lymphopenia and thrombocytopenia were seen in 47.6% and 38.1% of cases, respectively. Inflammatory markers were elevated in the majority of cases. Specifically, D-dimer and interleukin 6 (IL-6) were elevated in 95.2% and 90.5% of cases, respectively. Children with cardiovascular system involvement showed elevation of

Values are presented as mean±standard deviation or number (%) unless otherwise indicated.
IQR, interquartile range; COVID-19, coronavirus disease 2019.
[a)]Organ system involvement was classified as cardiovascular, gastrointestinal, respiratory, nervous, musculoskeletal, hematological, or renal based on clinical features and investigations.

Table 2. Laboratory test results

Parameter	Number (%)	Definition
Blood counts		
Anemia	4/21 (19)	Hb <10 g/dL in <1 yr Hb <9 g/dL in ≥1 yr
Neutrophilia	16/21 (76.2)	ANC >7.7×10^3 cells/μL
Lymphopenia	10/21 (47.6)	ALC <1.5×10^3 cells/μL in child >8 mo ALC <4.5×10^3 cells/μL in child <8 mo
Thrombocytopenia	8/21 (38.1)	Platelet <150×10^3 cells/mm^3
Thrombocytosis	6/21 (28.6)	Platelet >500×10^3 cells/mm^3
Inflammatory markers		
Elevated ESR	17/20 (85)	≥40 mm/hr
Elevated CRP	20/20 (100)	≥0.6 mg/dL
Elevated procalcitonin	5/5 (100)	≥0.5 ng/mL
Elevated ferritin	9/21 (42.9)	>500 ng/mL
Elevated IL-6	19/21 (90.5)	≥7 pg/mL
Elevated LDH	11/16 (68.8)	LDH >300 U/L
Electrolytes		
Hyponatremia	12/17 (70.6)	Sodium <135 mEq/L
Hypokalemia	8/17 (47.1)	Potassium <3.5 mEq/L
Liver function test		
Elevated AST	6/17 (35.3)	AST >40 U/L
Elevated ALT	5/17 (29.4)	ALT >40 U/L
Hypoalbuminemia	9/17 (52.9)	Albumin <3 g/dL
Cardiac biomarkers		
Elevated troponin-T	4/13 (30.8)	≥14 pg/mL
Elevated NT-proBNP	12/15 (80)	>450 pg/mL
Coagulation profile		
Elevated D-dimer	20/21 (95.2)	≥0.5 mg/L FEU
Deranged coagulation	2/8 (25)	INR ≥1.2

Hb, hemoglobin; ANC, absolute neutrophil counts; ALC, absolute lymphocyte counts; ESR, erythrocyte sedimentation rate; CRP, C-reactive protein; IL, interleukin; LDH, lactate dehydrogenase; AST, aspartate aminotransferase; ALT, alanine aminotransferase; NT-proBNP, N-terminal prohormone of brain natriuretic peptide; FEU, fibrinogen equivalent units; INR, international normalized ratio.

cardiac biomarkers, and NT-proBNP (80%) was found to be more commonly elevated than troponin-T (30.8%). Electrolyte imbalances like hyponatremia and hypokalemia were seen in 70.6% and 47.1% of cases, respectively, which were managed appropriately.

Echocardiography was performed in all the children, and abnormality was noted in 16 children (76.2%). A greater number of children had a combination of abnormalities rather than a single abnormal finding. Coronary artery abnormality (57.1%) was the most common finding, followed by pericardial effusion (52.4%), left ventricular dysfunction (23.8%), and mitral regurgitation (23.8%). Gastrointestinal imaging studies like x-ray, ultrasound, and computed tomography were done as indicated, and ascites (50%) was the most common abnormality, followed by dilated bowel loops (35.7%), and mesenteric lymphadenitis (35.7%). Of the 17 patients who underwent chest imaging (x-ray or computed tomography), pleural effusion and lung infiltrates were observed in 3 (17.6%) and 1 patient (5.9%),

Table 3. Results of COVID-19 tests and imaging studies

Variable	Number (%)
COVID-19 test results	
Positive serology alone	19 (90.4)
Positive RT-PCR alone	1 (4.8)
Both serology and RT-PCR positive	1 (4.8)
Chest imaging (n=17)	
Pleural effusion	3 (17.6)
Lung infiltrates	1 (5.9)
Gastrointestinal imaging (n=14)

Table 4. Treatment details and outcomes

Variable	Value
Highest level of care	
PICU admission	11 (52.4)
Duration of PICU stay (hr)	74.8±41.6
Respiratory support	
Supplemental oxygen requirement	3 (14.3)
Duration of oxygen requirement (hr)	39.6±28.6
High flow nasal cannula	1 (4.8)
Circulatory support	
Inotropic support	4 (19)
Duration of inotrope requirement (hr)	37±24.5
Pharmacotherapy	
Antibiotics	18 (85.7)
Intravenous immunoglobulin alone	9 (42.9)
Steroids (intravenous or oral) alone	6 (28.6)
Both intravenous immunoglobulin and steroids	3 (14.3)
Aspirin	14 (66.7)
Anticoagulant	3 (14.3)
Antiepileptics	1 (4.8)
Outcomes	
Length of hospital stay (day), median (IQR)	6 (5–8)
Mortality	0 (0)
Follow-up	16 (76.2)

Values are presented as mean±standard deviation or number (%) unless otherwise indicated.
PICU, pediatric intensive care unit; IQR, interquartile range.

respectively. Of the 3 children with central nervous system involvement, 1 had encephalopathy with features of cerebellar involvement, 1 had seizures, and another had headache with bilateral papilledema. All 3 children with central nervous system involvement showed normal neuroimaging. Two children underwent cerebrospinal fluid analysis, and findings of aseptic meningitis were seen in the patient who presented with encephalopathy.

Treatment details and outcomes are summarized in Table 4. Eleven children (52.4%) required pediatric intensive care unit (PICU) admission and the mean duration of PICU stay was 74.8 hours. Three children (14.3%) required supplemental oxygen, and none of the children required mechanical ventilation. Four children (19%) required inotropic support for hemodynamic instability, and the mean duration of inotrope requirement was 37 hours. Nine children (42.9%) were treated with intravenous immunoglobulin (IVIG) alone, 6 (28.6%) were treated with steroids alone and 3 (14.3%) were treated with both IVIG and steroids. None of the cases required other immunomodulators for treatment.

An 8-year-old girl presented with features of acute appendicitis, and an emergency surgery was done, which revealed a perforated appendix with abscess collection. She was subsequently diagnosed as MIS-C and was treated with IVIG.

The median length of hospitalization was 6 days in this series. Table 5 shows the results of univariate analysis for prolonged hospital stay (≥7 days). Children who were either overweight or obese (P=0.035), had elevated ferritin (P=0.019), or had mucocutaneous involvement (P=0.040) were found to be significantly associated with prolonged hospital stay. Further extensive analysis could not be performed due to small sample size. There was no mortality in patients of our study, and all patients were discharged home. At the time of writing this article, 16 patients (76.2%) had attended follow-up visits.

Table 5. Results of univariate analysis of factors associated with prolonged hospital stay (n=21)

Variable	Hospital stay<7 days (n=14), n (%)	Hospital stay≥7 days (n=7), n (%)	*P* value	OR (95% CI)
Age groups			0.376	-

Table 6. Common clinical characteristics in our study versus those of other studies

Clinical feature	Our study (n=21)	Whittaker et al.[10] (n=58)	Dhanalakshmi et al.[11] (n=19)
Fever	21 (100)	58 (100)	19 (100)
Vomiting	12 (57.1)	26 (45)	6 (31.5)
Abdominal pain	11 (52.4)	31 (53)	8 (42)
Diarrhea	11 (52.4)	30 (52)	3 (15.8)
Rash	8 (38.1)	30 (52)	12 (63.2)
Bilateral conjunctival congestion	12 (57.1)	26 (45)	9 (47.4)
Cervical lymphadenopathy	3 (14.3)	9 (16)	6 (31.5)
Strawberry tongue±cracked lips	7 (33.3)	17 (29)	9 (47.4)
Oedema/erythema of hands and feet	6 (28.6)	9 (16)	10 (52.6)

Values are presented as number (%).

Among them, 11 children (52.4%) had attended one follow-up visit, and 5 (23.8%) had attended 2 follow-up visits, all of whom had no clinical concerns. Among 16 children with abnormal echocardiography, 12 (75%) underwent follow-up echocardiography, and their cardiac imaging showed partial or complete resolution of previous abnormalities. Further follow-up echocardiography was recommended to some of them.

Discussion

MIS-C is an evolving concept of disease and its exact incidences in different geographic areas are uncertain. The focus of this study was to analyze the clinical spectrum and short-term outcomes of children with MIS-C managed in a tertiary care teaching hospital in south India. We described 21 children under the age of 16 years with MIS-C associated with SARS-CoV-2 infection. All these children had evidences of previous or active COVID-19 infection. The spectrum of clinical presentations in our study was broadly consistent with available literatures. The mean age of children in this study was 6.9 years, and 61.9% of affected children were above 5 years, which was similar to studies by Kaushik et al.,[9] Whittaker et al.,[10] and Dhanalakshmi et al.[11] The male preponderance in this study was also identical to previous reports by Kaushik et al.,[9] Whittaker et al.,[10] and Gupta et al.[12] Table 6 shows the comparison between common clinical features of children in this study and 2 previous studies.[10,11] Concordant to previous reports, a greater number of children in our series had multiorgan involvement with gastrointestinal and cardiovascular systems being the most commonly affected systems.[11,13-15]

The incidence of hematological abnormalities like lymphopenia (47.6%) and thrombocytopenia (38.1%) in our study was in agreement with previous reports.[11,14,16] The majority of children in this study had raised inflammatory markers, which was similar to previous reports by Kaushik et al.,[9] Dhanalakshmi et al.,[11] Feldstein et al.,[13] and Mamishi et al.[16] In contrast to previous studies by Dhanalakshmi et al.,[11] Feldstein et al.,[13] Toubiana et al.,[15] and Miller et al.,[17] none of the children in this series had acute kidney injury. The incidence of hyponatremia (70.6%) in this study was higher than in previous reports by Dhanalakshmi et al.[1] and Mamishi et al.[16] Hypokalemia was found in 47.1% of children, and it was more common in children with gastrointestinal manifestations, which was not reported in any previous studies. Hypoalbuminemia was noted in 52.9% of children in this study, which was almost similar to previous reports by Dhanalakshmi et al.[1] and Mamishi et al.[16] The elevation of cardiac biomarkers was also concordant to previous reports by Whittaker et al.[10] and Mamishi et al.[16] The incidence of echocardiographic abnormalities in this study was comparable to previous reports by Ramcharan et al.[15] and Toubiana et al.[18] The abnormalities seen in gastrointestinal imaging studies in this study were comparable to the previous report by Miller et al.[17]

Since MIS-C is an emerging disease, guidelines regarding the management are still evolving and there is a lack of consistency in management. The majority of patients in our study were treated with either IVIG, steroids, or a combination of both and, none required other immunomodulators. The treatment decision for the patients in our study was made based on severity of the illness and the treating physician's discretion. Significant differences in treatment strategies were noted among studies from different parts of the world, which could be due to lack of standard treatment protocols in the initial phase of disease evolution.[9-11,14,16] However, a considerable number of studies would be required for developing standard treatment protocols. Concordant to previous reports by Torres et al.[14] and Dhanalakshmi et al.,[11] 52.4% of children in this series required PICU admission. The median length of hospital stay was 6 days which was comparable to previous reports.[9,14,15] Although previous studies showed variable rates of mortality, no death was reported in this study.[11,14,15,17] The follow-up rate in this study was 76.2%. All children had no health concerns at the time of follow-up, and most echocardiographic abnormalities had resolved. However, these children should be followed up at regular intervals to know the long-term consequences of the disease.

A major limitation of this study is that it was conducted in a single center over a limited period of time, and has a small sample size. Another limitation is that this study only included children under the age of 16 years, because our institutional policy defined children under 16 years to be admitted to the pediatric department. It might have missed MIS-C patients older than 16

years of age.

In conclusion, MIS-C is a novel disease that can present in a myriad of ways with variable severity, and a high index of suspicion is necessary in this era of COVID-19 pandemic for early identification, appropriate management, and favorable outcomes of patients. Further research is essential to develop optimal treatment strategies.

Abstract

In 2017, Tamil Nadu, a southern state, had the second highest number of dengue cases from India. In the present study, the serotype-specific differences in the clinical manifestations and laboratory parameters among hospitalized children with dengue were investigated and molecular characterization of the circulating dengue virus (DENV) serotypes during 2017 in Tamil Nadu was performed. Eighty children with dengue-like symptoms consecutively admitted to a tertiary care hospital and positive for DENV NS1 antigen were investigated for DENV serotype utilizing a real-time reverse transcriptase based polymerase chain reaction assay. Complete envelope (E) gene sequencing of the DENV strains was performed. Seventy samples were positive for serotyping (25 DENV-1, 17 DENV-2, six DENV-3, and 22 DENV-4). DENV-4 infections were associated with elevated levels of liver enzymes; Alanine aminotransferase ($P = .021$) and aspartate aminotransferase ($P = .001$). However, none of the serotype was associated with any specific clinical features and severe dengue. Asian and American/African genotypes of DENV-1 were cocirculating. The circulating genotype was cosmopolitan for DENV-2 with multiple lineages, genotype III for DENV-3 and genotype I for DENV-4. Unique mutations were present in the 2017 DENV-4 isolates. The present study suggests the association of DENV-4 with elevated liver enzymes in children hospitalized for dengue. Further, the study reports the genetic diversity of DENV circulating in Tamil Nadu during 2017. The study calls for continuous monitoring of the circulating serotypes and genotypes at regional level in India which might result in a region wise database useful in predicting future outbreaks.

1 | INTRODUCTION

Dengue is the commonest arthropod borne viral disease that affect millions of individuals globally each year and has been listed by the World Health Organization (WHO) as one of the major threats to mankind.[1] Infection with any of the four serotypes of dengue virus (DENV) results in a range of clinical presentations. Symptomatic dengue infections are categorized into nonsevere dengue and severe dengue (SD). The nonsevere dengue cases are again classified into those without warning signs (DwoWS) and with warning signs (DwWS). The case fatality rate is less than 1% if proper intervention is initiated at an early stage of the disease.[2] Disease severity is influenced by both virus and host factors. Immune status determined as primary infection or secondary infection with a different serotype of DENV has been reported to be associated with dengue severity by various epidemiological studies. Age, gender, nutritional status, host immune response, and host genetics contribute to differences in the clinical outcomes.[3,4] Among the viral factors, infecting serotype and the genotype within each serotype also contributes to disease severity.[3] Replacement of the circulating serotype/genotype of DENV with a different one contributes to outbreaks of higher magnitude.[5,6]

In the last decade, highest number of dengue cases were reported during 2017 in India. Within India, West Bengal and Tamil Nadu accounted for approximately 30% of the reported dengue cases.[7] Before 2017, Tamil Nadu witnessed large number of cases during 2012 and DENV-1 was the most common serotype despite the presence of other serotypes. Replacement of American/African (AM/AF) genotype with Asian genotype of DENV-1 was observed during 2012 in Tamil Nadu.[8] However, the serotypes and genotypes circulating during 2017 were not known. The present study was aimed at identifying the serotype-specific differences in the clinical symptoms and laboratory parameters in DENV infected children. Moreover, the study also intended to identify the dominant circulating serotype(s) and genotype(s) associated with dengue in Tamil Nadu during 2017.

2 | MATERIALS AND METHODS

2.1 | Study subjects

The study was a cross-sectional prospective study conducted at PSG institute of Medical Science and Research, a tertiary care teaching hospital located in western Tamil Nadu between August and December 2017. Children aged between 6 months to 15 years who fulfilled the inclusion criteria were consecutively enrolled in the study. Children admitted in the hospital with undifferentiated fever of less than 5 days duration with clinical suspicion of dengue and positive for the presence of NS1 antigen were included in the study. Exclusion criteria include: negative test for the presence of NS1 antigen, fever beyond 5 days, unwillingness to participate in the study and patients who were not admitted. The parents or the legal guardians were explained about the study purpose and an informed consent was obtained from them. The parents or the caretakers of the patients were interviewed for their demographic characteristics such as gender, age, and previous dengue episodes. The patients were observed for clinical symptoms including warning signs till their discharge and clinical features and lab data were collected in a predesigned data collection tool. Based on the clinical symptoms and laboratory parameters, the patients were categorized into dengue without warning signs (DwoWS), dengue with warning signs (DwWS), and severe dengue (SD) based on the WHO 2009 guidelines.[9] Plasma or serum samples collected from the participants at the time of entry into the study, were separated and stored at −80°C. The samples were transported in dry ice to ICMR-National Institute of Virology for identifying the serotype. The study was approved by the institutional human ethics committee (IHEC) of PSGIMS&R, Coimbatore, Tamil Nadu. Molecular characterization of the circulating DENV was performed at ICMR-NIV as a part of Apex referral laboratory activity for the year 2017 which was approved by the IHEC of ICMR-NIV.

2.2 | Serological assays

Serological assays were performed in the hospital laboratory. Presence of DENV NS1 antigen was tested by a antigen capture ELISA kit (Panbio Dengue Early ELISA) as per the manufacturer's protocol. Dengue-specific immunoglobulin M (IgM) and immunoglobulin G (IgG) antibodies were tested using ELISA kits (Panbio IgM [01PE20] and Panbio IgG capture ELISA kit [01PE10]) according to the instructions provided with the kit. The IgG capture ELISA kit used in the study detects high-titer IgG antibodies which is usually present in secondary infections. Test positive for IgG indicates secondary infection while test negative indicates primary infection.

2.3 | Detection of dengue virus serotypes

RNA was extracted using an RNA extraction kit (QIAamp viral RNA mini kit, Qiagen, Hilden, Germany) according to the manufacturer's protocol and used for DENV serotyping. Serotyping was performed by using an in-house real-time reverse transcription polymerase chain reaction (RT-PCR) assay. The sequences of the primers and probes were given in Table S1. Primer and probe sequences, the reaction mixture composition and cycling conditions for real-time RT-PCR have been reported previously.[10] The PCR cycle at which the fluorescence signals crossed the threshold values were detected for each sample and samples that had a cycle threshold (C_t) value ≤37 were considered as positive.[10]

2.4 | Isolation of dengue virus from clinical samples

Virus isolation was performed in samples which were positive for DENV RNA with increased viral load (C_t value ≤25) using C6/36 cell

line as reported previously.[10] Virus stocks were stored at −80°C in aliquots for further use.

2.5 | Sequencing of complete envelope gene of dengue virus

Randomly selected representative virus isolates from each serotype were used for sequencing of complete E gene (seven DENV-1, ten DENV-2, one DENV-3, and nine DENV-4 isolates) using primers reported earlier.[11-13] The sequences of the primers were provided in Table S1. RNA extraction, cDNA synthesis, reverse transcription, PCR amplification, gel purification, and sequencing was carried out as described earlier.[10]

2.6 | Phylogenetic analyses of dengue virus isolates

MEGA7.0 was used for multiple sequence alignment and phylogenetic analyses.[14] Seven DENV-1, ten DENV-2, one DENV-3, and nine DENV-4 sequences (GenBank accession number for the virus isolates provided in Table S2) from the current study along with the earlier Indian (44 DENV-1, 79 DENV-2, 39 DENV-3, and 31 DENV-4) and global sequences (36 DENV-1, 43 DENV-2, 54 DENV-3, and 47 DENV-4) from GenBank representing different genotypes were used for the phylogenetic analyses. Kimura-2 Parameter model was used to estimate the genetic differences and maximum likelihood (ML) method was used for the construction of the phylogenetic trees. A bootstrap test with 1000 replications was used to evaluate the reliability of position of the branches.[10]

2.7 | Statistical analyses

To compare univariate categorical data, Fisher's Exact tests or Pearson's X^2 was used. Parametric and nonparametric data from subjects infected with different dengue serotypes were compared using one-way analysis of variance and Kruskal-Wallis tests, respectively. Modified Poisson regression with adjustment for relevant clinical covariates, that is, age, gender, and fever at total day was utilized for performing the regression analyses. Data for one serotype was compared with other three serotypes. Except platelet count, the values of other laboratory parameters at the time of admission were used for comparison. The nadir for platelet count was used for comparison. A probability (*P*) value of <.05 was considered statistically significant. All the statistical analyses were carried out using statistical software R version 3.4.4.

3 | RESULTS

3.1 | Demographic profile of the study subjects

A total of 430 children with undifferentiated fever were admitted with clinical diagnosis of dengue fever of which 236 children fulfilled the inclusion criteria, 80 consecutively admitted children were enrolled in the study and were followed up prospectively. On analyzing for the serotype, 10 samples were negative and hence excluded and only 70 subjects were analyzed. Almost equal proportion of boys and girls were observed and the median age was 9 years (6 months to 15 years) (Table 1).

TABLE 1 Demographic profile of the dengue cases infected with different dengue virus (DENV) serotypes

*X^2 test was used to compare categorical variables (gender and locality) and one–way analysis of variance was used to compare the continuous variables (age, fever day at presentation and fever at total days).

3.2 | Serotype-specific differences in the clinical features, lab parameters and disease severity

All four serotypes were observed to be circulating in the study population with the prevalent serotype being DENV-1, (n = 25, 35.7%), followed by DENV-4 (n = 22, 31.4%), and DENV-2 (n = 17, 24.3%). DENV-3 was identified in 8.6% (n = 6) of the subjects. Apart from a slight female preponderance among DENV-1 infected children, gender, age, and duration of fever were not different between the children infected with different serotypes (Table 1).

A similar modified Poisson regression analysis adjusted for age, gender, and day of fever was performed for various lab parameters. A statistically significant increase in liver enzymes, aspartate aminotransferase (median with range 131.5 [22-1156] $P = .001$) and alanine aminotransferase (median with range 63 [14-594] $P = .021$) were found in DENV-4 infected children compared to children infected with other serotypes. There was no significant difference in the level of liver enzymes between primary and secondary infections. The mean ± standard deviation of liver enzymes, SGPT and SGOT in children with primary and secondary dengue were 99.18 ± 123.91, 66.83 ± 79.09 ($P = .255$) and 172.25 ± 225.03, 139.38 ± 164.15 ($P = .443$). Other hematological parameters including platelet count during the hospital period were not significantly different among children infected with different serotypes (Table 2).

After adjustment for age, gender, and duration of fever, we observed no statistically significant correlation between the infecting serotype and the clinical features (Table 3). A majority of the children had secondary dengue infection (n = 52 [67.5%]). However, immune status was not associated with disease severity (Table 3).

Classifying the children based on disease severity according to WHO 2009 criteria, there were 38 cases with DwoWS, 26 with DwWS, and 6 had SD. There was no significant association between disease severity and infecting serotype (Table 3).

3.3 | Results of virus isolation

A total of 51 samples were used for virus isolation. Virus isolation was positive in 34 samples (seven DENV-1, 13 DENV-2, two DENV-3, and 12 DENV-4). Complete E gene of the representative virus isolates (seven DENV-1, ten DENV-2, one DENV-3, and nine DENV-4) was sequenced.

3.4 | Circulating genotypes of DENV-1

DENV-1 was classified into five genotypes as described earlier.[15] Since there were confusions with regard to the Roman number based nomenclature, geographical names were provided.[16] Seven DENV-1 virus isolates were sequenced. The ML method-based phylogenetic tree (Figure 1) revealed that five isolates grouped with the Asian genotype (GI). Two isolates clustered with the American African (AM/AF) genotype (GV). Asian genotype isolates obtained during

[a]Modified Poisson regression was used for calculating the relative risk adjusted for age, gender, and fever days at admissionadmission.

2017 from Tamil Nadu clustered with Indian strains isolated during 2012-2017 from Kerala, Maharashtra, and Tamil Nadu and strains from Sri Lanka and Singapore. Five lineages, India-I to India-IV and Afro India, have been described within the AM/AF genotype earlier.[12] The present study isolates clustered with India-IV lineage strains. Comparison of amino acid sequences of the Indian isolates belonging to Asian genotype with the isolates from Singapore and Sri Lanka revealed that most of the 2017 isolates from Tamil Nadu had three conservative changes (T329S, L475P, and L484M) and one nonconservative change (F337I) that were not observed in earlier isolates (Table S3).

3.5 | Circulating genotype of DENV-2

DENV-2 was classified into five genotypes as described earlier.[17] Further, subclassifications within the cosmopolitan genotype was performed as described recently.[18] For DENV-2, ten isolates were sequenced for E gene. All sequenced isolates grouped within the cosmopolitan genotype. Within cosmopolitan genotype, Tamil Nadu isolates clustered with strains from two lineages—Cosmopolitan I (C-I) and C-III. Within C-I, five isolates were part of C-IA sublineage, and one isolate was part of C-IB (Figure 2). Amino acid sequence analysis within the 2017 Tamil Nadu isolates revealed that C-I strains had Q at 52nd position while it was H in C-III isolates. C-I had a V at 141st position of E protein while isolates from C-IB and C-III had I. Isolates from C-IB and C-III had I at 322nd position while V was present in C-IA (Table S4).

3.6 | Circulating genotypes of DENV-3 and DENV-4

Five genotypes have been reported for DENV-3.[19] One DENV-3 isolate was sequenced which clustered with earlier isolates from India, China, Pakistan, Singapore, and Senegal into GIII genotype and lineage C (Figure S1). For DENV-4, there were five genotypes.[20] Recently, an additional genotype (GVI) has been proposed.[21] Nine DENV-4 isolates were sequenced. All the 2017 isolates from Tamil Nadu grouped within the GI genotype. In the G1 genotype, 2017 isolates from Tamil Nadu along with the strains from India, Pakistan, and Sri Lanka formed lineage C. Strains from Cambodia, China, Singapore, and Thailand formed the lineage B while those from China, Japan, Philippines, and South Korea formed lineage A (Figure 3). Comparison of amino acid sequences of the E protein from the current study isolates with earlier India isolates revealed the presence of altogether 53 unique nonconservative changes in the nine 2017 isolates from Tamil Nadu (Table S5).

Among the five genotypes, Asian, American/African (AM/AF) and Sylavatic genotypes were only shown

4 | DISCUSSION

Forty percent of world's population lives in places endemic to DENV infection and at least 12 000 to 24 000 deaths happen annually in children aged below 15 years.[2] During the study period, admission of 430 undifferentiated fever cases with clinical features suggesting dengue in the pediatric services of one tertiary care hospital alone explains the magnitude of the disease in this endemic region. Circulation of all the four serotypes of DENV has been reported from different regions of India. In 2017, DENV-1 and DENV-3 were more prevalent in Maharashtra, Western India.[10] DENV-1 was the most prevalent serotype while DENV-4 was the least observed one in the 2012 dengue season in Tamil Nadu.[8] In contrast to 2012, DENV-1, DENV-2, and DENV-4 were the prevalent serotypes during 2017 in the study region and could have accounted for the large number of cases from the state. Persistent circulation of DENV-1 might have led to herd immunity permitting the emergence of other serotype viruses. Circulation of multiple serotypes suggests the hyperendemic nature of dengue in this region. The study also suggests the emergence of DENV-4 along with DENV-1 and DENV-2 in Tamil Nadu during 2017.

Studies in the past on disease severity and infecting serotypes have discordant results. A study based on the data from 1994-2006 in Thai children has suggested the association of DENV-2 infection with severe dengue.[22] Further the same study revealed that the risk of SD was more in secondary infections with DENV-2 and DENV-3.[22] A study on adult patients from Singapore revealed that infection with DENV-1 had an increased risk of dengue hemorrhagic fever than DENV-2, whereas a study from Vietnam revealed no difference in the risk of developing severe disease among hospitalized adults infected with DENV-1 and DENV-2.[23,24] A study from Brazil reported that patients infected with DENV-1 serotype had higher risk of severe clinical and laboratory features compared to those infected with DENV-4.[25] A systematic review analyzing the factors associated with

FIGURE 2 Phylogenetic tree of dengue virus-2 (DENV-2) based on E gene sequences All the current study sequences (n = 7) highlighted in Red. Apart from the current sequences, 79 global sequences and 43 Indian sequences were used for generating the phylogenetic tree

dengue shock syndrome, the most severe form of dengue, has revealed DENV-2 as a risk factor.[3] Contradicting all the studies, a study from Bali reported lack of association between DENV serotypes and disease severity.[26] In the present study, as there were less number of children who progressed to SD during hospital stay, for the purpose of analysis, children with SD and DwWS were grouped together and compared with DwoWS. Overall, there were more children with DwoWS than DwWS/SD and none of the serotypes showed any statistically significant increased risk for developing DwWS/SD. Immune status was also not associated with DwWS/SD. However, DENV-4 infections were significantly associated with elevated levels of liver enzymes. A study on pediatric dengue cases from Thailand also has reported that DENV-3 and DENV-4 infection tended to have abnormal elevation of liver enzymes.[27] This observation was contrary to a study from Northern India which has reported an association of elevated levels of liver enzymes with DENV-2.[28] Whether this association of elevated enzymes with DENV-4 can generalized to other regions depends on multiple factors such as the circulating genotype of DENV-4, host immune status, and age of the patients and a study with larger sample size is needed to further confirm the finding.

Phylogenetic analyses indicated the circulation of DENV-1 Asian and AM/AF genotypes, multiple lineages of cosmopolitan genotype of DENV-2, DENV-3 GIII genotype and DENV-4 GI genotype with unique mutations in Tamil Nadu. Cocirculation of DENV-1 Asian and AM/AF genotypes has been reported from Maharashtra in recent years while cocirculation of multiple lineages of DENV-2 cosmopolitan genotype has been reported from Northern India.[10,29,30] A recent study reported that the proportion of Asian genotype among the DENV-1-positive cases in Tamil Nadu had decreased from 90% in 2012 to 57% in 2017.[29] It is possible the DENV-1 Asian genotype viruses might have evolved over the years to become a virus with less epidemic potential phenotype. However, further comparative susceptibility studies in vectors and animal models are needed. In

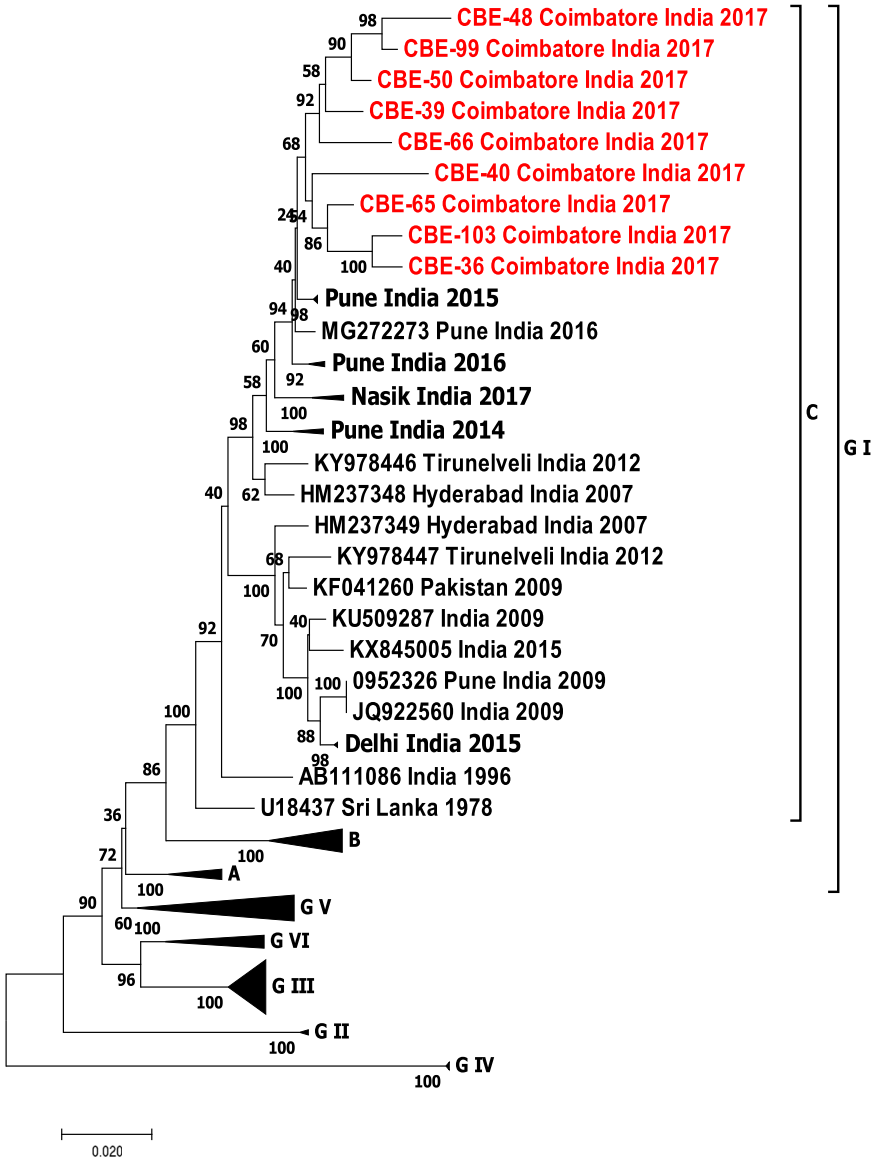

FIGURE 3 Phylogenetic tree of dengue virus-4 (DENV-4) based on E gene sequences. All the current study sequences (n = 9) highlighted in Red. Apart from the current sequences, 47 global sequences and 31 Indian sequences were used for generating the phylogenetic tree

the present study, E gene sequencing of DENV-4 isolates revealed unique mutations which were not observed in earlier Indian DENV-4 strains. The envelope protein has three structural domains I-III. Mutations in the domain II and domain III have more significance since domain II contains the fusion loop which is essential for the interaction between the host endosomal membrane and the virus envelope leading to virus membrane fusion while domain III contains epitopes that are essential for serotype-specific neutralization. Mutations in these domains might affect virus entry as well as the neutralization by serotype/genotype-specific antibodies.[31,32] DENV evolution is shaped by purifying selection in which deleterious mutations affecting viral fitness are removed with time. Further, mutations which confers fitness advantage to DENV in nature were positively selected and contributes to adaptive evolution of DENV.[33] Further follow up studies in the region are needed to discern how these mutations shape up the DENV-4 evolution. It is possible that differences in the viral factors as well as host factors might influence the variable outcomes in different studies. Monitoring the circulating serotypes and genotypes in different regions might result in a region wise database useful in predicting future outbreaks of higher magnitude when changes are observed with regard to the dominant serotypes and new genotypes.

The strength of the present study is that the subjects enrolled were belonging to only to pediatric age, they were prospectively followed up for the outcome and disease severity was classified based on latest guidelines recommended by WHO. Few limitations are, the small sample size, study participants were only hospitalized children from a particular geographic area, hence cannot be extrapolated to general population or other parts of the country. All the patients were recruited within 5 days of fever onset and hence early hospitalization and effective fluid management might have influenced the final outcome. Nonhospitalized cases with undifferentiated febrile illness, which forms the major proportion of DENV cases, were not included in the study and investigation of both hospitalized as well as nonhospitalized cases might help in

identifying the DENV serotypes associated with DwWS and severe dengue.

To conclude, the study reports the activity of all the four serotypes in Tamil Nadu during 2017 with the dominance of DENV-1, DENV-2, and DENV-4. Persistent cocirculation of DENV-1 Asian and AM/AF genotypes, cocirculation of multiple lineages of DENV-2 cosmopolitan genotype and emergence of DENV-4 GI genotype with unique mutations were observed. DENV-4 infection was associated with elevated levels of liver enzymes among hospitalized children. Serotypes and immune status were not associated with disease severity among children hospitalized for dengue.

ABSTRACT

Background: The prevalence and magnitude of childhood obesity is increasing in pediatric age group. Incidence of metabolic syndrome is high among obese children and adolescents leading to increased risk of cardiovascular morbidity in long term. For this reason, recognition of metabolic syndrome in obese children is of great importance.
Methods: This study was a cross-sectional study carried out among children aged 10-18 years from both urban and rural schools in Coimbatore. Children were screened, sample for metabolic studies collected after consent and analyzed.
Results: Total 1582 children in the age group of 10-18 years were screened. 300 children were recruited. Among the studied group, 19.3% were overweight, 30.7% were obese. Metabolic syndrome was present in 55.1% of obese and overweight children. Hyperinsulinemia was present in 30% of obese children.
Conclusions: This study done in adolescent school children showed a strong association between obesity and early onset of metabolic syndrome. Early intervention with lifestyle modifications is strongly recommended to prevent long term cardiovascular morbidity.

Keywords: Adolescent children, Metabolic syndrome, Obesity

INTRODUCTION

The prevalence and magnitude of childhood obesity is alarmingly increasing in pediatric population. Incidence of metabolic syndrome is high among obese children and adolescents, and it proportionately increases with worsening obesity. There is significantly increased risk of coronary morbidity and mortality in early adulthood among obese adolescents.[1] For this reason, the recognition of the metabolic syndrome in obese children is of great importance from a clinical and public health perspective. There are only few studies regarding the prevalence of the metabolic syndrome in children and adolescents in India.[2-4] This cross-sectional study was done to evaluate the pattern and prevalence of metabolic syndrome among adolescents aged between 10-18 years in Coimbatore, India. Metabolic syndrome was defined by using WHO and modified National Cholesterol Education Program Adult Treatment Panel III [NCEP ATP III] criteria.

In 1988, Reaven and colleagues coined the term Metabolic Syndrome (MetS) that refers to a combination of hypertension, abdominal obesity, insulin resistance, and hyperlipidemia and it was closely associated with obesity and increased risk for atherosclerotic cardiovascular disease.[5,6] What was first considered as adult condition has now been recognized in children.[7] With increasing prevalence of childhood obesity, it is very likely that pediatric metabolic syndrome will also be more prevalent recently, with implications for future increase in cardiovascular morbidity and mortality.

The International Association for the Study of Obesity (IASO) and International Obesity Task Force (IOTF) estimate that 200 million school children are either overweight or obese.[8]

A recent study among 38,296 children aged 8-18 y from five cities of India reported the prevalence of overweight and obesity (based on IOTF reference) as 14.4% and 2.8% respectively.[9] This may have major implications towards increasing prevalence of non-communicable diseases like diabetes, hypertension and cardiovascular disease in early adulthood.[10] Worldwide estimates of the prevalence of MetS range from 1.2% to 22.6% for youth and 9.0% to 35.0% for adults, depending on the definition of MetS used, the region, the study design, the years of the study, and the age group and study population.[11-15] Only very few data are available in India in this context.

METHODS

This study was a cross-sectional study and was carried out among children aged 10-18 years from schools in Coimbatore, including urban and rural areas. Children were screened for overweight and obesity based on BMI and waist circumference.

Weight was measured while the subjects were minimally clothed without shoes in upright position using digital scales and recorded to the nearest 0.1 kg. Height was measured in a standing position, without shoes, using a stadiometer and inch tape to the nearest 0.1 cm. BMI was calculated as weight in kilograms divided by height in meters squared. Waist circumference was measured in centimeters to the nearest 0.1 cm using a non-stretchable measuring tape, without any pressure to body surface at the narrowest level between the lower border of ribcage and iliac crest. Those adolescents classified under overweight and obesity are further evaluated for the presence of metabolic syndrome. Age and sex matched normal children were taken as control. They were selected by simple random sampling.

Informed consent was obtained from parent/guardians and assent from the children. A qualified physician measured blood pressure two times with the subject in a seated position during physical examinations after one initial measurement for determining peak inflation level using a standard mercury sphygmomanometer. The mean of two measurements was considered to be the participant's blood pressure. The systolic blood pressure was defined as the appearance of the first sound (Korotkoff phase 1) and diastolic blood pressure was defined as the disappearance of the sound (Korotkoff phase 5) during deflation of the cuff at a 2 - 3 mm/s decrement rate of the mercury column.

Fasting blood samples for the serum glucose and lipid profile was drawn after the subjects had fasted overnight. Samples were collected for rural children from rural health centre and urban children at PSG Hospital respectively. Fasting plasma glucose was measured on the day of blood collection by the glucose oxidase peroxide method, and lipid profile was measured by enzymatic assay on a Hitchi 704 system auto-analyzer. Lipid profiles [(triglyceride (TG), total cholesterol (C), high-density lipoprotein-cholesterol (HDL-C), low-density lipoprotein-cholesterol (LDL-C), and very-low-density lipoprotein-cholesterol (VLDL-C)] were determined in the fasting blood samples.

Fasting insulin was measured. Pubertal stage was determined in each patient using Tanner's criteria and hyperinsulinism (H1) was defined according to the norms for fasting insulin according to pubertal stage: prepubertal ≥ 15 mIU/L, mid-puberty (breast, genital stages 2-4)≥30 mIU/L post-pubertal≥20 mIU/L. Insulin resistance (IR) was analyzed using the homeostasis model assessment of insulin resistance (HOMA-IR). HOMA-IR was calculated by the following formula: fasting insulin* fasting glucose/22.5. An HOMA-IR value greater than 3.16 was used to determine IR in pubertal students.

Definition of metabolic syndrome

For the diagnosis of MetS, the presence of at least three of the following criteria (in accordance with the WHO and National Cholesterol Education Program Adult Treatment Panel III [NCEP ATP III] recommendations) was considered. These criteria included:

- Obesity: BMI≥95th percentile for age and gender (6-18 years, WHO growth charts)
- Abnormal glucose homeostasis: the presence of one of the following:
  - Hyperinsulinemia and insulin resistance (using fasting blood insulin appropriate for pubertal stage or sum of insulin levels in the first 120 min of oral glucose tolerance test)
  - Elevated fasting glucose (EPG): FG≥110 mg/dL
  - Impaired glucose tolerance (IGT), glucose at 120 min: 140-200 mg/dL
- Hypertension: systolic/diastolic blood pressure ≥95th percentile for age and sex.
- Dyslipidemia: presence of one of the following: (AAP Clinical Report on Lipid Screening in children).
  - High TG (≥95th percentile for age and sex)
  - Low HDL-C levels (<5th percentile for age and sex).
  - High total or LDL-C (≥95th percentile for age and sex).

Inclusion criteria

Children and adolescents aged between 10-18 years of age studying in urban and rural schools in Coimbatore, India. Study was done over a period of one year.

Sample size

Previous studies have estimated the prevalence of metabolic syndrome to be 4%. With this prevalence, the power of 80% and excluding the underweight children (prevalence of 30%), the screening sample size calculated as 1582. Considering the prevalence of 8% for overweight and obese children, sample size for second stage was calculated to be 150 with equal number of normal children. The samples were distributed evenly through urban and rural areas.

The data were entered in individual proforma. The collected data were then converted to excel format.

Data analysis

All statistical analyses were performed using the Statistical Package for Social Sciences (SPSS Inc., Chicago, IL) version 19. Data expressed as percentage. Chi square test was used to find out association between categorical variables.

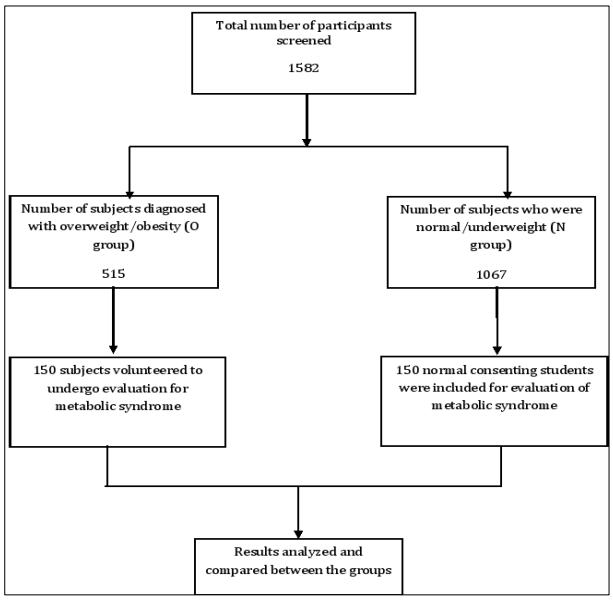

Figure 1: Flow diagram of subject recruitment.

RESULTS

Total number of school children recruited for this study in the age group of 10-18 years were 300, among whom 149 (49.7%) were boys and 151 (50.3%) were girls; in our study, there was almost equal distribution of boys and girls. Among the studied group 58 (19.3%), 92 (30.7%), 124 (41.3%), 26 (8.7%) children were overweight, obese and normal weight and underweight children respectively. Abnormal FBS (>110mg/dL) was seen in 5% of obese children and 2.1% in normal weight group, which was statistically significant. Abnormal total cholesterol level was found in 6% of obese and overweight group and 3.3% in normal group. (p value = 0.27) Triglyceride level was abnormal in 40.6% of O group children and 12.6% in N group children which was statistically significant (p=0.0001%). HDL was abnormal in 24.6% of O group children and 9.3% in N group children also had statistically significant difference (p=0.0001%). Hyperinsulinemia was present in 30% of O group children and 9.3% of N group children. HOMA - IR elevated in 60.6% of O group children and 22% in N group children. Both are statistically significant. Elevated BP was observed in 4.6% of N group children and 7.3% of O group children. Stage 1 hypertension seen in 3.3% of N group children and 14% of O group children which was statistically significant (p=0.002%). Among studied group MS was present in 55.1% in obese, overweight children. MS was more evidenced in the age group of 10-12 years (38.3%) as compared to the other age groups.

Table 1: Baseline characteristics of the study population.

Parameters		Number	Percentage
Age in years	10-12	122	40.7
	13-15	121	40.3
	16-17	57	19
Sex	Males	149	49.7
	Females	151	50.3
Overweight		58	19.3
Obese		92	30.7
Normal		124	41.3
Underweight		26	8.7

Table 2: Lipid profile, HOMA-IR, insulin levels, blood pressure between normal and overweight/obese children.

Variables		Overweight and obese(%)	Normal and underweight(%)	Chi square and p-value
TC		6	3.3	1.19,0.27
TGL		40.6	12.6	30.06,0.0001*
HDL		24.6	9.3	12.49,0.0001*
LDL		11.3	8.6	0.793,0.441
HOMA-IR		60.6	22	46,2,0.0001*
Insulin		30	9.3	20.27,0.0001*
BP	Normal	78.6	92	12.29, p- 0.002
	Elevated	7.3	4.6	
	Stage1	14	3.3	

Table 1 indicating baseline characteristics of the study population including 1. Age group, majority of the children studied were between 10-15 years of age (81%). 2. Equally distributed between both sexes. 3. 30.7% children were obese and 19.3% were overweight.

Table 2 depicting the variables of lipid profile, insulin levels and blood pressure between normal and overweight, obese group.

Table 3 depicts that 50% of children with obesity in the study population had criteria to fulfill metabolic syndrome. 5.1% of children in the overweight group and 3.3% in the normal weight group had metabolic syndrome.

Table 3: Metabolic syndrome in the study population.

Category	Number	Percentage
Normal and under weight	5	3.3
Overweight	3	5.1
Obese	46	50

Table 4 shows the distribution of metabolic syndrome, age wise amongst overweight and obese children. 38.3%between 10-12 years, 28.5% between 13-15 years and 21.4 percent 16 and 17 years fulfilled criteria for metabolic syndrome. This indicates that screening and interventions should be planned early.

Table 4: Distribution of metabolic syndrome age-wise among overweight and obese children.

Age	Number	Percentage
10-12	28	38.3
13-15	18	28.5
16-17	3	21.4

DISCUSSION

Metabolic syndrome is a group of risk factors which has been increasingly prevalent concurrent with obesity.[16] Consistently high prevalence of MS has been recorded in obese and overweight adolescents across the globe varying from 24% to 38.8% of obese children (Turkey). These figures have varied in accordance with the criteria used. Using a combination of WHO and ATP-III criteria in the present study, we found that 50% of obese and 5.1% of overweight adolescent had MS respectively. Such figures in children is a potential harbinger of adult onset cardiovascular morbidity and mortality thereon. In this study, we found that there was equal preponderance of male and female adolescents for MS.

The children between 10-12 years had higher percentage of MS as compared to older adolescents.[17] This fact highlights early screening and dietary and lifestyle modifications for younger adolescents.

Authors observed that there was no statistically significant difference in total cholesterol and LDL levels between the 2 groups. However, the circulatory triglyceride levels were statistically more in the overweight and obese children with MS. High TG has been reported in studies.[2,17,18] The significance of hypertriglyceridemia in adolescents as a harbinger of adult onset of cardiovascular disease is gradually being appreciated. (Another factor noted in this study was that a small subsect of normal weight adolescents had triglyceride values above the age specific cutoff with other parameters remaining normal.) Levels of HDL were statistically significantly lower in the overweight and obese groups as quoted by other studies.[17,19,2] Hyperinsulinemia was present in 30% of obese and overweight adolescents qualifying for MS as observed by Mehmet Atabek.[20] Acanthosis nigricans as an external marker for hyperinsulinemia was seen in 3% of obese adolescents. High FBS (>110mg/dL) was found in 5% of obese and overweight children in the study. HOMA - IR was found to be elevated in 60.6% of the overweight and obese group which was statistically significant (p value 0.0001).11 adolescents (7.3%) in the overweight and obese group had elevated BP and 14% of children in the group and high BP qualifying for stage I hypertension.

Limitation of the study was that detailed dietary assessment could not be done as it was a school based study. Exact duration of physical activity was not included in the proforma.

CONCLUSION

This study done in children between 10-18 years has shown a strong association between obesity and incidence of metabolic syndrome. Early intervention with lifestyle modifications is strongly recommended to prevent long-term cardiovascular morbidity.

Clinical spectrum and short-term outcomes of multisystem inflammatory syndrome in children in a south Indian hospital

Muruganantham Balagurunathan, MD*, Thrilok Natarajan, MD, MRCPCH (UK)*, Jothilakshmi Karthikeyan, DNB, Venkateshwaran Palanisamy, MD

Department of Pediatrics, PSG Institute of Medical Sciences and Research, Tamilnadu, India

Background: Multisystem inflammatory syndrome in children (MIS-C) is a new hyperinflammatory variant that evolved during the coronavirus disease 2019 pandemic. Although the precise pathophysiology of MIS-C is uncertain, it is thought to be due to immune dysregulation occurring after recovery from acute infection.

Purpose: Our study aimed to analyze the clinical spectrum, laboratory parameters, imaging characteristics, treatment strategies, and short-term outcomes of children with a diagnosis of MIS-C.

Methods: This retrospective and prospective observational study included children less than 16 years of age who were admitted to the pediatric unit of a tertiary care teaching hospital in south India between August 2020 to January 2021 with a diagnosis of MIS-C according to World Health Organization criteria.

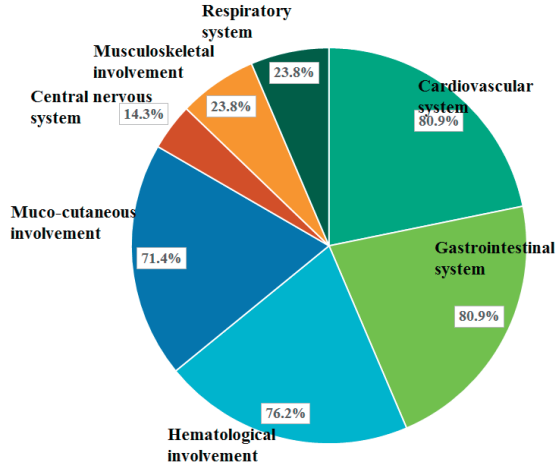
Results: Twenty-one children were included in the analysis; all had fever with variable combinations of other symptoms. The mean age was 6.9 years; 71.4% were male. Gastrointestinal (80.9%) and cardiovascular (80.9%) systems were the most commonly affected. The majority of children had elevated inflammatory markers, and 16 (76.2%) had echocardiographic abnormalities mimicking Kawasaki disease. Eleven children (52.4%) required intensive care admission, 3 (14.3%) required supplemental oxygen, and 4 (19%) required inotropes. Nine (42.9%) were treated with intravenous immunoglobulin alone, 6 (28.6%) with steroids alone, and 3 (14.3%) with steroids and immunoglobulin. The median hospital stay was 6 days; there were no fatalities. Overweight/obesity, elevated ferritin, and mucocutaneous involvement were significantly associated with a prolonged hospital stay (≥7 days). Sixteen children (76.2%) were followed up till now and all of them had no clinical concerns.

Conclusion: MIS-C is an emerging disease with variable presentation. A high index of suspicion is necessary for its early identification and appropriate management. Further research is essential for developing optimal treatment strategies.

Key words: Clinical spectrum, Coronavirus disease 2019, Kawasaki disease, Multisystem inflammatory syndrome in children

Key message

- **Question:** What are the clinical spectrum, course, and short-term outcomes of multisystem inflammatory syndrome in children (MIS-C)?
- **Finding:** MIS-C can have variable clinical manifestations. Fever is most common, followed by gastrointestinal and cardiovascular symptoms. Early identification and appropriate management lead to favorable outcomes.
- **Meaning:** MIS-C can present in a myriad of ways and severities. High suspicion is necessary to ensure its early identification and appropriate management and favorable patient outcomes.



Introduction

The coronavirus disease 2019 (COVID-19) pandemic in India is a part of the global pandemic caused by severe acute respiratory syndrome corona virus-2 (SARS-CoV-2). India is one of the countries with the highest burden of confirmed COVID-19 cases in the world and ranks second in the list of countries with a maximum number of cases.[1] Earlier reports suggested that children infected with COVID-19 were highly resilient and could present with only a mild upper respiratory illness.[2-4] But in April 2020, clinicians in the United Kingdom reported a cluster of previously healthy children presenting with shock, fever, and hyper inflammation.[5] The Royal College of Paediatrics and Child Health referred to this acute condition as pediatric inflammatory multisystem syndrome temporally associated with SARS-CoV-2.[6] As the pandemic progressed and the number of such cases increased globally the illness was labelled as multisystem inflammatory syndrome in children (MIS-C) by the Centers for Disease Control and Prevention and

Clinical Spectrum of Multisystem Inflammatory Syndrome in Children

- Intensive care admission – 52.4 %
- Supplemental oxygen requirement – 14.3%
- Inotrope requirement – 19 %
- Abnormal ECHO – 76.2%
- Mortality - 0%
- Follow-up – 76.2%

Graphical abstract

the World Health Organization (WHO).[7,8] Although the exact pathophysiology of MIS-C is uncertain, it is thought to be due to immune dysregulation occurring after recovery from acute infection. As the burden of COVID-19 infection is increasing in India, more children are being recognized with this condition. Although many articles are reported from western countries there is a dearth of published reports from Asian countries.

Our study aimed at analyzing the clinical spectrum, laboratory parameters, and imaging characteristics of children less than 16 years admitted with a diagnosis of MIS-C. In addition, this study aimed to analyze the treatment strategies and short-term outcomes.

Methods

1. Study design and setting

This study was a partly retrospective and partly prospective observational study done in children admitted with a diagnosis of MIS-C in a tertiary care teaching hospital in south India from August 2020 to January 2021. The hospital is one of the largest COVID-19 care centers in south India and receives referrals from a radius of 200 kilometers. The study was approved by the Institutional Human Ethics Committee of PSGIMS&R (project No. 20/262 dated 27th November, 2020). Informed written consent was obtained from parents prior to the inclusion of children in the prospective part of the study. Waiver of consent was obtained for the retrospective collection of data.

2. Participants

Children less than 16 years of age diagnosed with MIS-C as per WHO criteria were included in the study. The following parameters were considered for diagnosis: (1) fever ≥3 days, (2) 2 of the following: a) rash or bilateral nonpurulent conjunctivitis or mucocutaneous inflammation signs (oral mucosa, hands, or feet), b) hypotension or shock, c) features of myocardial dysfunction, pericarditis, valvulitis, or coronary abnormalities (including echocardiography findings or elevated troponin/N-terminal pro-B-type natriuretic peptide [NT-proBNP]), d) evidence of coagulopathy (by prothrombin time, partial thromboplastin time, elevated D-dimers), e) Acute gastrointestinal problems [diarrhea, vomiting, or abdominal pain], (3) elevated markers of inflammation such as erythrocyte sedimentation rate, C-reactive protein, or procalcitonin, (4) no other obvious microbial cause of inflammation, including bacterial sepsis, staphylococcal or streptococcal toxic shock syndromes, (5) evidence of COVID-19 (real-time reverse transcription polymerase chain reaction [RT-PCR], antigen test or serology positive), or likely contact with patients with COVID-19.

3. Data collection

Data on demographics, clinical features, laboratory results, imaging studies, treatment details, outcomes, and follow-up were collected. All the investigations and treatment were carried out as per institutional protocol and treating physician's discretion.

COVID-19 infection was confirmed by testing for SARS-CoV-2 antibody by chemiluminescence immunoassay (VITROS 3600 immunodiagnostic system, Ortho Clinical Diagnostics, Raritan, NJ, USA) and/or RT-PCR as recommended by Indian Council of Medical Research. The laboratory values were interpreted as either increased or decreased based on the age-specific normal reference ranges. Organ system involvement was described based on clinical features, laboratory reports, and imaging studies. Echocardiography was performed in all children by the pediatric cardiologist to identify the following abnormalities; (a) left ventricular dysfunction (ejection fraction

less than 55%), (b) pericarditis or pericardial effusion, (c) coronary artery abnormalities (dilatation, aneurysm, or irregular nontapering coronary arteries), or (d) valvular regurgitation. The dimension of the coronary artery was measured as per standard criteria and a coronary z score above 2 was reported as dilated. Other imaging studies were done as clinically indicated.

4. Statistical analysis

Data analysis was done using Microsoft Excel 2019 (Microsoft Corp., Redmond, WA, USA). Descriptive statistics were used to summarize population characteristics. Categorical variables were expressed as frequency or percentage and continuous variables were expressed as mean with standard deviation or median with interquartile range. IBM SPSS Statistics ver. 26.0 (IBM Co., Armonk, NY, USA) was used to perform univariate analysis and a *P* value of <0.05 was considered significant.

Results

From August 2020 to January 2021, twenty-one children met the WHO MIS-C criteria and were included in the analysis. Among them, only 2 children were admitted with active coronavirus-2 infection and were subsequently diagnosed as MIS-C. The demographic and clinical characteristics of the study population are mentioned in Table 1. The mean age of the study population was 6.9 years and 71.4% were male. All children were previously healthy and 9.5% were either obese or overweight.

All patients had fever with a variable combination of other symptoms. Gastrointestinal symptoms like abdominal pain, diarrhea, and vomiting were the most common presenting symptoms. The mean duration of symptoms prior to admission was 4.8 days and the mean total duration of fever was 7.9 days. The majority of children in this series had multiorgan involvement. Gastrointestinal (80.9%) and cardiovascular (80.9 %) systems were the most commonly affected organ systems. This was followed by hematological (76.2%), mucocutaneous (71.4%), and central nervous system (14.2%) involvement. None of the children had acute kidney injury in this series. Two children in this series had been treated for COVID-19 3 weeks prior to the diagnosis of MIS-C, and 5 children had history of confirmed exposure to COVID-19 patients in the preceding 3 to 4 weeks. In other children, no history associated with COVID-19 was revealed.

In the study population, 19 children (90.4%) had positive COVID-19 antibody tests, 1 (4.8%) had positive COVID-19 RT-PCR test, and another (4.8%) had both positive COVID-19 RT-PCR and antibody tests. The results of laboratory tests and imaging studies are summarized in Tables 2 and 3. Lymphopenia and thrombocytopenia were seen in 47.6% and 38.1% of cases, respectively. Inflammatory markers were elevated in the majority of cases. Specifically, D-dimer and interleukin 6 (IL-6) were elevated in 95.2% and 90.5% of cases, respectively. Children with cardiovascular system involvement showed elevation of

Table 2. Laboratory test results

Parameter	Number (%)	Definition
Blood counts		
Anemia	4/21 (19)	Hb <10 g/dL in <1 yr Hb <9 g/dL in ≥1 yr
Neutrophilia	16/21 (76.2)	ANC >7.7×10^3 cells/μL
Lymphopenia	10/21 (47.6)	ALC <1.5×10^3 cells/μL in child >8 mo ALC <4.5×10^3 cells/μL in child <8 mo
Thrombocytopenia	8/21 (38.1)	Platelet <150×10^3 cells/mm^3
Thrombocytosis	6/21 (28.6)	Platelet >500×10^3 cells/mm^3
Inflammatory markers		
Elevated ESR	17/20 (85)	≥40 mm/hr
Elevated CRP	20/20 (100)	≥0.6 mg/dL
Elevated procalcitonin	5/5 (100)	≥0.5 ng/mL
Elevated ferritin	9/21 (42.9)	>500 ng/mL
Elevated IL-6	19/21 (90.5)	≥7 pg/mL
Elevated LDH	11/16 (68.8)	LDH >300 U/L
Electrolytes		
Hyponatremia	12/17 (70.6)	Sodium <135 mEq/L
Hypokalemia	8/17 (47.1)	Potassium <3.5 mEq/L
Liver function test		
Elevated AST	6/17 (35.3)	AST >40 U/L
Elevated ALT	5/17 (29.4)	ALT >40 U/L
Hypoalbuminemia	9/17 (52.9)	Albumin <3 g/dL
Cardiac biomarkers		
Elevated troponin-T	4/13 (30.8)	≥14 pg/mL
Elevated NT-proBNP	12/15 (80)	>450 pg/mL
Coagulation profile		
Elevated D-dimer	20/21 (95.2)	≥0.5 mg/L FEU
Deranged coagulation	2/8 (25)	INR ≥1.2

Hb, hemoglobin; ANC, absolute neutrophil counts; ALC, absolute lymphocyte counts; ESR, erythrocyte sedimentation rate; CRP, C-reactive protein; IL, interleukin; LDH, lactate dehydrogenase; AST, aspartate aminotransferase; ALT, alanine aminotransferase; NT-proBNP, N-terminal prohormone of brain natriuretic peptide; FEU, fibrinogen equivalent units; INR, international normalized ratio.

cardiac biomarkers, and NT-proBNP (80%) was found to be more commonly elevated than troponin-T (30.8%). Electrolyte imbalances like hyponatremia and hypokalemia were seen in 70.6% and 47.1% of cases, respectively, which were managed appropriately.

Echocardiography was performed in all the children, and abnormality was noted in 16 children (76.2%). A greater number of children had a combination of abnormalities rather than a single abnormal finding. Coronary artery abnormality (57.1%) was the most common finding, followed by pericardial effusion (52.4%), left ventricular dysfunction (23.8%), and mitral regurgitation (23.8%). Gastrointestinal imaging studies like x-ray, ultrasound, and computed tomography were done as indicated, and ascites (50%) was the most common abnormality, followed by dilated bowel loops (35.7%), and mesenteric lymphadenitis (35.7%). Of the 17 patients who underwent chest imaging (x-ray or computed tomography), pleural effusion and lung infiltrates were observed in 3 (17.6%) and 1 patient (5.9%),

PICU, pediatric intensive care unit; IQR, interquartile range.

respectively. Of the 3 children with central nervous system involvement, 1 had encephalopathy with features of cerebellar involvement, 1 had seizures, and another had headache with bilateral papilledema. All 3 children with central nervous system involvement showed normal neuroimaging. Two children underwent cerebrospinal fluid analysis, and findings of aseptic meningitis were seen in the patient who presented with encephalopathy.

Treatment details and outcomes are summarized in Table 4. Eleven children (52.4%) required pediatric intensive care unit (PICU) admission and the mean duration of PICU stay was 74.8 hours. Three children (14.3%) required supplemental oxygen, and none of the children required mechanical ventilation. Four children (19%) required inotropic support for hemodynamic instability, and the mean duration of inotrope requirement was 37 hours. Nine children (42.9%) were treated with intravenous immunoglobulin (IVIG) alone, 6 (28.6%) were treated with steroids alone and 3 (14.3%) were treated with both IVIG and steroids. None of the cases required other immunomodulators for treatment.

An 8-year-old girl presented with features of acute appendicitis, and an emergency surgery was done, which revealed a perforated appendix with abscess collection. She was subsequently diagnosed as MIS-C and was treated with IVIG.

The median length of hospitalization was 6 days in this series. Table 5 shows the results of univariate analysis for prolonged hospital stay (≥7 days). Children who were either overweight or obese (P=0.035), had elevated ferritin (P=0.019), or had mucocutaneous involvement (P=0.040) were found to be significantly associated with prolonged hospital stay. Further extensive analysis could not be performed due to small sample size. There was no mortality in patients of our study, and all patients were discharged home. At the time of writing this article, 16 patients (76.2%) had attended follow-up visits.

Table 5. Results of univariate analysis of factors associated with prolonged hospital stay (n=21)

Variable	Hospital stay<7 days (n=14), n (%)	Hospital stay≥7 days (n=7), n (%)	*P* value	OR (95% CI)

Table 6. Common clinical characteristics in our study versus those of other studies

Clinical feature	Our study (n=21)	Whittaker et al.[10] (n=58)	Dhanalakshmi et al.[11] (n=19)
Fever	21 (100)	58 (100)	19 (100)
Vomiting	12 (57.1)	26 (45)	6 (31.5)
Abdominal pain	11 (52.4)	31 (53)	8 (42)
Diarrhea	11 (52.4)	30 (52)	3 (15.8)
Rash	8 (38.1)	30 (52)	12 (63.2)
Bilateral conjunctival congestion	12 (57.1)	26 (45)	9 (47.4)
Cervical lymphadenopathy	3 (14.3)	9 (16)	6 (31.5)
Strawberry tongue±cracked lips	7 (33.3)	17 (29)	9 (47.4)
Oedema/erythema of hands and feet	6 (28.6)	9 (16)	10 (52.6)

Values are presented as number (%).

Among them, 11 children (52.4%) had attended one follow-up visit, and 5 (23.8%) had attended 2 follow-up visits, all of whom had no clinical concerns. Among 16 children with abnormal echocardiography, 12 (75%) underwent follow-up echocardiography, and their cardiac imaging showed partial or complete resolution of previous abnormalities. Further follow-up echocardiography was recommended to some of them.

Discussion

MIS-C is an evolving concept of disease and its exact incidences in different geographic areas are uncertain. The focus of this study was to analyze the clinical spectrum and short-term outcomes of children with MIS-C managed in a tertiary care teaching hospital in south India. We described 21 children under the age of 16 years with MIS-C associated with SARS-CoV-2 infection. All these children had evidences of previous or active COVID-19 infection. The spectrum of clinical presentations in our study was broadly consistent with available literatures. The mean age of children in this study was 6.9 years, and 61.9% of affected children were above 5 years, which was similar to studies by Kaushik et al.,[9] Whittaker et al.,[10] and Dhanalakshmi et al.[11] The male preponderance in this study was also identical to previous reports by Kaushik et al.,[9] Whittaker et al.,[10] and Gupta et al.[12] Table 6 shows the comparison between common clinical features of children in this study and 2 previous studies.[10,11] Concordant to previous reports, a greater number of children in our series had multiorgan involvement with gastrointestinal and cardiovascular systems being the most commonly affected systems.[11,13-15]

The incidence of hematological abnormalities like lymphopenia (47.6%) and thrombocytopenia (38.1%) in our study was in agreement with previous reports.[11,14,16] The majority of children in this study had raised inflammatory markers, which was similar to previous reports by Kaushik et al.,[9] Dhanalakshmi et al.,[11] Feldstein et al.,[13] and Mamishi et al.[16] In contrast to previous studies by Dhanalakshmi et al.,[11] Feldstein et al.,[13] Toubiana et al.,[15] and Miller et al.,[17] none of the children in this series had acute kidney injury. The incidence of hyponatremia (70.6%) in this study was higher than in previous reports by Dhanalakshmi et al.[1] and Mamishi et al.[16] Hypokalemia was found in 47.1% of children, and it was more common in children with gastrointestinal manifestations, which was not reported in any previous studies. Hypoalbuminemia was noted in 52.9% of children in this study, which was almost similar to previous reports by Dhanalakshmi et al.[1] and Mamishi et al.[16] The elevation of cardiac biomarkers was also concordant to previous reports by Whittaker et al.[10] and Mamishi et al.[16] The incidence of echocardiographic abnormalities in this study was comparable to previous reports by Ramcharan et al.[15] and Toubiana et al.[18] The abnormalities seen in gastrointestinal imaging studies in this study were comparable to the previous report by Miller et al.[17]

Since MIS-C is an emerging disease, guidelines regarding the management are still evolving and there is a lack of consistency in management. The majority of patients in our study were treated with either IVIG, steroids, or a combination of both and, none required other immunomodulators. The treatment decision for the patients in our study was made based on severity of the illness and the treating physician's discretion. Significant differences in treatment strategies were noted among studies from different parts of the world, which could be due to lack of standard treatment protocols in the initial phase of disease evolution.[9-11,14,16] However, a considerable number of studies would be required for developing standard treatment protocols. Concordant to previous reports by Torres et al.[14] and Dhanalakshmi et al.,[11] 52.4% of children in this series required PICU admission. The median length of hospital stay was 6 days which was comparable to previous reports.[9,14,15] Although previous studies showed variable rates of mortality, no death was reported in this study.[11,14,15,17] The follow-up rate in this study was 76.2%. All children had no health concerns at the time of follow-up, and most echocardiographic abnormalities had resolved. However, these children should be followed up at regular intervals to know the long-term consequences of the disease.

A major limitation of this study is that it was conducted in a single center over a limited period of time, and has a small sample size. Another limitation is that this study only included children under the age of 16 years, because our institutional policy defined children under 16 years to be admitted to the pediatric department. It might have missed MIS-C patients older than 16

years of age.

In conclusion, MIS-C is a novel disease that can present in a myriad of ways with variable severity, and a high index of suspicion is necessary in this era of COVID-19 pandemic for early identification, appropriate management, and favorable outcomes of patients. Further research is essential to develop optimal treatment strategies.

Abstract

Background: The association of serum vitamin D levels to clinical outcome in VLBW infants has not been studied. Our objective was to measure the cord blood levels, and the dose response for two doses of vitamin D in preterm infants and correlate the relationship of vitamin D levels to the clinical outcome.

Methods: We prospectively obtained cord blood levels in 80 preterm infants under 34 weeks gestation (mean gestation age 29±2 weeks and BW: 1210±350 gms). Infants were supplemented with 400 IU or 800-1000 IU vitamin D daily. Serun vitamin D levels were obtained at 2 - 3 weeks after supplementation and levels were correlated to clinical outcome.

Results: The mean cord blood vitamin D level was 12±8.5 ng/ml. Babies who developed sepsis and compared to those who did not develop these morbidities, ROP had vitamin D levels: 13.5±6 (ng/ml) versus 30.5±10 (ng/ml) ($p < 0.01$) and 15.7±11 (ng/ml) versus 34±18 (ng/ml) ($p <0.03$) respectively. Supplementation with 400 IU vitamin D resulted in levels of 17±8.6 (ng/ml) and infants given 800-1000 IU vitamin D had levels 46±17(ng/ml) ($p <0.001$).

Conclusions: These data suggest that cord blood vitamin D levels are low in preterm infants and 800-1000 IU vitamin D supplementation is advisable to achieve levels >30 ng/ml. Infants with low levels of vitamin D have higher incidence of sepsis, and ROP.

Keywords: Morbidity, Preterm Infants, Vitamin D levels

Introduction

Although there is no consensus on optimum levels of serum vitamin D levels, vitamin D deficiency is defined as a 25-hydroxy vitamin D level of less than 20 ng per millilitre (50 nmol per litre).[1-4] No specific definition exists for preterm infants. With the use of such definitions, it has been estimated that 1 billion people worldwide have vitamin D deficiency or insufficiency.[5-7] High prevalence of physiologically significant hypovitaminosis D among pregnant women and their term newborns have been reported in India.[8] The active metabolite of vitamin D, 1,25-dihydroxyvitamin D3 (1,25(OH)2D3), exerts its bio-logical actions by binding to a nuclear receptor, the vitamin D receptor (VDR) and these are present in almost every organ system in the body. It is speculated that there is a physiologic role for vitamin D and its metabolites in general health.[9,12,13]

The awareness of a role for vitamin D in the regulation of immune responses was triggered by the discovery of VDRs in almost all immune cells of the innate and adaptive immune system.[10] Moreover, immune signals can regulate expression levels of the VDR and the enzymes involved in vitamin D metabolism.[11]

The VDRs and vitamin D metabolizing enzymes have also been identified in both the vasculature and the heart

including cardiac myocytes, vascular smooth muscle cells, and endothelial cells. 1,25(OH)2D3 also inhibits angiogenesis, by inhibiting the proliferation of endothelial cells and/or by repressing the release of angiogenic factors such as TGF-a, epidermal growth factor, and vascular endothelial growth factor (VEGF).[20] The association of vitamin D levels to clinical outcome in VLBW infants has not been well studied. Objectives of the study were to determine the vitamin D levels in the cord blood of preterm infants, supplement vitamin D in two doses 400 IU daily and 800-1000 IU daily to randomly assigned preterm infants and to correlate the serum vitamin D levels to neonatal morbidity and outcome.

M□□□□□□□

The study was conducted in the neonatal intensive care unit of a tertiary care hospital in south India. The study was approved by the medical ethics committee. The criterion for enrolment was gestational age of ≤34 weeks. Infants born with severe asphyxia, chromosomal disorders and congenital infections were excluded from enrolment.

Previously we have noticed that several convalescent preterm infants had very low vit. D levels ranging from 3 to 10 ng/ml, although they were receiving 400 IU of vit. D daily. In order to determine vit. D levels at birth, we obtained cord blood levels of 25 hydroxy Vitamin D3 and followed their serum vitamin D levels 2 to 3 weeks after vitamin D supplementation. When infants were getting enteral feedings of 120ml/kg/day, they were randomly assigned to receive vitamin D supplementation of 400 IU (Group 1) or 800-1000 IU (Group 2) orally daily. Vitamin D levels were measured by chemiluminescence assay (Roche Diagnostics Limited, Sussex, UK). The baseline characteristics of these groups before supplementation with vitamin D are given in Table 1.

give rise to scarring fibrous tissue resulting in retinal detachment in severe cases. Therefore, there is great interest in the development and identification of agents that can inhibit the growth of new blood vessels. The anti-angiogenic properties of calcitriol (1,25-dihydroxyvitamin D3), has been studied in the mouse model and it has been mentioned as a potent inhibitor of retinal neovascularization and may be of benefit in the treatment of a variety of eye diseases with a neovascular component like ROP.[14,15,21] How calcitriol affects angiogenesis has been unclear.

It was also found that there is an association an association of vitamin D deficiency and late onset sepsis. Vitamin D has a role in regulating inflammation and chemokine production as well as an important role in immunomodulation.[16-18,22] Nearly all cells display a specific vitamin D receptor (VDR), including B and T lymphocytes (both resting and activated), monocytes and dendritic cells.[23] Vitamin D also facilitates neutrophil motility and phagocytic function. A major component of the antimicrobial action of Vitamin D is through the production of peptides which have antimicrobial as well as anti-endotoxin activity. Vitamin D stimulates the expression of potent antimicrobial peptides, such as cathelicidin and β defensin which exist in neutrophils, monocytes, natural killer (NK) cells and epithelial cells lining the respiratory tract.[24,25] Macrophages, lymphocytes and monocytes have VDRs that, with 25(OH)D stimulation, increase the expression of these antimicrobial peptides.[26,27] Jeng et al. noted a positive relationship between vitamin D levels and cathelicidin levels in acutely ill patients.[28] Cathelicidin is effective against gram-positive and gram-negative bacteria, fungi and mycobacteria at a variety of pathogen entry sites, including the skin and the mucosal linings of the respiratory and gastrointestinal sys-tems.[24] Patients with 25(OH) D levels less than 20 ng/mL may be unable to fully express cathelicidin, which could be associated with increased susceptibility to nosocomial infec-tions such as pneumonia, sepsis and central line infections.[28,29] A randomized controlled trial involving Japanese schoolchildren found a relative risk of influenza of 0.36 in those taking 1,200 IU/day compared with those taking 200 IU/day.[30] In-vitro studies have shown that vit-amin D3 has inhibitory activity on strains of *Staphylococcus aureus, Streptococcus pyogenes, Klebsiella pneumoniae, Escherichia coli* (E. coli) and other bacteria. In the presence of 50,000-90,000 IU/mL of vitamin D_3, the organisms were killed or demonstrated marked growth inhibition.[31] The risk of diseases comorbid with septicemia are generally inversely correlated with serum 25(OH)D levels.[32] Grant had reported that vitamin D supplementation of mother and infant can reduce the risk of sepsis in infants and neonates.[33,34]

The results of our study also indicate that the usual recommended dose of 400 IU Vitamin D in preterms is not sufficient to maintain normal physiological levels in our cohort of Indian infants. This has been observed in other Indian studies also.[35-37] It is quite possible that these infants had very low vitamin D levels at birth perhaps due to maternal vitamin D deficiency and required a higher dose of vitamin D supplementation postnatally. Although none of the infants in our study who received 800-1000 IU of vitamin D very high levels of serum vita-min D we recommend that serum vitamin D levels should be monitored at least once within a month of supplementation of this high dose of vitamin D. We did not correlate the cord blood vitamin D levels to postnatal vitamin D requirement. It is quite possible that the mothers of these infants might have low vitamin D levels during pregnancy which might have contributed to low cord blood levels of vitamin D in these infants. Whether if pregnant mothers are adequately supplemented with vitamin D leading to higher cord blood levels of vitamin D may lead to lower requirements of vitamin D postnatally in these infants is not known. We realize that this is not a randomized controlled study and the sample size is rather small but the results are very convincing that a larger multicenter trial may be warranted to confirm these findings.

□□□□□□□□□□

These data suggest that severe vit.D deficiency is common in preterm newborns at birth and postnatally. In infants with low levels of vit D: incidences of late onset sepsis and ROP are significantly higher. Retinal maturation of infants with low levels of vitamin D is delayed perhaps increasing their risk for development of ROP even in the absence of supplemental oxygen administration. AAP guidelines of supplementation with 400 IU is insufficient and most infants require 800-1000 IU vitamin D soon after birth to maintain vitamin D levels ≥ 30 ng/ml in developing countries especially if they are exclusively breast fed. These preliminary results will assist in planning a larger multicenter trial in this field.

Abstract

In 2017, Tamil Nadu, a southern state, had the second highest number of dengue cases from India. In the present study, the serotype-specific differences in the clinical manifestations and laboratory parameters among hospitalized children with dengue were investigated and molecular characterization of the circulating dengue virus (DENV) serotypes during 2017 in Tamil Nadu was performed. Eighty children with dengue-like symptoms consecutively admitted to a tertiary care hospital and positive for DENV NS1 antigen were investigated for DENV serotype utilizing a real-time reverse transcriptase based polymerase chain reaction assay. Complete envelope (E) gene sequencing of the DENV strains was performed. Seventy samples were positive for serotyping (25 DENV-1, 17 DENV-2, six DENV-3, and 22 DENV-4). DENV-4 infections were associated with elevated levels of liver enzymes; Alanine aminotransferase ($P = .021$) and aspartate aminotransferase ($P = .001$). However, none of the serotype was associated with any specific clinical features and severe dengue. Asian and American/African genotypes of DENV-1 were cocirculating. The circulating genotype was cosmopolitan for DENV-2 with multiple lineages, genotype III for DENV-3 and genotype I for DENV-4. Unique mutations were present in the 2017 DENV-4 isolates. The present study suggests the association of DENV-4 with elevated liver enzymes in children hospitalized for dengue. Further, the study reports the genetic diversity of DENV circulating in Tamil Nadu during 2017. The study calls for continuous monitoring of the circulating serotypes and genotypes at regional level in India which might result in a region wise database useful in predicting future outbreaks.

1 | INTRODUCTION

Dengue is the commonest arthropod borne viral disease that affect millions of individuals globally each year and has been listed by the World Health Organization (WHO) as one of the major threats to mankind.[1] Infection with any of the four serotypes of dengue virus (DENV) results in a range of clinical presentations. Symptomatic dengue infections are categorized into nonsevere dengue and severe dengue (SD). The nonsevere dengue cases are again classified into those without warning signs (DwoWS) and with warning signs (DwWS). The case fatality rate is less than 1% if proper intervention is initiated at an early stage of the disease.[2] Disease severity is influenced by both virus and host factors. Immune status determined as primary infection or secondary infection with a different serotype of DENV has been reported to be associated with dengue severity by various epidemiological studies. Age, gender, nutritional status, host immune response, and host genetics contribute to differences in the clinical outcomes.[3,4] Among the viral factors, infecting serotype and the genotype within each serotype also contributes to disease severity.[3] Replacement of the circulating serotype/genotype of DENV with a different one contributes to outbreaks of higher magnitude.[5,6]

In the last decade, highest number of dengue cases were reported during 2017 in India. Within India, West Bengal and Tamil Nadu accounted for approximately 30% of the reported dengue cases.[7] Before 2017, Tamil Nadu witnessed large number of cases during 2012 and DENV-1 was the most common serotype despite the presence of other serotypes. Replacement of American/African (AM/AF) genotype with Asian genotype of DENV-1 was observed during 2012 in Tamil Nadu.[8] However, the serotypes and genotypes circulating during 2017 were not known. The present study was aimed at identifying the serotype-specific differences in the clinical symptoms and laboratory parameters in DENV infected children. Moreover, the study also intended to identify the dominant circulating serotype(s) and genotype(s) associated with dengue in Tamil Nadu during 2017.

2 | MATERIALS AND METHODS

2.1 | Study subjects

The study was a cross-sectional prospective study conducted at PSG institute of Medical Science and Research, a tertiary care teaching hospital located in western Tamil Nadu between August and December 2017. Children aged between 6 months to 15 years who fulfilled the inclusion criteria were consecutively enrolled in the study. Children admitted in the hospital with undifferentiated fever of less than 5 days duration with clinical suspicion of dengue and positive for the presence of NS1 antigen were included in the study. Exclusion criteria include: negative test for the presence of NS1 antigen, fever beyond 5 days, unwillingness to participate in the study and patients who were not admitted. The parents or the legal guardians were explained about the study purpose and an informed consent was obtained from them. The parents or the caretakers of the patients were interviewed for their demographic characteristics such as gender, age, and previous dengue episodes. The patients were observed for clinical symptoms including warning signs till their discharge and clinical features and lab data were collected in a predesigned data collection tool. Based on the clinical symptoms and laboratory parameters, the patients were categorized into dengue without warning signs (DwoWS), dengue with warning signs (DwWS), and severe dengue (SD) based on the WHO 2009 guidelines.[9] Plasma or serum samples collected from the participants at the time of entry into the study, were separated and stored at −80°C. The samples were transported in dry ice to ICMR-National Institute of Virology for identifying the serotype. The study was approved by the institutional human ethics committee (IHEC) of PSGIMS&R, Coimbatore, Tamil Nadu. Molecular characterization of the circulating DENV was performed at ICMR-NIV as a part of Apex referral laboratory activity for the year 2017 which was approved by the IHEC of ICMR-NIV.

2.2 | Serological assays

Serological assays were performed in the hospital laboratory. Presence of DENV NS1 antigen was tested by a antigen capture ELISA kit (Panbio Dengue Early ELISA) as per the manufacturer's protocol. Dengue-specific immunoglobulin M (IgM) and immunoglobulin G (IgG) antibodies were tested using ELISA kits (Panbio IgM [01PE20] and Panbio IgG capture ELISA kit [01PE10]) according to the instructions provided with the kit. The IgG capture ELISA kit used in the study detects high-titer IgG antibodies which is usually present in secondary infections. Test positive for IgG indicates secondary infection while test negative indicates primary infection.

2.3 | Detection of dengue virus serotypes

RNA was extracted using an RNA extraction kit (QIAamp viral RNA mini kit, Qiagen, Hilden, Germany) according to the manufacturer's protocol and used for DENV serotyping. Serotyping was performed by using an in-house real-time reverse transcription polymerase chain reaction (RT-PCR) assay. The sequences of the primers and probes were given in Table S1. Primer and probe sequences, the reaction mixture composition and cycling conditions for real-time RT-PCR have been reported previously.[10] The PCR cycle at which the fluorescence signals crossed the threshold values were detected for each sample and samples that had a cycle threshold (C_t) value ≤37 were considered as positive.[10]

2.4 | Isolation of dengue virus from clinical samples

Virus isolation was performed in samples which were positive for DENV RNA with increased viral load (C_t value ≤25) using C6/36 cell

line as reported previously.[10] Virus stocks were stored at −80°C in aliquots for further use.

2.5 | Sequencing of complete envelope gene of dengue virus

Randomly selected representative virus isolates from each serotype were used for sequencing of complete E gene (seven DENV-1, ten DENV-2, one DENV-3, and nine DENV-4 isolates) using primers reported earlier.[11-13] The sequences of the primers were provided in Table S1. RNA extraction, cDNA synthesis, reverse transcription, PCR amplification, gel purification, and sequencing was carried out as described earlier.[10]

2.6 | Phylogenetic analyses of dengue virus isolates

MEGA7.0 was used for multiple sequence alignment and phylogenetic analyses.[14] Seven DENV-1, ten DENV-2, one DENV-3, and nine DENV-4 sequences (GenBank accession number for the virus isolates provided in Table S2) from the current study along with the earlier Indian (44 DENV-1, 79 DENV-2, 39 DENV-3, and 31 DENV-4) and global sequences (36 DENV-1, 43 DENV-2, 54 DENV-3, and 47 DENV-4) from GenBank representing different genotypes were used for the phylogenetic analyses. Kimura-2 Parameter model was used to estimate the genetic differences and maximum likelihood (ML) method was used for the construction of the phylogenetic trees. A bootstrap test with 1000 replications was used to evaluate the reliability of position of the branches.[10]

2.7 | Statistical analyses

To compare univariate categorical data, Fisher's Exact tests or Pearson's X^2 was used. Parametric and nonparametric data from subjects infected with different dengue serotypes were compared using one-way analysis of variance and Kruskal-Wallis tests, respectively. Modified Poisson regression with adjustment for relevant clinical covariates, that is, age, gender, and fever at total day was utilized for performing the regression analyses. Data for one serotype was compared with other three serotypes. Except platelet count, the values of other laboratory parameters at the time of admission were used for comparison. The nadir for platelet count was used for comparison. A probability (*P*) value of <.05 was considered statistically significant. All the statistical analyses were carried out using statistical software R version 3.4.4.

3 | RESULTS

3.1 | Demographic profile of the study subjects

A total of 430 children with undifferentiated fever were admitted with clinical diagnosis of dengue fever of which 236 children fulfilled the inclusion criteria, 80 consecutively admitted children were enrolled in the study and were followed up prospectively. On analyzing for the serotype, 10 samples were negative and hence excluded and only 70 subjects were analyzed. Almost equal proportion of boys and girls were observed and the median age was 9 years (6 months to 15 years) (Table 1).

TABLE 1 Demographic profile of the dengue cases infected with different dengue virus (DENV) serotypes

Fever at total days, median (range)	5 (4–8)	–	5 (3–9)	?	4.5 (4–5)	–	5 (3–8)	–	.188

*X^2 test was used to compare categorical variables (gender and locality) and one–way analysis of variance was used to compare the continuous variables (age, fever day at presentation and fever at total days).

3.2 | Serotype-specific differences in the clinical features, lab parameters and disease severity

All four serotypes were observed to be circulating in the study population with the prevalent serotype being DENV-1, (n = 25, 35.7%), followed by DENV-4 (n = 22, 31.4%), and DENV-2 (n = 17, 24.3%). DENV-3 was identified in 8.6% (n = 6) of the subjects. Apart from a slight female preponderance among DENV-1 infected children, gender, age, and duration of fever were not different between the children infected with different serotypes (Table 1).

A similar modified Poisson regression analysis adjusted for age, gender, and day of fever was performed for various lab parameters. A statistically significant increase in liver enzymes, aspartate aminotransferase (median with range 131.5 [22-1156] $P = .001$) and alanine aminotransferase (median with range 63 [14-594] $P = .021$) were found in DENV-4 infected children compared to children infected with other serotypes. There was no significant difference in the level of liver enzymes between primary and secondary infections. The mean ± standard deviation of liver enzymes, SGPT and SGOT in children with primary and secondary dengue were 99.18 ± 123.91, 66.83 ± 79.09 ($P = .255$) and 172.25 ± 225.03, 139.38 ± 164.15 ($P = .443$). Other hematological parameters including platelet count during the hospital period were not significantly different among children infected with different serotypes (Table 2).

After adjustment for age, gender, and duration of fever, we observed no statistically significant correlation between the infecting serotype and the clinical features (Table 3). A majority of the children had secondary dengue infection (n = 52 [67.5%]). However, immune status was not associated with disease severity (Table 3).

Classifying the children based on disease severity according to WHO 2009 criteria, there were 38 cases with DwoWS, 26 with DwWS, and 6 had SD. There was no significant association between disease severity and infecting serotype (Table 3).

3.3 | Results of virus isolation

A total of 51 samples were used for virus isolation. Virus isolation was positive in 34 samples (seven DENV-1, 13 DENV-2, two DENV-3, and 12 DENV-4). Complete E gene of the representative virus isolates (seven DENV-1, ten DENV-2, one DENV-3, and nine DENV-4) was sequenced.

3.4 | Circulating genotypes of DENV-1

DENV-1 was classified into five genotypes as described earlier.[15] Since there were confusions with regard to the Roman number based nomenclature, geographical names were provided.[16] Seven DENV-1 virus isolates were sequenced. The ML method-based phylogenetic tree (Figure 1) revealed that five isolates grouped with the Asian genotype (GI). Two isolates clustered with the American African (AM/AF) genotype (GV). Asian genotype isolates obtained during

Abbreviations: DENV, dengue virus; DwoWS, dengue without warning signs; DwWs, dengue with warning signs; SD, severe dengue.
[a]Modified Poisson regression was used for calculating the relative risk adjusted for age, gender, and fever days at admissionadmission.

2017 from Tamil Nadu clustered with Indian strains isolated during 2012-2017 from Kerala, Maharashtra, and Tamil Nadu and strains from Sri Lanka and Singapore. Five lineages, India-I to India-IV and Afro India, have been described within the AM/AF genotype earlier.[12] The present study isolates clustered with India-IV lineage strains. Comparison of amino acid sequences of the Indian isolates belonging to Asian genotype with the isolates from Singapore and Sri Lanka revealed that most of the 2017 isolates from Tamil Nadu had three conservative changes (T329S, L475P, and L484M) and one nonconservative change (F337I) that were not observed in earlier isolates (Table S3).

3.5 | Circulating genotype of DENV-2

DENV-2 was classified into five genotypes as described earlier.[17] Further, subclassifications within the cosmopolitan genotype was performed as described recently.[18] For DENV-2, ten isolates were sequenced for E gene. All sequenced isolates grouped within the cosmopolitan genotype. Within cosmopolitan genotype, Tamil Nadu isolates clustered with strains from two lineages—Cosmopolitan I (C-I) and C-III. Within C-I, five isolates were part of C-IA sublineage, and one isolate was part of C-IB (Figure 2). Amino acid sequence analysis within the 2017 Tamil Nadu isolates revealed that C-I strains had Q at 52nd position while it was H in C-III isolates. C-I had a V at 141st position of E protein while isolates from C-IB and C-III had I. Isolates from C-IB and C-III had I at 322nd position while V was present in C-IA (Table S4).

3.6 | Circulating genotypes of DENV-3 and DENV-4

Five genotypes have been reported for DENV-3.[19] One DENV-3 isolate was sequenced which clustered with earlier isolates from India, China, Pakistan, Singapore, and Senegal into GIII genotype and lineage C (Figure S1). For DENV-4, there were five genotypes.[20] Recently, an additional genotype (GVI) has been proposed.[21] Nine DENV-4 isolates were sequenced. All the 2017 isolates from Tamil Nadu grouped within the GI genotype. In the G1 genotype, 2017 isolates from Tamil Nadu along with the strains from India, Pakistan, and Sri Lanka formed lineage C. Strains from Cambodia, China, Singapore, and Thailand formed the lineage B while those from China, Japan, Philippines, and South Korea formed lineage A (Figure 3). Comparison of amino acid sequences of the E protein from the current study isolates with earlier India isolates revealed the presence of altogether 53 unique nonconservative changes in the nine 2017 isolates from Tamil Nadu (Table S5).

Apart from the current sequences, 36 global sequences and 44 Indian sequences were used for generating the phylogenetic tree KH Cambodia/VN-Vietnam/KR-Korea, Republic of/TW-Taiwan/MM-Myanmar/CN-China/ID-Indonesia/MY-Malaysia. Among the five genotypes, Asian, American/African (AM/AF) and Sylavatic genotypes were only shown

4 | DISCUSSION

Forty percent of world's population lives in places endemic to DENV infection and at least 12 000 to 24 000 deaths happen annually in children aged below 15 years.[2] During the study period, admission of 430 undifferentiated fever cases with clinical features suggesting dengue in the pediatric services of one tertiary care hospital alone explains the magnitude of the disease in this endemic region. Circulation of all the four serotypes of DENV has been reported from different regions of India. In 2017, DENV-1 and DENV-3 were more prevalent in Maharashtra, Western India.[10] DENV-1 was the most prevalent serotype while DENV-4 was the least observed one in the 2012 dengue season in Tamil Nadu.[8] In contrast to 2012, DENV-1, DENV-2, and DENV-4 were the prevalent serotypes during 2017 in the study region and could have accounted for the large number of cases from the state. Persistent circulation of DENV-1 might have led to herd immunity permitting the emergence of other serotype viruses. Circulation of multiple serotypes suggests the hyperendemic nature of dengue in this region. The study also suggests the emergence of DENV-4 along with DENV-1 and DENV-2 in Tamil Nadu during 2017.

Studies in the past on disease severity and infecting serotypes have discordant results. A study based on the data from 1994-2006 in Thai children has suggested the association of DENV-2 infection with severe dengue.[22] Further the same study revealed that the risk of SD was more in secondary infections with DENV-2 and DENV-3.[22] A study on adult patients from Singapore revealed that infection with DENV-1 had an increased risk of dengue hemorrhagic fever than DENV-2, whereas a study from Vietnam revealed no difference in the risk of developing severe disease among hospitalized adults infected with DENV-1 and DENV-2.[23,24] A study from Brazil reported that patients infected with DENV-1 serotype had higher risk of severe clinical and laboratory features compared to those infected with DENV-4.[25] A systematic review analyzing the factors associated with

FIGURE 2 Phylogenetic tree of dengue virus-2 (DENV-2) based on E gene sequences All the current study sequences (n = 7) highlighted in Red. Apart from the current sequences, 79 global sequences and 43 Indian sequences were used for generating the phylogenetic tree

dengue shock syndrome, the most severe form of dengue, has revealed DENV-2 as a risk factor.[3] Contradicting all the studies, a study from Bali reported lack of association between DENV serotypes and disease severity.[26] In the present study, as there were less number of children who progressed to SD during hospital stay, for the purpose of analysis, children with SD and DwWS were grouped together and compared with DwoWS. Overall, there were more children with DwoWS than DwWS/SD and none of the serotypes showed any statistically significant increased risk for developing DwWS/SD. Immune status was also not associated with DwWS/SD. However, DENV-4 infections were significantly associated with elevated levels of liver enzymes. A study on pediatric dengue cases from Thailand also has reported that DENV-3 and DENV-4 infection tended to have abnormal elevation of liver enzymes.[27] This observation was contrary to a study from Northern India which has reported an association of elevated levels of liver enzymes with DENV-2.[28] Whether this association of elevated enzymes with DENV-4 can generalized to other regions depends on multiple factors such as the circulating genotype of DENV-4, host immune status, and age of the patients and a study with larger sample size is needed to further confirm the finding.

Phylogenetic analyses indicated the circulation of DENV-1 Asian and AM/AF genotypes, multiple lineages of cosmopolitan genotype of DENV-2, DENV-3 GIII genotype and DENV-4 GI genotype with unique mutations in Tamil Nadu. Cocirculation of DENV-1 Asian and AM/AF genotypes has been reported from Maharashtra in recent years while cocirculation of multiple lineages of DENV-2 cosmopolitan genotype has been reported from Northern India.[10,29,30] A recent study reported that the proportion of Asian genotype among the DENV-1-positive cases in Tamil Nadu had decreased from 90% in 2012 to 57% in 2017.[29] It is possible the DENV-1 Asian genotype viruses might have evolved over the years to become a virus with less epidemic potential phenotype. However, further comparative susceptibility studies in vectors and animal models are needed. In

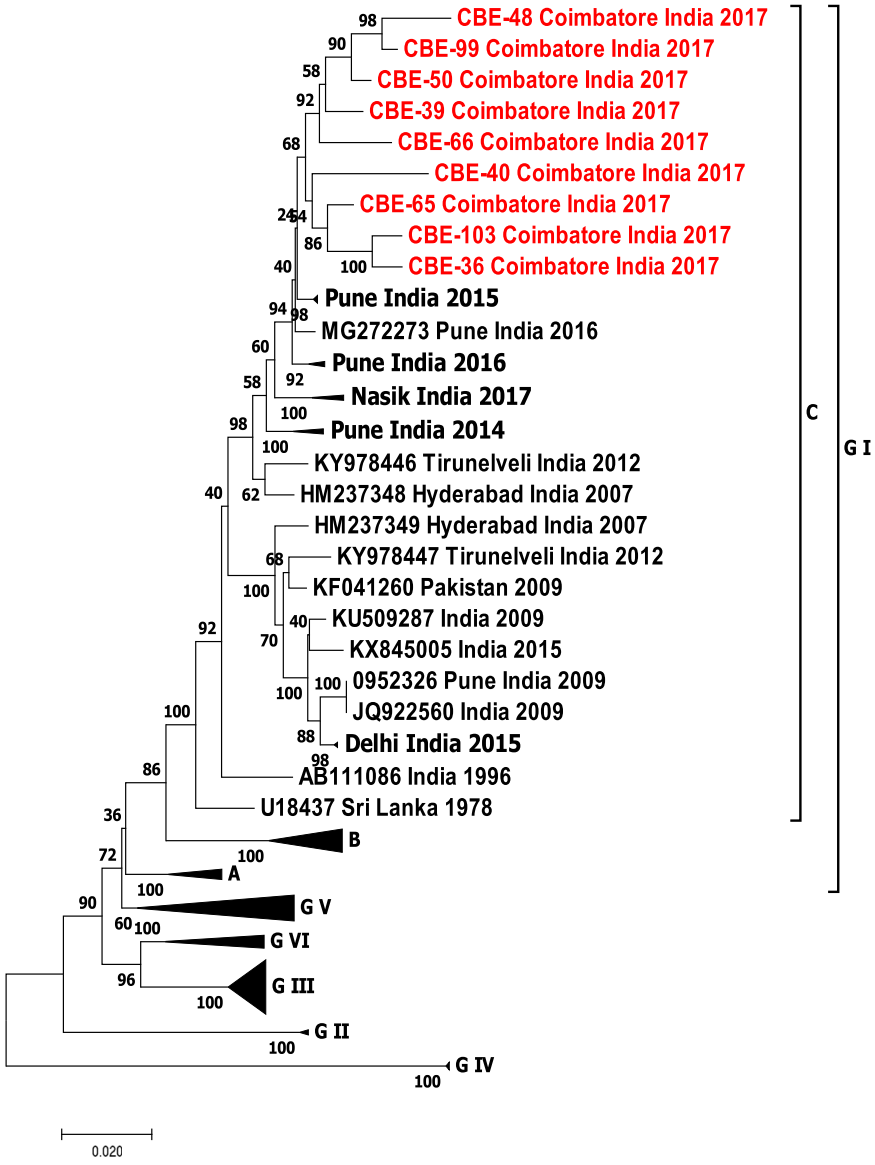

FIGURE 3 Phylogenetic tree of dengue virus-4 (DENV-4) based on E gene sequences. All the current study sequences (n = 9) highlighted in Red. Apart from the current sequences, 47 global sequences and 31 Indian sequences were used for generating the phylogenetic tree

the present study, E gene sequencing of DENV-4 isolates revealed unique mutations which were not observed in earlier Indian DENV-4 strains. The envelope protein has three structural domains I-III. Mutations in the domain II and domain III have more significance since domain II contains the fusion loop which is essential for the interaction between the host endosomal membrane and the virus envelope leading to virus membrane fusion while domain III contains epitopes that are essential for serotype-specific neutralization. Mutations in these domains might affect virus entry as well as the neutralization by serotype/genotype-specific antibodies.[31,32] DENV evolution is shaped by purifying selection in which deleterious mutations affecting viral fitness are removed with time. Further, mutations which confers fitness advantage to DENV in nature were positively selected and contributes to adaptive evolution of DENV.[33] Further follow up studies in the region are needed to discern how these mutations shape up the DENV-4 evolution. It is possible that differences in the viral factors as well as host factors might influence the variable outcomes in different studies. Monitoring the circulating serotypes and genotypes in different regions might result in a region wise database useful in predicting future outbreaks of higher magnitude when changes are observed with regard to the dominant serotypes and new genotypes.

The strength of the present study is that the subjects enrolled were belonging to only to pediatric age, they were prospectively followed up for the outcome and disease severity was classified based on latest guidelines recommended by WHO. Few limitations are, the small sample size, study participants were only hospitalized children from a particular geographic area, hence cannot be extrapolated to general population or other parts of the country. All the patients were recruited within 5 days of fever onset and hence early hospitalization and effective fluid management might have influenced the final outcome. Nonhospitalized cases with undifferentiated febrile illness, which forms the major proportion of DENV cases, were not included in the study and investigation of both hospitalized as well as nonhospitalized cases might help in

identifying the DENV serotypes associated with DwWS and severe dengue.

To conclude, the study reports the activity of all the four serotypes in Tamil Nadu during 2017 with the dominance of DENV-1, DENV-2, and DENV-4. Persistent cocirculation of DENV-1 Asian and AM/AF genotypes, cocirculation of multiple lineages of DENV-2 cosmopolitan genotype and emergence of DENV-4 GI genotype with unique mutations were observed. DENV-4 infection was associated with elevated levels of liver enzymes among hospitalized children. Serotypes and immune status were not associated with disease severity among children hospitalized for dengue.

Abstract

Objective The objective of this study is to study the profile of apolipoprotein E (*APOE*) gene polymorphism and lipid profile among intrauterine growth restriction (IUGR) and appropriate for gestational age (AGA) neonates. This is an observational study. This study was done at the neonatal unit of a teaching hospital in South India. All consecutively born IUGR neonates (cases) of more than 32 weeks' gestational age and AGA neonates (controls) were enrolled for the study. Genomic DNA extraction was done from a total of 102 peripheral venous blood samples. Genotyping of the APOE rs429358 and rs7412 defining the ε2, ε3, and ε4 alleles was done by polymerase chain reaction–restriction fragment length polymorphism method. Prefeed venous blood was collected and analyzed for lipid profile estimation. The allelic frequencies of cases versus control were ε2—9 (8.7%) versus 3 (2.9%); ε3—88 (84.6%) versus 81 (79.4%); and ε4–7 (6.7%) versus 18 (17.6%). The frequency of ε4 isoform allele, associated with adult onset of metabolic diseases was less among the IUGR group. The mean total cholesterol (TC), Low-Density Lipoprotein (LDL), High-Density Lipoprotein, and triglyceride (TG) were 107.59 ± 35.99, 51.69 ± 24.68, 21.75 ± 9.58, and 151.22 ± 61.84 mg/dL, respectively, in the IUGR group. The mean TC and LDL levels in IUGR group were marginally higher than AGA neonates (107 ± 35.99 vs. 100.37 ± 22.69 mg/dL and 51.69 ± 24.68 versus 46.9 ± 19.51 mg/dL, $p > 0.05$). In both groups, the mean TC and TGL levels were elevated in the ε4 isoform subgroup ($p > 0.05$). In our study, the ε2 allele was the second most predominant APOE isoform and the ε4 allele of the *APOE* gene associated with adult-onset diseases was not increased among IUGR neonates. Neonates with ε4 allele showed an abnormal lipid profile in both study groups suggesting a possible association.

Introduction

The term intrauterine growth restriction (IUGR) has been defined as the subnormal rate of fetal growth with respect to the growth potentials of a specific fetus in accordance to the gender and race. These neonates are born with clinical features of in utero malnutrition and may or may not have a birth weight less than 10th centile for the particular gestational age.[1] Approximately 78% of all IUGR infants delivered globally are seen in Asian continent with highest incidence seen in India.[2] The IUGR infants are prone for short-term and long-term complications making them high-risk neonates. Few of the short complications include perinatal asphyxia, persistent pulmonary hypertension,

Background: Objective of study was to compare the clinical features and laboratory parameters at admission and differentiate severe dengue from scrub typhus in children.

Methods: Retrospective analysis of case records and comparison of clinical and laboratory parameters at admission of all children with a diagnosis of severe dengue and scrub typhus was done.

Results: A total of 72 children were included (severe dengue =40; scrub typhus =32) during the study period. The mean (SD) age of children with severe dengue and scrub typhus was 7.9(3.8) and 11.8(5.8) years, respectively. Majority of children with severe dengue presented with hypotension, 21(52.5%) vs 3(9.4%) in scrub typhus. Children with severe dengue had a relatively low ANC ($2.6\pm1.97x10^3/mm^3$ vs $3.9\pm2.06x10^3/mm^3$), low platelet count ($50.23\pm35.55x10^3/mm^3$ vs $140\pm95.0x10^3/mm^3$) and low mean ESR at 1hour (8.1±6.82mm vs 33.88±13.79mm) than scrub typhus.

Conclusions: Compared to scrub typhus, severe dengue was significantly associated with hypotension, lower ANC, ESR and platelets.

Introduction

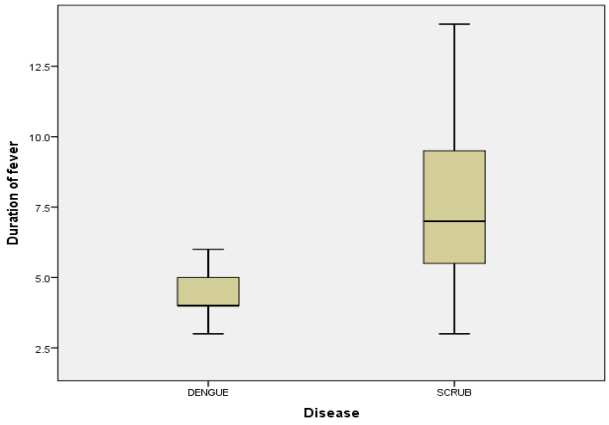
Globally 390 million dengue infections per year are reported, of which 96 million manifests clinically carrying high morbidity.[1] Dengue viruses (DV) belong to the family flaviviridae and is transmitted by vectors Aedes aegypti and Aedes albopictus.[2] Scrub typhus (ST) is another hemorrhaegic fever caused by Orientia tsutsugamushi that is spread by the bite of trombiculid mite. ST is increasingly recognized in tropical countries contributing upto 50% of patients with undiagnosed acute febrile illnesses.[3] In many parts of India, these two infections together comprise more than half of all acute undifferentiated febrile illnesses, more so in south Indian states due to the favorable tropical climatic conditions. Their similar clinical features and laboratory findings often pose diagnostic difficulty for the treating physician.[4] Early diagnosis of the illnesses is life saving to improve patient outcomes and promote timely public health interventions. In this retrospective study we have compared the clinical features and laboratory parameters of children with severe dengue and scrub typhus and attempted to derive the parameters that differentiate severe dengue from scrub typhus.

Methods

This retrospective study conducted over a period of 1 and ½ year (January 2015 to June 2016) in the department of pediatrics of PSG Institute of Medical sciences and research, a tertiary care teaching hospital in South India. Case records of all children (≤18 years) discharged with a

diagnosis of severe dengue and scrub typhus were identified, and those who had a serological confirmation were included for analysis. Severe dengue was diagnosed based on revised WHO criteria and included in the study.[5] Children with or without warning signs, without serological confirmation were excluded. The data was recorded on specified data collection form. The data included demographic parameters, clinical features, and laboratory parameters (CBC, RFT, LFT, serology, culture if any). The serological diagnosis of Dengue fever was based on dengue IgM-ELISA (Panbio dengue IgM & IgG capture ELISA) where values <9 PanBio ELISA units were considered negative, 9-11 equivocal, and more than 11 positive, as per the manufacturer's instructions). Similarly, serological diagnosis of scrub typhus was based on scrub typhus detect^{TM}IgM ELISA system. Children with SD were treated with normal saline, monitored for complications and treated according to the physician's discretion. Children with ST were treated with antibiotics and offered symptomatic care for the illness. The Institution's Human ethical committee approved the study.

Statistical analysis



Kolmogorov-Smirnov test was used for testing normality of the data. Normally distributed continuous variables were compared using *t*-test and non-parametric variables using Wilcoxon signed-rank and Mann-Whitney U tests. Chi-square analysis was done for comparisons of proportional data among groups. Multiple logistic regression models were used to assess the association of severe dengue and scrub typhus with relevant clinical and laboratory parameters.

□□□□□□□

A total of 7926 children got admitted as inpatients during the study period of which 6737 children were admitted for evaluation of fever. 747 children were serologically confirmed as dengue fever of which a total of 40 children were diagnosed with severe dengue fever with mean (±SD) age 7.9 (±3.80) years, and male: female ratio was 1.1:1. The mean (±SD) duration of fever at admission was 4.5(±1.13) and the mean (±SD) duration of hospital stay was 5.58 (±1.13) as in Figure 1.

Among children with severe dengue, 31(77.5%) had vomiting, 27(67%) had abdominal pain and 23(57.5%) had oliguria as presenting complaints. A majority of them (31; 77.5%) had evidence of plasma leakage, and 17(42.5%) had skin and mucosal bleeds at admission. None of the children had any alternate provisional diagnosis at admission other than severe dengue based on the clinical presentation.

A total of 32 children were serologically diagnosed as scrub typhus with mean (±SD) age of 11.8 (±5.83) years, and male:female ratio was 2.2:1. The mean (±SD) duration of fever at admission was 7.34 (±2.46) days. Of 32 children, 14 (43.8%) presented with vomiting and 11 (34.4%) presented with abdominal pain at admission. On examination, 5 (15.6%) had maculopapular rash and 15 (46.9%) had hepatosplenomegaly. Only 8 (25%) were found to have eschar to support the clinical diagnosis of scrub typhus. Other clinical parameters are presented in Table 1.

□Expressed as Mean ±SD, NS-Non significant

We compared the clinical and laboratory characteristics among children with severe dengue and scrub typhus as shown in Table 2. We found that the mean age at presentation and duration of fever was higher among scrub typhus compared to severe dengue, 7.97±3.8 years

vs 11.8±5.83 years (p = 0.001) and 4.5±1.13 days vs 7.34±2.46 days (p<0.001), respectively. A greater proportion of children with dengue presented with vomiting, abdominal pain, oliguria, skin bleeds, edema and hypotension. There existed a statistically significant difference in the proportions of the above-mentioned variables between both groups (p<0.05). Interestingly erythematous rash was present in equal proportions between both groups (15% vs 15.6%, p = 0.14).

Table 2 Comparison of clinical features between dengue and scrub typhus

	Dengue fever	Scrub typhus	p value
Hemoglobin# (g/dL)	13.3±1.70	12.24±1.63	0.003
Hematocrit#	41.45±5.78	37.6±5.14	0.001
TLC #(x10^3/cu.mm)	5.19±3.03	7.64±3.45	0.002
ANC# (x10^3/cu.mm)	2.6±1.97	3.9±2.06	0.002
Platelet# (x10^3/cu.mm)	50.23±35.55	140±95.0	<0.001
ESR#	8.1±6.82	33.88±13.79	<0.001
SGPT#	138.75±213.75	91.9	0.31

Expressed as Mean ±SD

The mean haemoglobin (and hematocrit) values were higher among children with dengue (13.3±1.7 vs 12.24±1.63, p = 0.003). The white blood cell (WBC) count and absolute neutrophil count (ANC) were markedly different in both groups. The children with dengue had a relatively low WBC count and ANC (5.19±3.03x10^3/mm^3, 2.6±1.97x10^3/mm^3 respectively) on comparing children with scrub. The platelet count at admission was lower in children with dengue when compared to scrub typhus (50.23±35.55x10^3/mm^3 vs 140±95x10^3/mm^3, p<0.001). Also, the mean Erythrocyte Sedimentation Rate (ESR)at 1hour was lower in children with dengue fever compared to scrub typhus (8.1±6.82mm vs 33.88±13.79mm, p<0.001). The mean serum Alanine Transaminase (ALT) levels were higher in children with severe dengue compared to scrub typhus (138.75±213.75 vs 91.9IU/L). But this difference did not achieve statistical significance (p = 0.19).

From the data obtained at admission, variables between these two illnesses that had statistically significant difference were applied to a logical regression model. We found a high probability of severe dengue compared to scrub typhus was associated independently with hypotension, lower ANC, low ESR and platelets as in Table 3. With a probability cut-off of >90%, the predictive model gave a sensitivity of 100%, specificity of 87.5%, positive predictive value of 88.8% and negative predictive value of 100%, for dengue compared to scrub typhus with ANC 0.93 (0.79-0.99) as shown in Figure 2.

Table 3 Multivariate logistic regression analysis of clinical and laboratory parameters between dengue and scrub typhus

Parameter	Increase/decrease	Multivariate odds ratio (95% CI)	p value
ANC	2x10^3/cu.mmincrease	1.98 (1.18-3.30)	0.012
Platelet count	40000/cu.mmdecrease	2.47 (1.63-4.23)	<0.001
ESR	6mm decrease	5.69 (2.88-15.97)	<0.001

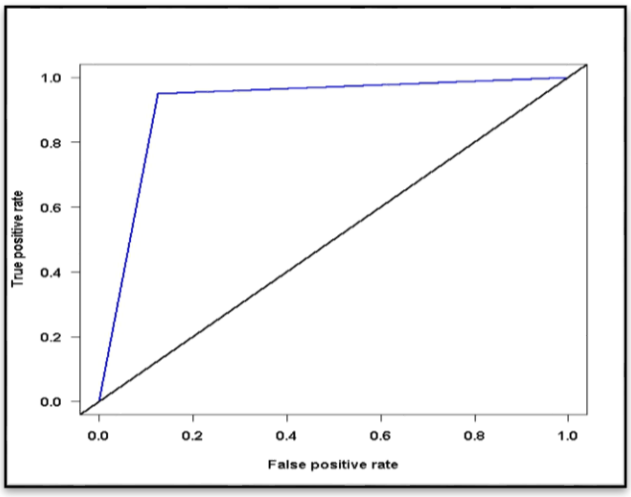

Figure 2 Receiver operating characteristic curve for ANC in predicting dengue fever from scrub typhus

Discussion

Dengue fever and scrub typhus caused by different vectors present in similar demographic distribution and clinical features. Any delay in recognition of these infectious diseases results in significant morbidity and mortality as well. Management of severe dengue is largely supportive with emphasis on fluid resuscitation and hemodynamics monitoring, whereas in scrub typhus the early initiation of antibiotics is mainstay.

Making the correct diagnosis with the available preliminary investigations while awaiting confirmatory test results might help in better management and relieve parent's anxiety. In this retrospective study we attempted to compare the clinical and laboratory parameters between these two similar diseases at initial presentation to the health care facility.

The mean age at presentation of children with severe dengue was less as compared to scrub typhus (7.9 +/- 3.80 vs 11.8 +/- 5.83) and the mean age at presentation of the latter was comparable to that reported previously by Kumar M et al.[6]

The male:female ratio of children with severe dengue was less than that of scrub typhus (1.1:1 vs 2.2:1). This difference in gender ratio could probably due to similar exposure risk for mosquito bites in-doors and higher prevalence of chigger exposure while playing outdoors by boys. A similar observation was made by Bhat NK et al, who documented a higher male to female ratio (1.44:1) in scrub typhus. Among the symptoms and signs between the study groups at presentation, mean duration of fever, abdominal pain, edema, oliguria and hypotension were strikingly different. Though these differences have been witnessed in children with scrub typhus in previous studies their incidence was much lesser in the present study, when compared to children with severe dengue.[7]

In our present study, there was significant difference in clinical features among the study groups. Children with severe dengue had a short mean duration of fever (4.5 +/- 1.13 vs 7.34 +/- 2.46 days) at presentation. Majority of children (77.5%) with severe dengue in our study presented with vomiting and edema. Two third had abdominal pain and oliguria and almost half of them presented with skin bleeds and hypotension at admission. Almost ninety percent of children presented with significant hepatomegaly and none had splenomegaly. Pothapregada S et al, in his clinical profile of children with dengue also observed a similar occurrence with fever (94.6%) being the commonest symptom and persistent vomiting as the frequent warning sign (75.1%).[8] Among children with scrub typhus, almost half of them had hepatosplenomegaly. Clinical features like rash, edema, respiratory distress, oliguria was less observed in children with scrub typhus. Only twenty-five percent of children with scrub typhus had eschar in our study population. Rose W et al, found 40.8% of their children having the characteristic eschar at the presentation but most studies project a lesser percentage.[9] Babu et al, in their prospective study found only 34.6% of serologically confirmed scrub typhus to have eschar.[10] Absence of eschar could be secondary to previous exposure to ricketssial antigen and variation in cutaneous immune response and that could be possible reason for absence of eschar in majority of our study children.

In our study, we found that the striking difference in clinical parameters between the two groups was hypotension, lower ANC, low ESR and significantly low platelet values and thus provides the best ability to differentiate between severe dengue fever and scrub typhus. ANC has been statistically high in children with scrub typhus than severe dengue. The predominance of lymphocytes with leucopenia and severe thrombocytopenia might be an additional pointer to the diagnosis of severe dengue. In the guideline of Indian academy of pediatrics on ricketssial diseases, marked leukocytosis with the shift to the left in later stages, raised ESR and thrombocytopenia were laboratory features suggestive of these infections, as noted in children with ST in the present study.[11] Liver dysfunction has been observed in children with severe dengue and scrub typhus.[12] Similar to the present study, Kumar J et al noted a 10-fold increase in the mean serum ALT levels in children with DF and could be used in differentiating these diseases.[13]

Few limitation of our study is the retrospective model, small sample size and restricted to a hospital – based population. The observation and predictive model may not be applicable to differentiate other febrile illnesses in children and the clinical utility the model needs to be tested prospectively and also validated. In a resource limited setting among endemic areas, our predictive model could be utilized to differentiate hemorrhagic fever due to scrub typhus and severe dengue, helping to initiate appropriate treatment.

Abstract

Background: Chronic abdominal pain is a common gastrointestinal symptom in children that significantly lowers their quality of life. In adults, Gall bladder (GB) hypomotility / dyskinesia is associated with many functional abdominal disorders but there is scarcity of evidence on its role in childhood gastro-intestinal disorders. Aim of the study is to evaluate the GB motility in children with chronic functional abdominal pain (FAP).

Methods: Children aged 5-15 years with chronic abdominal pain fulfilling ROME-III criteria and healthy controls were included and all study participants were subjected to ultrasonographic evaluation of the gall bladder volume in fasting state and post - Fatty test meal (FTM) and its ejection fraction was calculated.

Results: Sixtysix children including 31 with chronic FAP underwent sonographic evaluation for GB motility. The mean ejection fraction (EF) of cases and controls were 51.72±17.76% and 57.3±23.26% (p value - 0.158). The mean EF of cases with upper abdominal pain and lower/peri-umbilical abdominal pain were 41.7±17.1% and 57.2±15.9% respectively (*p* value < 0.0001). Increasing BMI had no significant association with GB motility among the participants.

Conclusions: There is lack of significant association between children with chronic FAP and GB hypomotility. Children with upper abdominal pain have lesser GB EF, suggesting a possible abnormal GB motility.

Keywords: Childhood functional abdominal pain, Gallbladder, Ultrasonography

Introduction

Chronic abdominal pain is a common gastrointestinal symptom in children presenting to outpatient department. In United states and Europe, its prevalence rates ranges from 0.3 – 19% among school-going children and accounts for about 2% to 4% of all pediatric office visits.[1,2] Though it is not associated with any organic gastrointestinal pathology, children with FAP have a significantly lower quality of life and it contributes for school – absenteeism.[3] In 1999, the term abdominal pain related-functional gastrointestinal disorders in pediatric ROME II criteria, which included functional dyspepsia, functional abdominal pain (FAP), irritable bowel syndrome and abdominal migraine. These terminologies were further redefined based on duration of symptoms before diagnosis in ROME III criteria.[3]Many functional gastrointestinal disorders like functional dyspepsia, irritable bowel syndrome and disorders of Gall bladder (GB) has been studied for any possible association with abnormalities in GB motility, but the results are inconclusive.[4] In adults, GB hypomotility/dyskinesia is well established in idiopathic constipation and functional dyspepsia, but there is scarcity of evidence on its role in childhood functional abdominal disorders.[5,6] Our study

was designed to study the GB motility in children with functional abdominal pain.

M□□□ □ □□

This crosssectional study was done in the outpatient department of pediatrics, PSG institute of medical sciences from January 2016 to August 2017. Children aged 5-15 years attending the OPD of the institution with chronic abdominal pain fulfilling ROME-III criteria, without any obvious cause for abdominal pain and with no previous abdominal surgeries were included in the study. Healthy children who visited the hospital for routine health visit or vaccination were included as controls. Institutional Human ethical committee approved the study and all study participants were included after obtaining informed consent. A detailed history including dietary and allergy history was obtained and clinical assessment was done. They were documented in a pre-designed data collection tool.

A total of 31 cases and 35 controls were recruited in the study and all study participants were subjected to ultrasonographic evaluation of the gall bladder in fasting state. A radiologist experienced in pediatric Sonography performed the evaluation using Philips iU22 xMATRIX ultrasound system. The Gall bladder was assessed for its area, thickness and volume, where area was derived by trace method and maximum GB width and length were measured using transverse and longitudinal images of the GB.

The volume of GB was calculated in fasting and 30-minutes following a fatty test meal using Dodd's formula, Volume (in cm^3) = 0.52 x [L x W x A], where L is the greatest length, W- greatest transverse width, and A-greatest anteroposterior diameter of the GB. The gallbladder ejection fraction (EF) for each examination was obtained from two-volume data using the following equation. Where V_0 = gallbladder volume in fasting state, Vn = gallbladder volume after the fatty test meal,

□□□□□□□□□□□□□□□EF (%) = [(Vo-Vn) / Vo] X 100

For the purpose of this study, Children with ejection fraction of less than 40% were considered to have gallbladder hypomotility.

Statistical analysis was done using statistical package for the social science version-19 (SPSS) software. The fasting and post-prandial GB volume was expressed as mean ± SD and students t test was used to compare their means between groups. Chi-squared testing was applied to look for possible association between EF and BMI. A p-value less than 0.05 was considered significant.

□□□□ □□□□

There were a total of 66 children included in this study. The mean age of cases and controls were 10.14±2.71 years and 11.54±1.94 years respectively. The mean height of the cases group was 132.9±15.9 (range – 100 to 165cms) and that of controls was 145.14±11.6 (range – 110 to 159cms). The mean weight of cases and controls were 27.3 ± 10.5 Kg and 33.8 ± 6.6 Kg respectively. The mean body mass index (BMI) was 14.9±2.8 kg/m^2 (range of 11.3 to 26.3 kg/m^2) in case group and 15.9±1.8 kg/m^2 (range from 11.9 to 19.5 kg/m^2) in the control group. Out of 31 cases there were 11 boys (35.5%) and 20 (64.5%) girls respectively and in 35 controls there were 23 (65.7%) boys and 12 (34.3%) girls respectively (Table 1).□

The mean fasting and post-prandial gallbladder volumes of cases and controls were 8.20±3.97 (cm^3), 7.52±3.13(cm^3) and 3.51±1.57 (cm^3) and 2.94±1.59 (cm^3) respectively. Though the fasting GB volumes were greater than post-test meal, in both groups, yet there was no statistical significance (P value – 0.390) (Table 2). The mean ejection fraction of cases and controls were 51.72±17.76% and 57.37±23.26% (p value – 0.158).

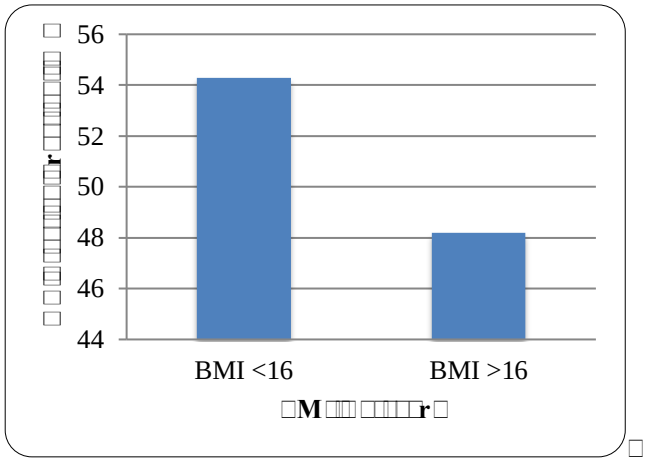
*Student's T-Test



The ejection fraction of GB were compared among children with functional abdominal pain who presented predominantly with upper or lower / peri-umbilical regions, to identify any possible association between the site of abdominal pain with GB motility. The mean ejection fractions of cases with upper abdominal pain and lower/peri-umbilical abdominal pain were 41.7±17.1% and 57.2±15.9% respectively (p value <0.0001), but the former did not qualify for the definition of GB hypomotility i.e. EF<40% (Table 3).

P-value*	0.497	0.25	0.019

*Student's T-Test

In order to identify any possible association between increasing BMI and GB contractility among cases, they were sub-grouped as, BMI<16 and BMI ≥ 16. There was equal number of children (n=4) in each subgroup with EF<40%, suggestive of GB dysmotility and their mean EF were 54.28 ± 17.99 % and 48.19 ± 17.53 % respectively (*p*-value < 0.001) (Figure 1).

[illegible]

[illegible]

In our study, we found no significant difference in the gall bladder volume (in fasting state and post Fatty test meal) among the cases and controls with equal number of children in both groups with GB ejection fraction <40%. Children who presented with upper abdominal pain had significantly lesser ejection fraction than those with lower abdominal pain. Many adult studies have recognized GB hypomotility in obese patients than non-obese patients. Sari et al found a positive correlation between fasting gallbladder volume and body mass index and body fat weight in obese women than non-obese women, but no such studies were available for comparison in children.[7] In the present study there existed no significant association in GB dysmotility and increasing BMI among cases.

The exact pathogenesis for FAP remains unclear, but visceral hypersensitivity, abnormal brain - gut interaction, immune dysregulation and altered gut motility has been postulated for the occurrence of the symptoms.[8,9] Gall bladder dyskinesia has been associated with various gastrointestinal symptoms like bloating, dyspepsia, post prandial epigastric pain and upper abdominal fullness.[10]

Mehra et alm observed gall bladder hypomotility in children with functional constipation, thus strengthening the claim of GB dyskinesia as a possible claim for functional abdominal symptoms in children.[11] Several imaging modalities like oral choledochocystography and syntigraphy are utilized to assess GB contraction but Sonography has been reliably used for assessing the GB area and volume, their changes following a fatty meal.[12] Ultrasonography could be preferred for its noninvasive nature and no radiation exposure that accompanies other modalities.

In our study we found 8 (26.7%) of the children with FAP healthy and 9 (25%) controls with mean GB Ejection fraction <40% suggesting that GB hypomotility could possibly be unrelated for the abdominal pain. Interestingly children who had predominant upper abdominal pain had low GB Ejection fraction compared to the children with lower abdominal pain (41.73±17.13% vs 57.87±16.12%) as noted by Hofeltd et al, in their study where a majority of children (96.67%) who underwent laproscopic cholecystectomy for biliary dyskinesia had upper quadrant pain.[13] A similar study with more subjects with FAP localized predominantly to upper abdominal could establish an association with GB motility.

Few limitations in our study are firstly the children were consecutively enrolled and sample size of the study is too small for drawing strong conclusions. Secondly the co-existing infection like H. pylori or parasitic infection of gut could possibly have an impact on the abdominal pain that was under evaluation. Nonetheless the present study is the first of its kind that has meticulously evaluated the GB volume and contractility in children with FAP and has found a possible association of GB dyskinesis with upper abdominal pain.

[illegible]

To conclude, abnormality in GB motility could be a cause for FAP presenting predominantly as upper abdominal pain in children thus necessitating its evaluation and a larger well-controlled study might help in better understanding of the entity.

Oral Feeds with or without Dextrose Half Normal Saline for Treatment of Hypernatremia in Breastfed Late Preterm and Term Neonates: A Comparison Study

Ramesh Srinivasan, Suvetha Kannappan[1]

Departments of Pediatrics and [1]Community Medicine, PSG Institute of Medical Sciences and Research, Coimbatore, Tamil Nadu, India

Abstract

Aim: The aim of this study was to compare the effect of treatment with oral feeds alone or oral feeds and 5% dextrose in 0.45% normal saline (½ dextrose normal saline [DNS]) on the rate of decline in serum sodium in breastfed late preterm and term neonates with hypernatremia. **Materials and Methods:** The study was conducted using retrospective data from July 2013 to June 2016. Babies with gestational age ≥ 34 weeks, birth weight ≥2000 g, age at diagnosis ≤5 days, and serum sodium 150–160 mEq/L were included in the study. Babies with congenital anomalies, sepsis, prior intravenous (IV) fluid therapy, or diseases-causing dyselectrolytemias were excluded from the study. Oral feeds group (Group 1) received breastfeeds, and formula feeds liberally. Oral feeds and IV fluid group (Group 2) received ½ DNS in addition to liberal oral feeds. Decline in serum sodium ≤0.5 mEq/L/h was considered as safe. **Results:** The study population consisted of 77 babies in Group 1 and 78 in Group 2. Baseline characteristics and serum sodium at admission were comparable. Group 1 had slower decline in serum sodium (P = 0.002), more babies with safe decline in serum sodium (P = 0.02), and lesser weight gain (P = 0.000). A similar result was observed in babies with serum sodium 150–155 mEq/L. No difference in treatment outcome was seen in babies with serum sodium 156–160 mEq/L. No complications or death were seen. About three fourth of cases came for follow-up, and one baby in Group 1 had a developmental delay with seizure disorder. **Conclusion:** In hypernatremic breastfed neonates with serum sodium 150–155 mEq/L, more babies are likely to have a safe decline in serum sodium on treatment with liberal oral feeds alone.

Keywords: *Breastfeeding, hypernatremia, intravenous fluids, oral feeds, rate of decline in serum sodium*

Introduction

Exclusive breastfeeding for the first 6 months of life is recommended for optimal growth and development of infants.[1] However, neonates who receive inadequate milk from their mother, are likely to develop hypernatremic dehydration and malnutrition.[2] Hypernatremic dehydration is a medical emergency and is considered as a dangerous type of dehydration due to the complications associated with disease evolution and its therapy.[3] Until date, there is no consensus on the treatment of hypernatremic dehydration in breastfed neonates. A systematic review of breastfeeding-associated hypernatremia has found that the available data about the management of this condition is inadequate.[4]

The management of hypernatremia in breastfed neonates is clouded with controversies. Although intravenous (IV) fluids were commonly used for hypernatremia correction, the volume of fluid needed and sodium content of the IV fluid was not well defined.[3-6] Oral rehydration

for correcting hypernatremic dehydration in breastfed babies was also reported. Oral feeds were given either alone or along with IV fluids for correction.[7] However, irrespective of the nature of treatment, all authors uniformly recommend frequent monitoring of serum sodium during correction as the rapid fall in serum sodium is associated with complications.[3,6] The usual recommended rate of fall in serum sodium during correction is not to exceed 0.5 mEq/L/h.[3,6]

In our neonatal unit, oral feeding is allowed liberally to all hypernatremic babies along with 5% dextrose in 0.45% normal saline (½ Dextrose Normal Saline [DNS]). Some babies had received only oral feeds for correction due to the refusal of consent for IV fluid therapy by the parents. This study was planned to compare the outcome among babies treated with oral feeds alone or oral feeds and ½ DNS. The primary objective of this study was to compare the effect of treatment with oral feeds alone or with oral feeds and ½ DNS on the rate of decline in serum sodium in otherwise healthy breastfed late preterm and term neonates with hypernatremia. The secondary objectives were to compare serum sodium at the end of treatment, percentage of weight gain at the end of treatment, complications during therapy, duration of hospital stay, and neurodevelopmental impairment at follow-up.

Materials and Methods

The study was conducted at a tertiary care teaching hospital in Tamil Nadu state of India. The institution has a policy of exclusive breastfeeding for all healthy babies. As per the unit protocol, all babies were weighed daily and any baby with total weight loss of more than 10% from birth weight or weight loss per day of more than 5% were considered to have excess weight loss, and their serum sodium was measured. Serum sodium ≥150 mEq/L was considered as hypernatremia.

All babies with hypernatremia were encouraged to take liberal oral feeds. This consists of counseling and supporting the mothers to adequately breastfeed their babies and to give top up formula feeds (sodium content-7 mEq/L) only if the baby does not get satisfied after completing breastfeeds. Breast milk sodium was not checked in any mother. ½ DNS was used for IV fluid therapy. The volume of IV fluid was based on the severity of dehydration and is usually administered at half of the daily maintenance fluid requirement. The treatment target was to reduce serum sodium below 150 mEq/L.

This comparative study was conducted using the retrospective data collected from July 2013 to June 2016. The Institutional Ethics Committee approved the study. Babies with hypernatremia during the study period, were identified from the hospital database, and their case records scrutinized. Since the response to treatment and complications depends on the severity and duration of hypernatremia, only babies with similar serum sodium level and age at diagnosis were considered for comparison. The inclusion criteria consist of (1) gestational age ≥ 34 weeks, (2) birth weight ≥ 2000 g, (3) age at diagnosis ≤ 5 days, (4) serum sodium 150–160 mEq/L, and (5) treated with oral feeds alone or with oral feeds and ½ DNS. A subgroup analysis for babies with serum sodium of 150–155 mEq/L and 156–160 mEq/L was also planned. The babies, with major congenital anomalies, culture-positive sepsis, received IV fluid within 48 h before the diagnosis of hypernatremia, suspected endocrine disorders or any other significant illness which may affect adequate oral feeding or fluid and electrolyte balance, were excluded from the study.

The following details were noted: maternal age, parity, mode of delivery, gender, gestational age as completed weeks, age at diagnosis as completed days of life, birth weight, weight at diagnosis, feeding problem reported by mother, nature of feed, clinical features, infusion rate of ½ DNS, serum sodium level during treatment, duration of hospital stay, condition of the baby at discharge, and condition at follow-up. The complications such as seizures, acute kidney injury, intracranial bleed, vascular thrombosis, apnea, and bradycardia, were noted.

The total weight loss, weight loss per day, and weight gain after treatment were calculated as a percentage of birth weight. The rate of decline in sodium was calculated with the serum sodium at the beginning and end of the treatment and the time taken to attain it. The rate of decline in serum sodium ≤ 0.5 mEq/L/h was considered as safe decline, and > 0.5 mEq/L/h was considered as nonsafe decline. Acute kidney injury was defined as an increase in serum creatinine by more than 0.3 mg/dl in 24 h or serum creatinine more than 1.5 mg/dl with normal maternal serum creatinine levels. Babies were said to be normal at the time of discharge if their serum sodium was < 150 mEq/L and were taking feeds well. At follow-up, the neurodevelopment of these babies was screened with Trivandrum development screening chart (TDSC), as per the unit protocol. The babies were said to be normal neurologically, if they have attained age-appropriate developmental milestones as per TDSC and had no other neurological problem.

IBM SPSS statistics for Windows- Version 24.0. (Released in 2016. IBM Corp., Armonk, N.Y., USA) was used for analysis. Numerical data were presented as mean ± standard deviation or median ± interquartile

range as appropriate. Categorical data were presented as percentages and analyzed using the Chi-square test. Ordinal data were analyzed with Mann–Whitney U-test or Student's *t*-test. P <0.05 was considered as statistically significant.

Results

During the study period, there were 155 babies satisfying the inclusion and exclusion criteria. Among them, 77 babies were treated with oral feeds alone (Group 1), and 78 babies were treated with oral feeds and ½ DNS (Group 2) [Figure 1]. The baseline characteristics between the two groups were comparable [Table 1]. Serum sodium at diagnosis was comparable between the two groups in analysis of both the whole study population and the subgroups.

In the whole study population, the median rate of sodium decline was significantly slower and within the safer limits in Group 1 babies. About 68% of babies had a safer decline in serum sodium in Group 1 compared to 49% in Group 2, and this difference was statistically significant. Although the median serum sodium at the end of treatment in Group 1 was slightly higher than Group 2, this was not statistically significant. The median weight gain percentage after treatment was significantly less in Group 1 [Table 2].

In babies with serum sodium 150–155 mEq/L, the median rate of sodium decline was within the safer limits in both the groups; however, Group 1 babies had a significantly slower decline compared to Group 2 babies. Babies, with safer decline in serum sodium, were significantly more in Group 1 (73%) than in Group 2 (52%). Median serum sodium at the end of treatment was slightly more in Group 1 compared to Group 2, and this was not statistically significant. The median weight gain percentage was significantly less in Group 1 [Table 3]. Eight (10%) babies in Group 1 left against medical advice due to personal reasons, before achieving targeted serum sodium.

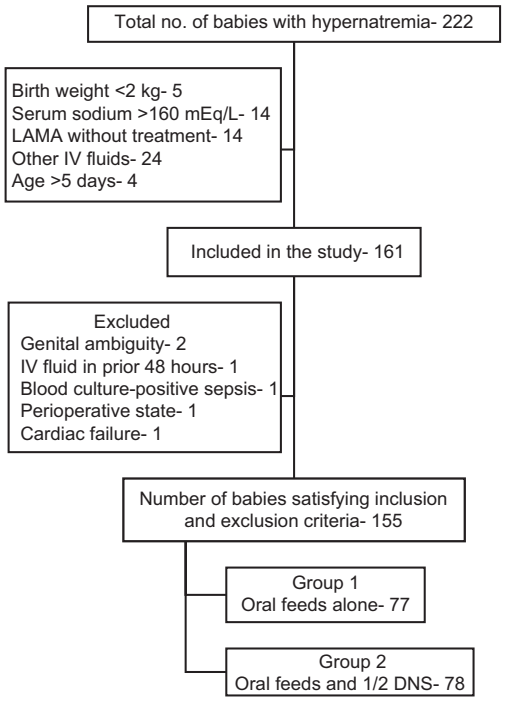

Figure 1: Flow of cases in the study. *½ DNS - 5% dextrose in 0.45% normal saline; IV fluid – Intravenous fluid; LAMA – Left against medical advice

In babies with serum sodium 156–160 mEq/L, there was no difference between the two groups in serum sodium at the end of treatment, number of babies with safer decline in serum sodium, and median weight gain percentage. Although the median rate of sodium decline was significantly higher in Group 1 compared to Group 2, it was in the nonsafe limits in both the groups.

Complications during treatment, were not seen in any baby. The median duration of hospital stay was similar in both the groups. There was no death in the study population. The number of babies followed up was similar in both the groups across the whole study population and in the subgroups. On follow-up, only one female baby in Group 1 had developmental delay, nystagmus, and seizure disorder. This baby's serum sodium at admission was 150 mEq/L, and the rate of sodium decline was 0.32 mEq/L/h. She also had prolonged jaundice requiring phototherapy for 9 days in the neonatal period.

Discussion

In this study, we have found that significantly more number of hypernatremic babies treated with oral feeds had safer fall in serum sodium compared to babies treated with oral feeds and ½ DNS. In one of the early reports on oral rehydration, Ng *et al*. have successfully treated four out of five babies with serum sodium of 151–154 mEq/L using only oral feeds. The authors have commented that their infants were less symptomatic, and oral therapy with breast milk and formula milk have corrected the dehydration in most of their cases.[7] Cagler *et al*. recommend using breast milk or formula milk or both, as the first-line therapy in well-appearing hypernatremic neonates.[8] Greenbaum suggests oral rehydration for mild-to-moderate hypernatremia but cautions that infant formulas, if given with IV fluids, may cause a rapid fall in serum sodium because of their low sodium content.[3]

Erdemir *et al*. have compared oral feeds and IV fluids for correcting hypernatremia in breastfed neonates. Babies with no feeding difficulties, were given breast

Table 1: Baseline characteristics of the compared population

Characteristics	Orals feeds alone (*n*=77)	Oral feeds + ½ DNS (*n*=78)	*P*
Male-to-female ratio	1:1	1.3:1	0.52

milk/formula, and those with poor feeding or vomiting received only IV fluids. At 24 h of therapy, 80% of oral feeds group had a safe decline in serum sodium compared to only 36% in IV fluid group.[9] In this study, a safe decline in serum sodium was seen in 68% of babies on oral feeds alone and in 49% of babies on IV fluids + oral feeds. In Erdemir *et al*. study, among babies with serum sodium 156–168 mEq/L, 69% had a safe decline in serum sodium with oral feeds, and none had safe decline with IV fluids.[9] Whereas in our study, among babies with serum sodium 156–160 mEq/L, the safe decline in serum sodium was seen in about 30% of babies in both the groups. In this study, ½ DNS was used for correction along with oral feeds whereas Erdemir *et al*. have used 1/5 normal saline along with daily maintenance fluids.[9] It was also observed in our study that the percentage of babies with rate of decline in serum sodium ≤ 1 mEq/L/h was almost the same in both groups across all serum sodium ranges.

Oral therapy for hypernatremia correction may be complicated by feed intolerance, necrotizing enterocolitis, and spontaneous intestinal perforation.[10,11] However, all babies in this study tolerated the feeds well. Bolat *et al*., in their study, on the treatment of hypernatremia using IV fluids, have concluded that serum sodium correction rate more than 0.5 mEq/l/h is an independent risk factor for death or convulsion.[12] However, in this study, no death or therapy-related complications were seen in babies with both safe and unsafe decline in serum sodium. Bilgin *et al*. have treated 149 babies with oral feeds or IV fluids depending on the severity, and no death was reported.[13] Similarly, Ozdogan *et al*. have treated 29 babies with oral feeds or IV fluids. There was no death, and all babies were neurologically normal at follow-up.[14] Yaseen *et al*. have treated 27 babies with oral feeds or IV fluids or both. Only one baby on IV fluids had seizures due to fast rehydration and had abnormal neurological examination at follow-up.[15]

On long-term follow up of our study population, only one baby in oral feeds alone group had neurodevelopmental impairment. This baby had safe decline in serum sodium but had a prolonged period of jaundice. It has been found in animal studies that hyperosmolar conditions can disrupt the blood–brain barrier and potentiate the neurotoxic effect of bilirubin.[16] Ergenekon *et al*. have shown that there is no correlation between serum sodium at admission and neurodevelopmental test scores at follow-up.[17] Bolat *et al*. have found no significant difference in neurodevelopmental outcome by the rate of correction of serum sodium.[12]

A recent systematic review by Bischoff *et al*. has found only two retrospective studies reporting the outcome of various therapies for hypernatremia in breastfed neonates, of which one has compared exclusive oral feeds with exclusive IV fluids.[5] We have tried to feed all the babies irrespective of IV fluid administration as babies with breastfeeding-associated hypernatremia are not only dehydrated but also starving.[18] We have shown that oral feeds can be safely given to all clinically stable babies with less severe hypernatremia.

This study has the following limitations. The volume of feeds ingested by the babies was not measured. Although all babies could have been fed with measured volume of expressed breast milk, this was not done since it may interfere with the assessment of breastfeeding and may affect the bonding between the mother and baby. Weighing the baby before and after direct breastfeed might have helped in roughly estimating the volume of milk ingested by the baby.[19] There is a chance for attrition bias in the study due to eight babies in Group 1 leaving the hospital before their serum sodium normalized. Follow-up details were not available for all cases and for one baby with developmental delay identified through TDSC, the diagnosis could not be refined using a confirmatory test such as Bayley scale of infant development. A randomized controlled trial comparing oral feeds with and without IV fluids administration may help to find the correct strategy for managing hypernatremia in otherwise healthy breastfed neonates.

Conclusion

In hypernatremic breastfed neonates with serum sodium 150–155 mEq/L, the treatment with liberal oral feeds alone using breastfeeds and/or formula feeds can cause safe decline in serum sodium in more number of babies compared to babies receiving IV fluids in addition. However, careful monitoring of the serum sodium is needed during hypernatremia correction irrespective of the nature of treatment given. A randomized control trial comparing oral feeds alone with oral feeds and IV fluids are needed to provide concrete evidence.

Author Help: Online submission of the manuscripts

Articles can be submitted online from http://www.journalonweb.com. For online submission, the articles should be prepared in two files (first page file and article file). Images should be submitted separately.

1) **First Page File:**
Prepare the title page, covering letter, acknowledgement etc. using a word processor program. All information related to your identity should be included here. Use text/rtf/doc/pdf files. Do not zip the files.
2) **Article File:**
The main text of the article, beginning with the Abstract to References (including tables) should be in this file. Do not include any information (such as acknowledgement, your names in page headers etc.) in this file. Use text/rtf/doc/pdf files. Do not zip the files. Limit the file size to 1 MB. Do not incorporate images in the file. If file size is large, graphs can be submitted separately as images, without their being incorporated in the article file. This will reduce the size of the file.
3) **Images:**
Submit good quality color images. Each image should be less than 4096 kb (4 MB) in size. The size of the image can be reduced by decreasing the actual height and width of the images (keep up to about 6 inches and up to about 1800 x 1200 pixels). JPEG is the most suitable file format. The image quality should be good enough to judge the scientific value of the image. For the purpose of printing, always retain a good quality, high resolution image. This high resolution image should be sent to the editorial office at the time of sending a revised article.
4) **Legends:**
Legends for the figures/images should be included at the end of the article file.

ABSTRACT

Background: Some studies suggested that a high rate of caesarean deliveries results in suboptimal breastfeeding outcomes. The relationship between mode of delivery and breastfeeding outcomes has been considered important given the rising prevalence of caesarean deliveries globally. The present study is to examine the relationship of mode of delivery with breastfeeding outcomes. **Materials and Methods:** This study was conducted at PSG Institute of Medical Science and Research, Coimbatore in the month of July 2018. Ethical clearance was obtained from the institution prior to the study. Chi square test was done to assess the association between socio-demographic variables, timely initiation of breastfeeding and exclusive breastfeeding with mode of delivery. The effect of caesarean on duration of breastfeeding was obtained by applying Kaplan-Meier method. **Result:** Prevalence of caesarean delivery was 36.2% and of vaginal delivery was 63.8%. A statistically significant association was obtained between caesarean deliveries and timely initiation of breastfeeding. However mode of delivery was not significantly associated with exclusive breastfeeding and duration of breastfeeding. **Conclusion:** The findings of our study indicates that caesarean deliveries have been associated with lower timely initiation n rates compared to vaginal deliveries.

Keywords: caesarean delivery, duration of breast feeding, exclusive breastfeeding, initial breastfeeding, vaginal delivery.

Introduction

Breastfeeding is a dynamic process comprising regulation between the mother's and infant's interconnected physiological, psychological, and behavioural systems [1]. Optimal infant and young child feeding is crucial for health and development.

Women are recommended to breastfeed exclusively for 6 months and to continue breastfeeding until the child is 2 years. Breastfeeding is widely acknowledged as the best and safest form of infant feeding [2].

The global average caesarean delivery rate is 12.4% with an average annual rate of increase of 4.4%.The use of caesarean delivery has increased in the last few decades particularly in middle- and high-income countries [3]. According to a recent analysis of national health survey data, caesarean deliveries in India has gone up from 10% to 30 % raising the country's average caesarean section rates from 5% to 18%. An independent analysis of data from the National Family Health Survey (NFHS) (199293 to 2015-16) and Rapid Survey on Children 2013-14,India's caesarean-section rate was at 18 per cent which was higher than the

Lancet report's estimate of 10 per cent[4]. It is necessary to find whether the mode of delivery affect the breastfeeding outcomes.

The primary aim of the study was to examine the association between mode of delivery and subsequent breastfeeding outcomes – initiation of breastfeeding within one hour of birth, exclusive breastfeeding up to six months and duration of breastfeeding.

Materials and Methods

This study was conducted at PSG Institute of Medical Science and Research, Coimbatore in the month of July 2018. Ethical clearance was obtained from the institution prior to the study. Informed consent was obtained from all mothers interested in participating. Questions about mode of delivery and breastfeeding were collected using questionnaire. A total of 527 mothers were studied. Eligible mother include those who with the children age below four years attending paediatric outpatient department. Babies with congenital anomalies that interfere with breastfeeding were excluded from the study. Socio economic status was measured using Prasad classification. The classification is done based on the Consumer Price Index (CPI) value of 279 for Coimbatore [5]. Class 1 include people having per-capita income greater than or equal to Rs.6180. Class 2, class 3, class 4 include the people having range of pre-capita income Rs.3090-6179, Rs.1850-3089, Rs.930-1849 respectively and class 4 include people having per-capita income less than Rs.930.

WHO recommends that for those children less than six months of age, who fed only on mother's milk in the 24 hours preceding the survey were considered as exclusive breastfeeding.

Chi square test was done to assess the association between mode of delivery with socio-demographic variables, initiation of breastfeeding and exclusive breastfeeding. p value<0.05 was considered as statistically significant.

The effect of caesarean on duration of breastfeeding was obtained by using Kaplan-Meier method. The duration of termination of breastfeeding was the outcome event and those mothers who are continuing the breastfeeding during the survey were considered as censored. Total probability of termination of breastfeeding till that time interval was calculated by multiplying all the probabilities of termination of breastfeeding at all time intervals preceding that time. The log rank test was used to assess the equality of survival curves of vaginal and caesarean delivery. The data were analysed using SPSS[5].

Results

The sample included 527 mothers. 36.2% of mothers were delivered by caesarean and 63.8% of mothers gave birth by vaginal delivery.

Table 1 depicts the various socio-demographic and clinical variables according to mode of delivery. Increased number of antenatal visits (p<0.05) and term delivery (p<0.01) were negatively associated with caesarean delivery.

Table 2 describes the association of mode of delivery with timely initiation of breastfeeding, exclusive breastfeeding and duration of breastfeeding. Timely initiation of breastfeeding was lower among caesarean deliveries compared to vaginal deliveries and the difference was statistically significant (p<0.001).The prevalence of exclusive breastfeeding was 60.1% for vaginal delivery and 55.5% for caesarean. However the difference was not statistically significant (p=0.301).There was no difference between duration of breastfeeding and mode of delivery (p=0.851).

Table1: Distribution of socio-demographic variables by modes of delivery

Characteristics		**Vaginal delivery (%)**	**Caesarean (%)**	**p value**
Mother's age	15-24	76(22.6)	32(16.8)	0.190

Discussion

We found that 56.5% of mothers surveyed reported initiating breastfeeding within one hour of birth and 58.4% reported exclusive breastfeeding for 6 months. The median duration of breastfeeding was 18 months. We observed a negative association between breastfeeding initiation within one hour and caesarean delivery. This contradicts the findings of Sara N K et al 2017[6] and supports the findings of Prior et al 2012 [7] and Hira Palla et al 2017 [8].

Despite the well-known benefits of nourishing infants exclusively with mother's milk, the rates of breastfeeding initiation, continuation and exclusive breastfeeding are still lower in India. Mothers and infants experiences during labour and delivery may affect lactation and breastfeeding outcomes. In this study we observed that caesarean deliveries have been associated with lower initiation rates compared to undergoing vaginal delivery. This may be due to the delay in mother-infant skin to skin contact, mother's post-surgery physical complications and effects of anaesthesia.

Research evidences showed that delayed onset of lactation is significantly higher among women with caesarean delivery compared to those with vaginal delivery. In addition, early contact with between mothers and infants during the first few hours after birth is important for forming a mother-infant bond that can lead to breastfeeding successful outcomes. Apart from it, operative care routines for post caesarean delivery can delay mothers from holding their infants and disrupt bonding between mother and infant. The mothers who undergo caesarean delivery stay longer in

hospital than mothers who experience vaginal delivery. Therefore a negative impact of surgical procedure delays breastfeeding initiation and babies were used to give formula feed from hospital.We did not find any association between mode of delivery and exclusive breast feeding. This supports the findings of Sara N K et al 2017[6] and contradicts the findings of Emily prior et al [7]. We did not find any association between mode of delivery and duration of breastfeeding which contradict the finding of Perez-Escamilla et al [9] and Amy J. Hobbs [10]. It has been suggested in these studies that lower duration of breastfeeding rates on women with caesarean delivery might be associated with physiologic mechanism that affect lactogens. However, in our study we could not establish a statistically significant association between type of delivery and duration of breastfeeding. The limitation of our study include response bias that contribute inaccurate information due to retrospective reporting. Another limitation is that the region of study has a generally higher socio-economic status and it was hospital based study. Further studies should address the obstacles based on delivery mode and other factors such as medical problems, women's knowledge around breastfeeding benefits, latching, and lifestyle changes on initiation of breastfeeding, exclusive breast feeding and duration of breastfeeding. In addition to mode of delivery, other factors that may influence breastfeeding initiation includes challenges encountered during nursing, availability of support systems, recommendation and attitudes of family, peers and health care professionals. Furthermore, large scale prospective cohort studies can provide more light in this area.

Conclusion

The findings of our study indicates that caesarean deliveries have been associated with lower timely breastfeeding initiation rates compared to mothers undergoing vaginal delivery.

Abstract

Background: Early or timely initiation of breastfeeding, specifically within 1 h of birth, refers to the best practice recommendation by the World Health Organization (WHO). Timely initiation of breastfeeding has the potential to prevent 22 % of neonatal deaths if all infants were breastfed within an hour after birth [1]. The primary objective of the paper is to estimate the prevalence of breast feeding initiation within first hour of life and the clinical correlates and socio demographic factors. **Material and methods:** This study was conducted at PSG Institute of Medical Science and Research, Coimbatore in the month of July 2018. Mothers with the children age below four years attending paediatric outpatient department were included in the study. Multivariate logistic analysis was usedto determine the factors associated with timely initiation breastfeeding practice. **Results:** The prevalence of timely initiation of breastfeeding within one hour was 56.5%. It was observed that the caesarean delivery, preterm delivery, sick condition of the baby, earlier breast surgery, lack of counselling after delivery and lack of skin to skin contact at birth were negatively associated with timely initiation of breastfeeding within one hour. **Conclusion:** The findings clearly indicated that nearly half of the mothers did not initiate breastfeeding within one hour of birth.

Key Words: breastfeeding, prevalence, sociodemographic factors, timely initiation.

Introduction

Timely initiation of breastfeeding is defined as putting the new born to the breast within one hour of birth [1] .Early or timely initiation of breastfeeding, specifically within 1 h of birth, refers to the best practice recommendation by the World Health Organization (WHO) [1]. Few studies revealed that breastfeeding initiation after the first hour of birth doubles the risk of neonatal mortality [2] and the promotion of breast feeding within one hour is a key component in child survival.

E-Mail: anilpsgmet@gmail.com

In addition it has also been shown that a total of 71% of neonatal mortality could be prevented by using antenatal, intra-partum and post natal interventions related to breastfeeding. In addition, many studies reported that the initiation of breast feeding within 24 hours of birth was significantly associated with reduction in 'all cause of mortality'. Recognizing the importance of timely initiation of breastfeeding, the Ethiopian government had developed infant and young child feeding guidelines giving appropriate emphasis to key messages on timely initiation of breastfeeding in 2004. Early initiation of breastfeeding (EIBF) promotes the release of oxytocin that enables contraction of the uterus and decreases postpartum haemorrhage [3]. Though the breast feeding within first hour of life is considered as an indicator of excellence of breast feeding and only 39% of the new born in the

developing countries are put to breast within one hour of birth. According to national family health survey 3, in India, the rate of early initiation of breast feeding stands low at 24.5% [4]. The characteristics associated with the practice have been little investigated. Hence the current aim is to estimate the prevalence of breastfeeding initiation within first hour of life and examine the factors associated with timely initiation of breastfeeding.

Materials and Methods

Study methods and participants

This study was conducted in the month of July 2018 at PSG Institute of Medical Science and Research, Coimbatore. Ethical clearance from the institution was obtained prior to the study. A total of 527 mothers of children under four years were participated in the study. Mothers with the children age below four years attending paediatric outpatient department were included in the study. Babies with congenital anomalies that interfere with breastfeeding were excluded from the study. A structured interviewer administered questionnaire was used to collect data from mothers about timely initiation of breast feeding related with youngest child. The mothers were asked how long after birth their babies were first put to the breast. Initiating breastfeeding within one hour was categorized as "yes", whereas later than one hour was categorized as "no". The socio-demographic characteristics considered were as education of the mother, age of the mother, occupation of the mother, education of the father, socio economic status, gender of the child, gestational age of the child, birth weight of the child, mode of delivery, condition of the child soon after delivery and counselling for breastfeeding after delivery. Modified BG Prasad socioeconomic scale has been inuse for determining the socio-economic status with people having per-capita income greater than or equal to Rs.6180 is included in class 1, class 2 ranging from Rs.3090-6179, class 3 ranging from Rs.1850-3089, class 4 ranging from Rs.930-1849 and below Rs.930 is included in class 5. The classification is done based on the Consumer Price Index (CPI) value of 279 for Coimbatore [5]. Each study participant was adequately informed about the objectives of the study and obtained consent for ensuring their confidentiality.

Statistical methods

The collected data were checked manually for completeness and entered in to SPSS (23) for analysis. Descriptive statistics was used to summarize and analyse the socio-demographic characteristics of the study participants and the prevalence of timely initiation of breast feeding. Proportions were compared by timely initiation of breast feeding using Chi-square test.To determine the factors associated with timely initiation breastfeeding practice, binary logistic regression analysis carried out. Variables that showed significant association with timely initiation of breastfeeding in the bivariate models were entered in a multivariable logistic model. Strength of association was measured using odds ratio and 95 % confidence intervals. p value < 0.05 was considered as statistically significant.

Results

A total of 527 women were studied. The socio-demographic characteristics of children and families were given in Table 1. The prevalence of timely initiation of breastfeeding within one hour was 56.5% (Table 2).

Table 1: Socio demographic characteristics of infants and Families

Characteristics		Number (%)
Infant characteristics Child's age(months) (Mean ± SD)		15.55 ± 11.92
Education of the Mother	Below 12th standard	138(26.2)
	Above 12th standard	389(73.8)
Mother's age (years)	15-24	108(20.5)
	25-34	388(73.6)
	35-44	31(5.9)

Mother's Occupation	House wife	403(76.5)
	Paid worker	124(23.5)
Education of the Father	Below 12th standard	129(24.5)
	Above 12th standard	398(75.5)
Socio economic status	Class 1 & 2	426(80.8)
	Class 3,4 & 5	101(19.2)
Gender of the child	Female	246(46.7)
	Male	281(53.3)
Gestational age of the child	Term	469(89.0)
	Pre term	58(11.0)
Birth weight of the child (gm)	<=2500	126(23.9)
	>2500	401(76.1)
Mode of delivery	Vaginal delivery	336(63.8)
	Caesarean	191(36.2)
Condition of the child	Well	454(86.1)
	Sick	73(13.9)
Counselling after delivery	Yes	326(61.9)
	No	201(38.1)

Table 2: Timely initiation of Breast Feeding (Hours)

Brest feeding in hours	**Number (%)**
Within one hour	298 (56.5)
Between 1-4hr	78(14.8)
After 4hr	151 (28.7)
Total	527 (100)

In logistic regression analysis, (Table 3) it was observed that the timely initiation of breast feeding was lower among caesarean delivery compared to vaginal delivery and the difference was statistically significant ($p<0.001$). The timely initiation of breastfeeding was more when the condition of mother was well as compared to those mothers with sick condition ($p<0.05$). Timely initiation of breastfeeding was lower among mothers having low birth weight children than children having normal birth weight ($p<0.001$). Late initiation of breast feeding was higher for pre- term babies than term babies($p<0.001$). It was also observed that the mothers with the well children tend to initiate breastfeeding within one hour than sick children ($p<0.001$). Increased number of antenatal visits had significantly higher prevalence of timely initiation of breastfeeding than less antenatal visits ($p<0.01$). The timely initiation of breastfeeding was less in mothers who had earlier breast surgery compared to mothers who had no earlier breast surgery ($p<0.05$). It was also observed that counselling about timely initiation of breastfeeding after delivery ($p<0.001$) and skin to skin contact at birth ($p<0.001$) were significantly associated with timely initiation of breastfeeding.

Table 3: Factors associated with timely initiation of breast feeding in univariate analysis

Discussion

Globally, around four million new born die, most from preventable causes each year. Death in the neonatal period accounts for 41 % of all deaths in children below four years. Timely initiation of breastfeeding can help to prevent neonatal deaths caused by infections such as sepsis, pneumonia and diarrhoea[6].In India, a multipronged strategy including large scale programmes, effective capacity building initiatives, strong partnerships, community-

based action, and strategic mass media communication led to an increase in the rates of early initiation of breastfeeding from 24.5% in 2006 to 44.6% in 2014 (i.e. a 1.8-fold increase) [7]. More recently, analyses on a large cohort of almost 100 000 new born from three large trials in Ghana, India and Tanzania has shown that, compared with infants who initiated breast feeding within the first hour of life, the risk of neonatal death among children who initiated breast feeding between 2 and 23 hours after birth was 41% higher (RR 1.41; 95% CI 1.24 to 1.62), and 79% higher among those who initiated breast feeding at 24–96 hours of birth (RR 1.79; 95% CI 1.39 to 2.30) [7].

In this study, caesarean delivery was associated with delayed breastfeeding initiation compared to vaginal delivery. Caesarean delivery is the most consistent predictor of late initiation of breastfeeding reported by many studies conducted in Ethiopia and abroad [8]. Mothers might be uncomfortable to breastfeed due to the pain experienced after surgery and the related factors associated with caesarean delivery.

It was observed that the gestational age of the child is a predictor of timely initiation of breastfeeding. The timely initiation of breastfeeding was significantly lower in preterm children. This result may be explained by the common problems, such as limited oral-motor skills, delayed lactogenesis in prematurely delivered mothers and babies and babies were used to give formula feed from hospital. Thus, effective antenatal care to prevent premature births will contribute to early breastfeeding initiation. The observational prospective study conducted on 500 new born delivered at Department of Rajkiya Mahila Chikitsalaya (RMC), Ajmer and out born section of Department of paediatrics, JLN MC, Ajmer reported that preterm infants had significantly lower rate of early initiation of breastfeeding than term infants [9].

Furthermore, condition of the baby was significantly associated with timely initiation of breastfeeding. It was observed that sick condition of the baby adversely affect the initiation of breastfeeding within one hour. Babies who may have sick at birth include those who experienced a difficult delivery, jaundice after delivery, those with birth defects, those born prematurely and these problems can lead to late initiation of breastfeeding. Fortunately for these babies special care is available. New born babies who need intensive medical attention are often admitted in to Neonatal intensive care unit (NICU) for hours after delivery. So mothers failed to initiate breastfeeding in the first hour after delivery.

Earlier breast surgery was found to be statistically significant with timely initiation of breastfeeding. Women undergo breast surgery for many reasons. Augmentations, reductions, mastectomies, lumpectomies, and biopsies, are often carried out on women of childbearing age.

These surgeries can adversely affect timely initiation of breastfeeding and the ability to make healthy breast milk supply for a child.

In addition we have also observed a significant association between timely initiation of breast feeding and counselling about timely initiation after delivery. Counselling about timely initiation has a major impact on timely initiation of breastfeeding. The findings suggest that more efforts are needed to create awareness in providing counselling for the timely initiation during antenatal visits and delivery time. This might be related to the fact that mothers received breastfeeding information/counselling immediately after delivery which is the most appropriate time for delivering key messages about breastfeeding[10].

Baby put on mother's abdomen (skin to skin contact between mother and baby) is found to be an important factor to initiate breast feeding early. WHO recommends that early skin to skin contact between mother and baby helps to initiate early breast feeding.

Birth weight of the child is a predictor in the association of timely initiation of breast feeding in univariate analysis. Socio economic status did not have any association with timely initiation of breast feeding. Previous studies showed that initiations of breastfeeding in low birth weight children were significantly delayed [9]. Also, here educational status of mother did not have any significant association with timely initiation of breast feeding ($p>0.05$). Prior findings showed that education was found to have predominant importance for timely initiation of breastfeeding. Parity and initiation of breast feeding were found to have a lack of association in this study.

This study involves several limitations. One limitation is the recall bias caused by difference in the accuracy or completeness of the recollections retrieved by study participants regarding the breastfeeding practice from the past (retrospective reporting). Another limitation is that the region of study has a generally higher socio-economic status and it was a hospital based study. Community based study program is an approach that emphasize on community empowerment as an important tool in health promotion. Even though the study has several strengths. We have obtained a large number of demographic and clinical data which can influence the association of timely initiation of breastfeeding. All respondents are asked the same basic questions in the same order by the same interviewer to minimize the potential observer bias. Advanced statistical analysis was used to analyse the association

of socio demographic and clinical correlates with timely initiation of breastfeeding.

Conclusion

This study revealed that the prevalence of timely initiation of breastfeeding was significantly lower than the present WHO recommendations [11]. The findings clearly indicate that appropriate strategies are needed to minimize delays in initiation of breastfeeding and for practising better timely initiation of breastfeeding within one hour of birth.

Objectives: To develop and assess Pediatric Appropriateness Evaluation Protocol for India (PAEP-India) for inter-rater reliability and appropriateness of hospitalization.

Design: Cross-sectional study.

Setting: The available PAEP tools were reviewed and adapted for Indian context by ten experienced pediatricians following semi-Delphi process. Two PAEP-India tools; newborn (≤28 days) and children (>28 days-18 years) were developed. These PAEP-India tools were applied to cases to assess appropriateness of admission and inter-rater reliability between assessors.

Participants: Two sets of case records were used: (*i*) 274 cases from five medical colleges in Delhi-NCR [≤28 days (*n*=51); >28 days to 18 years (*n*=223)]; (*ii*) 622 infants who were hospitalized in 146 health facilities and were part of a cohort (*n*= 30688) from two southern Indian states.

Interventions: Each case-record was evaluated by two pediatricians in a blinded manner using the appropriate PAEP-India tools, and 'admission criteria' were categorized as appropriate, inappropriate or indeterminate.

Main outcome measures: The proportion of appropriate hospitalizations and inter-rater reliability between assessors (using kappa statistic) were estimated for the cases.

Results: 97.8% hospitalized cases from medical colleges were labelled as appropriate by both reviewers with inter-rater agreement of 98.9% (k=0.66). In the southerm Indian set of infants, both reviewers labelled 80.5% admissions as appropriate with inter-rater agreement of 96.1% (*k*= 0.89).

Conclusions: PAEP-India (newborn and child) tools are simple, objective and applicable in diverse settings and highly reliable. These tools can potentially be used for deciding admission appropriateness and hospital stay and may be evaluated later for usefulness for cost reimbursements for insurance proposes.

Keywords: *Bed use, Cost, Hospital stay, In-patient, Utilization*.

Efficient and rationale allocation of health resources in India and other developing countries is essential. The recent National Health Policy of India and Ayushman Bharat Yojana aim at healthcare universalization and improving both out-patient and in-patient accessibility [1,2]. Hospitalizations consume a major proportion of healthcare resources in India and 50.9% of the resources are utilized for secondary (34.8%) and tertiary (16.1%) level services [3]. There is severe shortage of in-patient beds in India (0.7 beds/1000 population vs. world average of 3.96) with long waiting period for hospitalization particularly at government hospitals [4]. Standardizing admission and discharge processes has improved utilization, patient-flow and waiting time in several countries, and appropriateness evaluation protocols (AEP) are in wide use [5-7]. At present no Pediatric

Accompanying Editorial: Pages 1037-38

Appropriateness Evaluation Protocol (PAEP) tool is available for use in India.

We describe the development and pilot-testing of the PAEP-India tool to determine the inter-rater reliability for appropriateness of two sets of hospital admissions: (*i*) 274 in-patients from five medical colleges from Delhi and surrounding states and (*ii*) 622 hospitalized infants from a southern Indian cohort.

METHODS

Development of PAEP Tool

The tool development process used semi-Delphi technique [8]. The PAEP tool adaptation for India (PAEP-India) process followed the steps: (*i*) an expert group of ten experienced pediatricians from ten medical colleges, each with >10 years of clinical experience was constituted considering the differences in symptomology, diseases and threshold for hospitalization, the experts felt need for developing separate tools for newborns (≤28 days) and children (>28 days-18 years); (*ii*) review of the available literature was done and seven PAEPs (from 6 high- and 3 middle-income countries) were sourced [9-19]; (*iii*) two rounds of review and pilot testing of the tools was done by the experts; (*iv*) a face-to-face meeting was held for finalization of tools.

Each tool has two sections; 'admission criteria' to assess the appropriateness at admission and 'day of care' criteria for the appropriateness of hospitalization duration. For the PAEP- India (child) tool, the group made some amendments in both the admission criteria and day of care criteria for children (***Box* 1**).

The PAEP-India (newborn) tool was drafted with reference to the available management protocols for newborns [21-23]. The group did not suggest any change in the draft and finalized it. Finally, 'admission criteria' section comprised of 44 items in both the tools, and the 'day of care' for newborn and child tools comprised of 27 and 29 items, respectively (***Web Annexure* I** and **II**).

The group of ten pediatricians who participated in the development of the PAEP-India tools were invited as raters. Five pairs of raters were made and each pair was assigned the same set of case sheets in a blinded manner; raters in a pair were not from the same institution and did not know the other member of their pair. All the raters underwent orientation to have common understanding of using the PAEP reviewers' manual.

We had two sets of case-records drawn from different settings for inter-rater reliability assessment: 274 pediatric cases records drawn from five medical colleges located in Delhi and surrounding states (admitted during July-September 2015), and 622 cases-records from Kollam and Coimbatore, who were part of a cohort of 30688 infants recruited and followed-up in another study [24]. The case-records were anonymized and assigned unique study numbers.

The Ethics Committees of participating Institutes reviewed and approved the study. Waiver of informed consent was granted for data collection from the case records from five medical colleges. Informed consent was obtained for recruiting the infant cohort from Kollam and Coimbatore.

Statistical analysis: Inter-rater agreement was evaluated by the Cohen's kappa (*k*) statistic [25]. Landis and Koch guidelines were adopted as benchmark scales of κ coefficients (moderate: 0.41-0.60, substantial: 0.61-0.80, and almost perfect: 0.81-1.0) [26]. Statistical analyses was performed using STATA version 15.0 (StataCorp LLC, Texas, USA). Overall agreement was the proportion of judgements in which two raters agreed on categorizing as appropriate, inappropriate and indeterminate. We assessed the inter-rater reliability only for the 'admission criteria'; the 'day of care criteria' section could not be evaluated as complete clinical, nursing and laboratory assessment records were not available for most of the days in most of the case sheets in both datasets.

Box 1 ADMISSION CRITERIA AND DAY OF CARE CRITERIA FOR DEVELOPMENT OF PAEP-INDIA*(CHILD) TOOL

- "severity of illness" section, "any fever for >48 hours when a diagnosis has not been reached" was revised to ">72 hours".
- Considering accidents, "burns/inhalational injury" and "exposure to poison and snake/ scorpion bite" were added.
- Under the "severe electrolyte/acid base/ hematological abnormality" section, "hypocalcaemia", "raised creatinine", "thrombocytopenia", "increased respiratory rate" were added, modified "total leukocyte count cut-off to <5000/ mm^3" and added "raised diastolic blood pressure" to hypertension.
- Under the "intensity of services" section, revised "nebulisation use at least every 4 hours".
- Day of care criteria: added "lack of suitable care taker availability (for abandoned child)/protected place" under "patient condition" section; and clarified "unstable vitals in last 48 hours" under the "within 48 hours of the day reviewed" section.

TABLE I CLINICAL DIAGNOSES IN THE TWO DATA SETS USED FOR INTER-RATER AGREEMENT FOR APPROPRIATENESS OF ADMISSION USING PAEP-INDIA TOOLS

Characteristic	*Delhi and Surroundings (n=274)*	*Kollam and Coimbatore (n=622)*
Children >28 d -18 y		
Infections	122	524
Acute respiratory infections	23	427
Acute gastroenteritis	26	33
CNS infections	20	
Urinary tract infections	3	19
Acute febrile illness[@]	28	25
Other infections[#]	22	20
Congenital diseases[€]	4	26
Other systemic diseases	43	68
Seizure/CNS disorders	15	25
Other medical disorders*	28	43
Surgical conditions	54	4
Gastrointestinal	19	4[^]
Urological	12	0
Other surgical conditions	23	0
Neonates (<28 d)		_
Medical problems	42	_
Neonatal sepsis	24	_
Other medical disorders[$]	18	_
Surgical conditions	9	_

*[@]Acute febrile illness including malaria, dengue, enteric fever, urinary tract infection, and other for evaluation; [#]Multiple system infection involves infection of more than one organ, may be with features of sepsis; [€]Congenital diseases including cardiac and central nervous system (CNS) malformations and other parts; *Other medical conditions including malignancy, coagulopathy, severe acute malnutrition, drug reaction, poisoning, constipation, nephrotic syndrome and hematemesis; [^]All 4 children had intussusception; [$]Other medical conditions in neonates included preterm care, respiratory distress syndrome, hyperbilirubinemia, hypo/hyper-glycemia, and birth asphyxia.*

RESULTS

The age strata of 274 case-records from Delhi and surrounding states were: ≤28 days (*n*=51), >28 days-12 months (*n*=48), 13-59 months (*n*=67), and >5-18 years (*n*=108). There were 54 surgical cases (20.8%). Out of 622 cases from southern India cohort, 471 (75.7%) were from Kollam and 151 (24.3%) were from Coimbatore. The median age at entry and exit were 48 days (range 32-175 days) and 153 days (range: 67-562 days), respectively. There were equal proportion of boys (50.3%) and girls (49.7%) in the cohort (***Table* I**). Out of 622 cases hospitalized to 146 hospitals, 50% (*n*=311) were admitted to tertiary (level 3), 49% (*n*=304) to secondary (level 2) and 1% (*n*=7) were admitted to primary care (level 1) care facilities respectively.

TABLE II INTER-RATER AGREEMENT FOR APPROPRIATENESS OF HOSPITALIZATION USING PAEP-INDIA TOOLS

Reviewer 1	*Reviewer 2*		
	Appropriate	*Inappropriate*	*Indeterminate*
Medical colleges in Delhi and surrounding areas (n=274)			
Appropriate	268	0	1
Inappropriate	2	1	0
Indeterminate	0	0	2
Hospitals in Kollam and Coimbatore (infants) (n=622)			
Appropriate	480	13	0
Inappropriate	9	68	2
Indeterminate	0	0	50

Kappa (*k*) coefficient was 0.66 (95% CI 0.30, 1.0) for the overall dataset for hospitalized cases in medical college. Both raters categorized 97.8% admissions as appropriate. The observed inter-rater agreements were >98% for aggregated and the disaggregated data according to age and gender. The agreement for PAEP appropriate cases and inappropriate cases were >98% with values of 0.66 and 0.49, respectively (***Table* II**).

The *k* for overall dataset was 0.89 (95% CI 0.84, 0.93) for the Kollam and Coimbatore infants. Overall both raters categorized 80.5% admissions as appropriate. The appropriate admissions in public and private hospitals were 84.5% and 78.5%, respectively. The observed agreement was >90% in most categories except for the level 1 hospitals (85.7%) which had just seven admissions.

DISCUSSION

This is the first effort to develop a tool for assessing the appropriateness of pediatric admission and hospitalization duration in India. The PAEP-India tools performed well for admission appropriateness assessment, both for newborns and children and across different levels of hospitals.

In the absence of a gold standard and true valid measure of appropriateness, the consensual validity is reflected through inter-rater agreement. Studies on admission appropriateness using the PAEP tools in different countries have reported variable levels of both observed agreement and kappa statistic (0.29-0.89) [9-12,14,16,19]. With PAEP-India tools, observed agreements were uniformly high with both the datasets.

WHAT IS ALREADY KNOWN?

- Country- and context-specific Pediatric Appropriateness Evaluation Protocol (PAEP) tools are in use for rational use of in-patient facilities.

WHAT THIS STUDY ADDS?

- India-specific PAEP tools for the assessment of appropriateness of pediatric and newborn hospitalizations were developed and tested for reliability with two sets of hospitalized children.

Despite a high observed agreement, lower kappa values may be observed, when the marginal values are imbalanced. On the contrary, higher kappa value may be observed for asymmetrical imbalanced marginal totals. Kappa is affected by prevalence and may not be reliable for rare observations. Thus very low kappa values may not necessarily reflect low overall agreement. Decision on performance of a tool should also consider the observed *versus* expected agreement, consistency across contexts, and suitability of the criteria for specific settings besides kappa statistics [27,28].

The reported proportion of appropriate pediatric admissions reported in literature range between 68%-89.5% and 59.3%-98% in high- and middle-income countries, respectively [9-12,14-16,19]. The proportion of appropriate admissions in the present study was high, particularly in medical colleges, in view of the higher demand and pressure for admission. A previous study reported that one-third of the adult patients overstay in hospitals [29]; which was triangulated by the perceptions of 83% of resident doctors and 43% of nurses in another study [30].

Awareness of the raters about the source of cases in first dataset might have influenced the high expected and observed agreements (>90%). For the second dataset (southern Indian infant cohort), the raters were neither aware about the hospitals nor involved in the study implementation or patient care. We could not assess the appropriateness of the duration of hospitalization due to lack of necessary information at the time of discharge. In the first dataset, the experts involved in development of PAEP-India tools also applied the tools in cases drawn from some medical colleges where they worked. These factors might have increased observed agreement and categorization of cases as appropriate. The findings for the level one health facilities from southern India may not be generalized as the number of hospitalizations were too small.

In conclusion, the PAEP-India tools performed consistently in two different settings demonstrating consensual validity. The advantages of the PAEP-India tools is their simplicity, objectivity and applicability in different hospitals. Further application and evaluation of these tools is required in diverse settings across India including health facilities of all levels for triangulating the evidence of its utility. Meanwhile the PAEP-India tools have potential application in insurance systems, quality assessment processes, and resource-allocation.

MII RetCam assisted smartphone based fundus imaging for retinopathy of prematurity

T Lekha, S Ramesh[1], Ashish Sharma[2], G Abinaya

Purpose: The gold standard for evaluating Retinopathy of prematurity (ROP), a potentially blinding disease in preterm babies, is by indirect ophthalmoscopy which is quite subjective. Digital imaging with RetCam, an advanced wide field imaging system is more precise but it is not easily available or affordable. Smartphones are being explored as an alternate cost effective and accessible imaging tool. This is possible because of the good illumination and the built-in high resolution cameras available in modern smartphones. The aim of this study is to illustrate the utility of MII RetCam assisted smartphone based fundus imaging (MSFI) in the documentation and monitoring of ROP. **Methods:** Single-centre, retrospective observational study of all the preterm babies subjected to MSFI as part of ROP screening from September 2017 to November 2018. iPhone 4S and + 20 Diopter lens attached to the MII RetCam device was used for fundus imaging at baseline and during follow up. The statistical analysis used for the same is the SPSS statistical software. **Results:** Good quality images of central and peripheral retina could be captured in 33 out of 42 babies (78.57%) with ROP. Serial imaging done in 24 babies with ROP helped in precise monitoring of the disease and planning management. Incidentally detected non-ROP findings were also documented. Unique design of the device enabled imaging by a single examiner. Image database created was useful for academic and counselling purposes. Smaller field images which can cause difficulty in distinguishing the zones is a limitation. **Conclusion:** MSFI is a potential alternate imaging tool enabling objective documentation and monitoring of ROP in low resource settings.

Quick Response Code:

Key words: Fundus imaging, MII RetCam, retinopathy of prematurity, smartphone

The gold standard for evaluating Retinopathy of prematurity (ROP)—a potentially blinding disease in preterm babies—is by indirect ophthalmoscopy which is quite subjective.[1] Digital documentation with RetCam (Natus USA, formerly Clarity, MSI, USA) is more accurate but expensive.[2-4] Smartphones equipped with good illumination and high-resolution cameras have emerged as an alternate, affordable and reliable imaging tool.[5-7] Smartphone-based fundus imaging utilizing an innovative device "Make In India (MII) RetCam" has been found to achieve good quality imaging of central and peripheral retina.[8,9] We aim to demonstrate the utility of MII RetCam assisted smartphone-based fundus imaging (MSFI) in the documentation and monitoring of a peripheral retinal pathology like ROP, in resource limited settings.

Methods

This is a single-centre, retrospective observational study of the utility of MSFI done as part of the ROP screening from September 2017 to November 2018. Babies were referred for ocular evaluation by Neonatologist as per the screening guidelines for ROP.[10] All examinations were done by a single ophthalmologist trained in ROP (TL). Examination was done either in the ophthalmology department or in the neonatal intensive care unit (NICU). All babies remained awake during the procedure and a trained nurse assisted to hold the baby and keep the head steady. Mydriasis was achieved with Tropicamide (0.5%) with Phenylephrine (2.5%) eye drops and binocular indirect ophthalmoscopy (BIO) with scleral depression was done for complete evaluation of retinal periphery. Lid speculum placed under topical anesthesia with 0.5% Proparacaine eye drops ensured good separation of the eyelids and cornea was kept moist by applying normal saline.

This was followed by MSFI and video recording of retinal features. Smartphone used was iPhone 4S (Apple Inc., Cupertino, CA, USA) with its original settings. It was done as described below:

1. iPhone and Volk + 20 Dioptre (D) lens were inserted into the respective slots at either ends of the MII RetCam device. This enabled holding both with a single hand at appropriate distance in the same axis. The other hand was therefore free to manoeuvre the eyes and to perform scleral indentation
2. The device was held in front of the patient's eye by holding the handle near the smartphone end between

the palm and fingers in such a way that the screen of the smartphone is facing up and thumb of the same hand was used to turn on/off the video mode of the camera during recording [Fig. 1a]
3. The constant illumination in the video mode was switched on, and once the red glow was seen through the dilated pupil, it was slowly withdrawn till a clear image of the fundus was visualized on the smartphone screen
4. The video mode of the camera was then switched on with the thumb and then recorded until all the desired areas were imaged. The video mode was then similarly switched off
5. To get a good quality image, it is important to ensure that the image fills the entire 20D lens without any light reflection. This was achieved by slight back and forth movement or tilting of the device and stabilizing the baby's eyes with infant depressor. Good mydriasis also helped to reduce reflections
6. The smartphone camera lens and the 20 D lens should be cleaned well before the procedure to remove any dirt which can cause artefacts
7. The posterior pole was examined first followed by the entire peripheral retina in a sequential manner which was facilitated with the eye ball manoeuvred towards the desired direction using the scleral depressor. Tilting the baby's head slightly to the same side made it easier to visualize the extreme periphery
8. After completion of recording, the chosen good quality stills were extracted from the video sequence using the screenshot option in the smartphone (click and hold the top power button and the round menu button at the bottom simultaneously). The right hand of the examiner holding the device is not supported on the baby's face and can shake in between. Hence, capturing videos rather than still images were preferred
9. The snapshot images and video recordings were then transferred to a laptop which had a larger storage space. They were then archived in a separate folder along with the demographic data for each baby
10. Babies with immature retina and ROP were followed up as per the guidelines and the same protocol was repeated at each visit.

Study was approved by institutional human ethics committee and written informed consent was obtained from the parents of babies.

Results

132 babies with gestational age (GA) ranging from 27 to 39 weeks and birth weight (BW) ranging from 800 to 3400 grams were screened for ROP during the study period. Babies having GA more than 35 weeks and BW more than 1700 grams were included for screening at neonatologist's discretion. Fundus examination revealed mature retina in 52 babies. There were 36 babies with immature retina in zone 3, 19 babies with immature retina in zone 2, and 25 babies with ROP. They were all monitored according to the guidelines. During follow up, 17 more babies developed ROP resulting in a total of 42 babies (31.81%) with ROP. Types 1 ROP developed in 5 babies (3.79%) and were treated with laser.

MSFI captured good quality retinal images in 33 out of 42 babies with ROP (78.57%). In the remaining 9 babies image clarity was not good enough to assess the retinal changes. Serial imaging was done for 24 out of 33 babies with ROP, ranging from 2 to 11 imaging sessions. Imaging was also done for 4 babies with immature retina and 6 babies with mature retina which included 3 babies with incidental retinal findings. A total of 129 imaging sessions were done for 43 babies (mean 3). Posterior pole images helped to assess the disc, macula and plus disease [Fig. 1b and c]. None of the babies had Zone 1 disease. Peripheral images especially of the nasal and temporal periphery helped in accurate classification of ROP [Fig. 2]. Scleral depression made it possible to image the extreme peripheral retina till the ora. [Fig. 2 g and h]. Serial recordings during follow up helped to objectively monitor the disease and to study the changes associated with progression or regression of the disease [Figs. 3 and 4]. In eyes which were lasered, it was helpful to document the changes pre and post treatment [Fig. 3]. Imaging details of all the babies with ROP and their disease pattern at the time of initial and final diagnosis are shown in the Table 1. Photo documentation was comparable to clinical evaluation with BIO except in babies with stage 1 disease in zone 3. Other posterior segment findings detected in 3 babies during evaluation could also be documented which were bilateral preretinal haemorrhage, intraretinal hemorrhage, and cystoid edema at fovea, respectively. Imaging required an additional time of approximately 5 minutes and none of the babies had any systemic issues during the procedure.

Discussion

Modern smartphones with its constant, coaxial and powerful light source, coupled with 20D lens, creates a BIO like optical system enabling visualization of the fundus and the built-in automatic focus camera enables imaging of the fundus. The utility of smartphone imaging in ROP was first reported by Lin *et al.*, who recorded fundus images of 6 infants with ROP using the original settings of the camera in the smartphone.[7]

Table 1: The imaging data of babies with ROP

Zone/Stage of ROP	No of babies evaluated with BIO at initial diagnosis (*n*=42)	No of babies evaluated by MSFI at initial diagnosis (*n*=33)	No of babies evaluated with BIO at final diagnosis (*n*=42)	No of babies evaluated by MSFI at final diagnosis (*n*=33)
Zone 2 Stage 1	5	5	0	0
Zone 2 Stage 2	5	4	1	0
Zone 2 Stage 3	1	1	3	3
Zone 3 Stage 1	20	13	19	12
Zone 3 Stage 2	11	10	17	16
Zone 3 Stage 3	0	0	2	2

ROP: Retinopathy of prematurity; BIO: Binocular indirect ophthalmoscopy; n: Number; MSFI: MII RetCam assisted smartphone based fundus imaging

Biju Raju *et al*. and Oluleye TS *et al*., have documented ROP by smartphone based imaging and have found it to be effective.[11,12] Oluleye *et al*. used the app Filmic Pro to capture the images and app Aviary to edit the images. In all these techniques, the examiner holds the mobile phone in one hand and 20D lens in the other hand, and so an assistant is required for eye ball manipulation. The technique is thus more challenging to visualize the periphery, which is crucial in ROP. Also, all reports are based on single imaging session on a smaller number of babies.

In our study, MSFI was successful in objectively documenting ROP in 78.57% of patients. Though this is slightly less than that reported with the professional wide field imaging systems,[3] it has several practical advantages. The device is more affordable[8] compared to the RetCam, and a smartphone and 20D lens are available with any ophthalmologist. The technique can be learned with minimal practice within a week's time if one is well-versed with BIO and smartphone photography. As both imaging and globe manipulation is done by the same person, there is better control and coordination than the other smartphone-based models. The unique design of the device automatically ensured that smartphone and 20D lens were aligned in the same axis as the patient's eyes especially when eyeballs are rotated to the sides for peripheral examination. This ability to visualize the peripheral retina to the same extent as BIO is one of the distinct advantages of MSFI, making it superior to RetCam in evaluating the Zone 3 in premature babies. It has been found that, in comparison to BIO, RetCam had more difficulty in imaging peripheral retina till ora due to the restricted mobility of the equipment.[13]

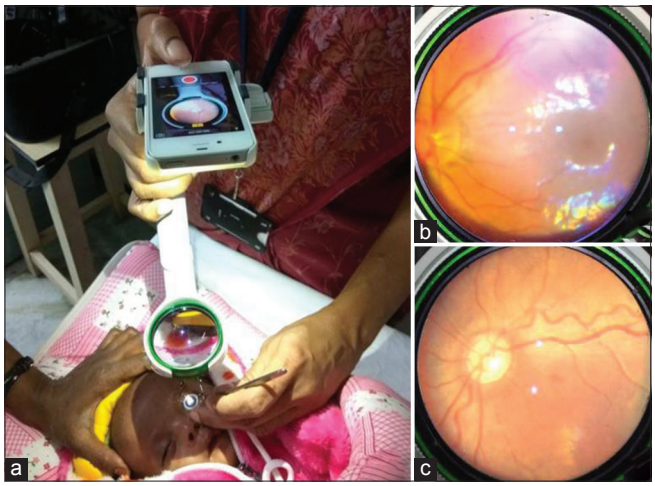

Figure 1: Showing (a) the technique of MII RetCam assisted fundus imaging. Fundus image is seen on the screen of the smartphone (b) Image of normal posterior pole (c) Image with plus disease

Serial imaging helped in improved monitoring of the course of disease over time by comparing with baseline photographs and to plan appropriate management. It also helped in more precise evaluation of plus disease, which is often inaccurately assessed by the limited bedside examination with BIO. To the best of our knowledge, serial imaging of ROP by smartphone fundoscopy has not been previously documented. This simple, non-contact, portable and user-friendly innovation can be practiced in any setting, irrespective of the systemic status of the baby or the location. Another advantage is the option to share these digital images directly from the smartphone because of its connectivity, for second opinion, in difficult situations avoiding direct referral of babies. The only other report of fundus photo documentation using MII RetCam for ROP is by Behera *et al*.[9] They used it for adult and pediatric cases and found it particularly useful in pediatric cases due to its portability. Till date, there is no published data comparing

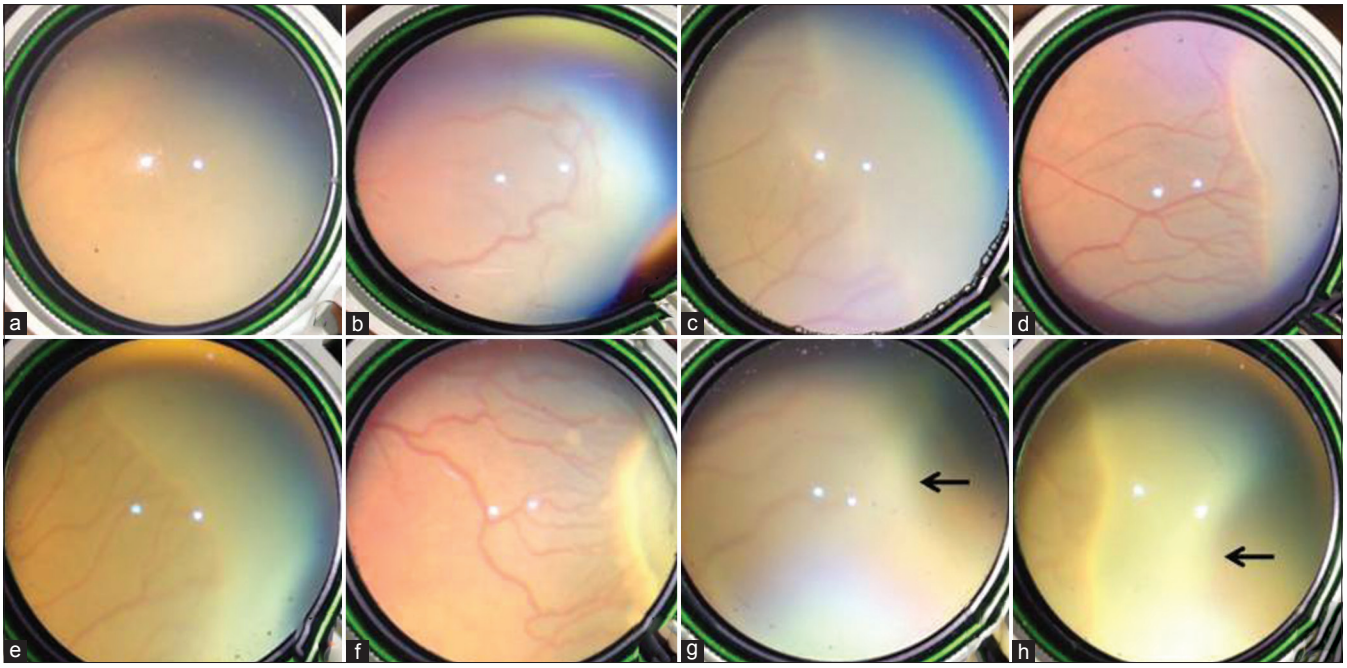

Figure 2: Showing (a) Immature retina (b) Vascular loops (c) Stage 1 ROP (d, e) Stage 2 ROP in the temporal and nasal periphery (f) Stage 3 ROP with plus disease and " popcorn" lesions (g and h) extreme periphery till ora (black arrow) in an eye (g) with mature retina and (h) with Stage 2 ROP

the quality of images obtained by smartphone in ROP to that with RetCam images or clinical examination. However, in a recent meta-analysis, smartphone image quality was found to agree substantially with the gold standards of clinical or photographic exams for evaluating other posterior segment pathologies like diabetic retinopathy.[14] We could also document other incidental posterior segment pathologies like retinal hemorrhages and foveal cystic changes. Routine ocular digital imaging in preterm babies have been emphasized by other authors who serendipitously detected significant and even life threatening conditions during ROP screening enabling timely intervention for treatable conditions.[15]

We used the iPhone 4S as it has been proved to be safe in retinal imaging.[16] Moreover, the technical feasibility of an iPhone as an ocular imaging device was found to be comparable to that of RetCam in a study by Jalil *et al*., and the authors recommend iPhone imaging in situations where expensive and complicated imaging equipment is unavailable.[17] They opine that flash illumination and autofocus in iPhones is well designed for ophthalmic imaging without the need for additional apps or much manual adjustment. Several apps like MII RetCam App, HopeScope App and Ullman Indirect App are available with different functionalities like data storage, brightness control and even short video recording, but we preferred the original settings in the iPhone and so no additional app was tried. Other authors have reported satisfactory imaging with different smartphones like iPhone 5, HTC One, Blackberry Z-10, Samsung S3 and Note3.[7,11,12,18] Another recommendation is to use micropore tapes to reduce unwanted reflections.[7]

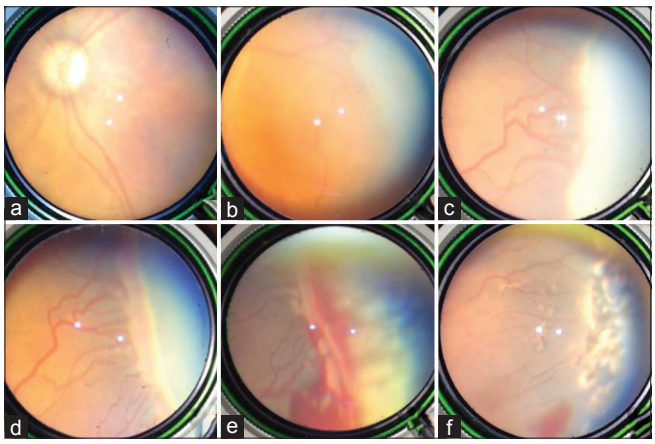

Figure 3: Serial imaging of a baby lasered for Type 1 ROP showing (a) posterior pole (b-d) progression of ROP from Stage 1 to 3 with plus disease (e) Immediate post laser with hemorrhage over ridge (f) 1 month post laser with decrease in plus disease and haemorrhage

Similar to previous reports,[8] we found that real time display of the fundus features on the smartphone screen during video recording was superior to conventional theoretical teaching of the residents in the evaluation of ROP. It was especially useful to demonstrate the peripheral retinal changes in ROP to the residents who were not competent in performing BIO in neonates. It also avoided too many doctors from directly handling the preterm babies and thus reduced the duration of examination as well as the risk of infection. Incorporating MSFI as a part of ROP screening will help to create a large image library useful for presentations, publications and research activities. It can be used as an easily available and inexpensive tool to train eye care workers.[18] It was extremely helpful in parental counselling, convincing them regarding treatment when needed and ensuring better compliance with follow up. Thus, it is a real asset in the practice of evidence-based medicine and can be a valuable proof in medico-legal situations.[8]

Our study has certain limitations as well. One of the important drawbacks of this technique is the limited field

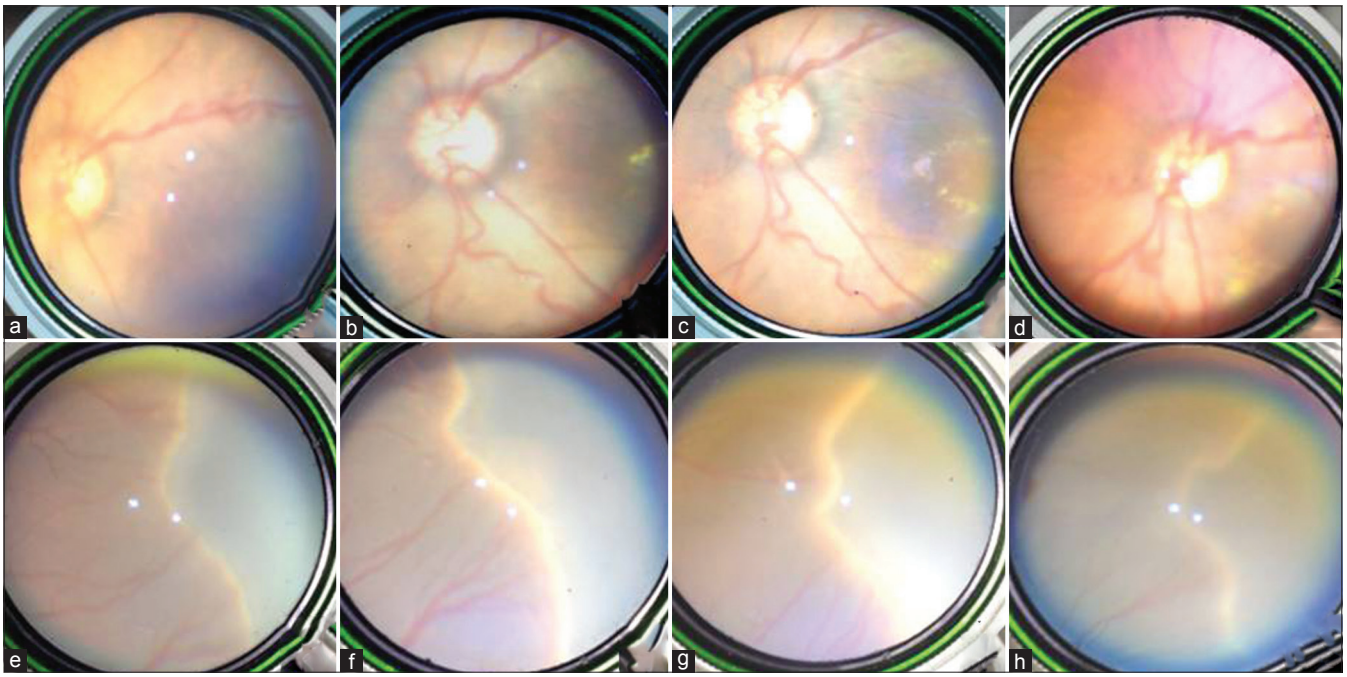

Figure 4: Serial imaging of the central (a-d) and peripheral retina (e-h) showing delayed natural regression. Stage 2 ROP noted at 36 weeks post conceptual age, worsened to Stage 3 with plus disease by 38 weeks, early regression by 40 weeks and further regression by 49 weeks

of view (<45°) when using the 20D lens, unlike the RetCam which provides a wide 130° field. This can cause difficulty in distinguishing the zones from a single static image. Using higher plus power lenses like 40 or 60D lens can increase the field up to 90°.[14] A superior option would be to use montage software programs for automated construction of mosaic photographs from multiple individual images as has been reported by Patel *et al*.[19] In their study, ROP experts interpreted individual fundus photographs and mosaic photographs of wide-angle retinal images and found that mosaic photographs were more accurate in image based diagnosis of clinically significant ROP. This is because mosaic photographs not only provides high resolution wide field images but also allows a continuous view with improved visualization of the ridge and vascular changes. In a novel study by Kim TN *et al*., software intelligence and automation-assisted smartphone based retinal imaging produced high quality 100° photomontages from 5 overlapping images in under one minute fully on-phone revealing various retinal abnormalities.[20] It was validated against clinical examination in diabetic retinopathy screening and found to have a sensitivity of 93.3% and specificity of 56.8%. More studies are needed to know if such automation techniques can enhance smartphone based imaging in ROP. Another deficiency of our study is the lack of objective grading of the quality of images by masked observers and validating it against the gold standard of BIO. The technique was more challenging in eyes with poor mydriasis, hazy media and in older babies due to the more active movements by the baby and these factors accounted for the difficulty in obtaining good images in 9 of our babies with ROP. Better case selection and availability of smartphones/apps with option of small pupil imaging can help to overcome these difficulties.

Smartphones have been successfully used as a diagnostic interface in teleophthalmology for ROP wherein retinal images taken using RetCam Shuttle at remote locations are transmitted electronically and viewed on smartphone using viewer software by experts.[21,22] Though telemedicine has tremendously improved the screening and management of ROP, it involves a significant initial investment to implement the telemedicine system (RetCam costs USD 83,500/- whereas MII RetCam device costs USD 380/-).[4,23] The availability of easily accessible and good quality imaging using smartphone offers a low cost substitute for RetCam imaging, adding another dimension to telescreening for ROP.

Conclusion

MSFI is a potential alternate imaging tool enabling objective documentation and monitoring of ROP in low resource settings. Creation of an image data base is useful for academic and research purposes. Prospective, double blinded study with a larger sample size and with comparison to RetCam will help to assess the sensitivity and specificity of this imaging modality. Improvements in software and automation techniques have the potential to widen its utility as a teleROP screening tool in future.

Background: According to the recommendations from The World Health Organization, exclusive breast feeding (EBF) should be given to infants for the first six months for healthy growth and development. However, developing countries have a wide range of variation in the practice of EBF. From this study, we aim to estimate the duration of EBF and find the impact of socio-demographic characteristics on EBF.

Materials and Methods: This study was conducted at PSG Institute of Medical Sciences and Research, Coimbatore in the month of July 2018. Mothers with children aged below 4 years attending the paediatric outpatient department were included in the study. Kaplan-Meier curve analysis and logistic regression analysis were employed.

Results: Our analysis indicates that the prevalence of EBF was 58.4% among infants up to 6 months of age with mean duration of EBF 4.52 months. It was observed that mothers of a younger age (15-24 years) and with lower socio-economic status were negatively associated with the practice of providing EBF to infants up to six months of age.

Conclusion: The findings clearly indicate that the interventions related to EBF up to six months of age should be targeted at women in the lower socio-economic status and at younger ages.

Keyword: Exclusive breast feeding, socio-economic status, mother's age.

Introduction

According to the recommendation of the World Health Organization (WHO), exclusive breastfeeding (EBF) should be given to infants for the first six months of life and continued breastfeeding up to two years of age or beyond for the healthy growth and development [1-3]. Recent literatures have suggested exclusive breastfeeding as a cost-effective intervention to reduce infant mortality rate in less developed countries [4, 5]. Globally, it is estimated that the lack of providing exclusive breast feeding to infants in the first 6 months of life results in 1.4 million deaths and 10% of disease in under-five children [6]. On the other hand, poor school performance, reduced productivity and impaired intellectual and social development are reported to be much higher due to the lack of EBF in the first 6 months of life.

In India, a large number of children, nearly 20 million, were not able to receive EBF for the first six months, according to the reports from National Family Health Survey (NFHS) [7]. Over the past several years, India has failed to witness any remarkable achievements in infant feeding practices. Only a small increment was recorded in EBF rates amongst infants in the 0-6 month age group from 41.2% in 1998-99 (NFHS 2) to 46.3% in 2005-2006 (NFHS 3). The mean duration of EBF among last born children is as brief as two months.

In 2016, the Government of India started various initiatives to tackle the health issues among children due to inappropriate breast-feeding practices. The Government of India developed the infant and young child feeding guidelines in 2016 in view of this initiative. However, more studies are needed to explore the factors associated with the low proportion of EBF. The present study aims to estimate the duration of EBF and to find the impact of socio-demographic characteristics influences on EBF practice.

Methodology

Study design and setting

A cross-sectional study was conducted at PSG Institute of Medical Sciences and Research, Coimbatore in the month of July 2018. The mothers of infants less than four years of age, who attended the paediatric outpatient department, were included in the study. The selected mothers were broadly classified into two groups: EBF and non-EBF. Mothers having children aged below 6 months and who were given only breast milk in the 24 hours preceding the survey were considered as EBF and others were in non-EBF group [8].

Sample size estimation

In order to estimate the EBF with the precision of 20% of the expected prevalence of 30%, with 95% CI, we require a minimum sample size of 300 for the study.

Data collection

Data were collected using direct interview method. Mothers were interviewed about the duration of EBF in months with respect to youngest child. The socio-demographic characteristics and breast-feeding related information were elicited from the selected mothers. The characteristics studied were educational status of the mother, age of the mother, working status of the mother, educational status of father, socio-economic status of the household, child's gender, gestational age of the child, birth weight of the child, mode of delivery, condition of the child soon after delivery, and counselling for breastfeeding after delivery. The socio-economic status was calculated using Prasad classification with class 1 as the person having per-capita income greater than or equal to Rs.6180, class 2 ranging from Rs.3090-6179, class 3 ranging from Rs.1850-3089, class 4 ranging from Rs.930-1849, and class 5 as person having per-capita income below Rs.930. The classification was done based on the Consumer Price Index (CPI) value of 279 for Coimbatore [9].

Exclusion criteria

Babies with congenital anomalies that interfered with breastfeeding were not included in the study.

Ethical approval

The study was approved by the Institutional Human Ethics Committee, PSG Institute of Medical Sciences and Research, Coimbatore.

Outcome variable

The outcome variable was the exclusive breast feeding (EBF) status of infants up to six months of age.

Explanatory variables

Mother's age, educational status of mother and father, working status of mother, gender, gestational age and birth weight of the child and socio-economic status of the household were the explanatory variables.

Statistical analysis

To estimate the mean and median duration of exclusive breast feeding among infants under study, the Kaplan-Meier Survival analysis method was applied and conditional probability of survival at monthly interval of time was then obtained. The termination of EBF was considered as outcome of the event of the occurrence. Accordingly, those women who fed their babies exclusively with breast feeding on the date of interview were considered as censored cases. In such cases, the duration of EBF was recorded as it was not known when they would discontinue EBF and start introducing adult diet. The duration of exclusive breastfeeding was sub grouped into smaller time intervals and for each interval all those who have been observed at least that long were used to calculate the probability of a terminal event occurrence in the interval. Then the overall probability of the event occurrence at different time

periods were estimated using the probabilities estimated from each interval. Survival probabilities, standard error, hazard rate, and mean and median survival time have been calculated. Log rank test was applied to compare the statistical significance for the equality of duration of exclusive breast feeding for different groups. In addition, logistic regression analysis was done to find the association of socio-demographic characteristics with EBF categorized as Yes or No. Odds ratio and then 95% confidence intervals were then calculated. Multivariate logistic regression analysis was done for those variables found significantly associated with the outcome variable of interest in the Univariate analysis. $p<0.05$ was considered as statistically significant. The data were analysed using SPSS (Ver. 23).

Results

A total of 527 women were studied. The socio-demographic characteristics of infants and families are given in Table 1. The prevalence of exclusive breast feeding was 58.4% among infants up to 6 months of age with the mean duration of EBF as 4.52 months.

Table 1: Socio-demographic characteristics of infants and families

Characteristics	Number (%)
Child's age (months) (Mean±SD)	15.55 ± 11.92
Mother's education	
Below 12th standard	138 (26.2)

On testing equality of the duration of EBF, it was observed that the mean duration of EBF was higher in mothers of age group 35-44 years than those aged 15-24 years and 25-34 years ($p<0.05$). The mean duration of EBF was more in class 1 and 2 of the socio-economic status than class 3,4, and 5 of the socio-economic status ($p<0.05$). The mean duration of EBF was more in children whose father's education was above 12th standard than those less than 12th standard ($p<0.05$). It was also observed that the mothers with the sick children tend to do less EBF than those with well children ($p<0.05$). The findings are presented in Table 2.

In the logistic regression analysis (Table 3), the prevalence of EBF was higher among the mothers of age group 25-34 years than those aged 15-24 years ($p<0.05$) and it was significantly higher among class 1 and 2 of the socio-economic status than class 3, 4, and 5 of socio-economic status ($p<0.01$). The multivariate logistic regression analysis also shows that the socio-economic status of class 1 and 2 had significantly higher prevalence of exclusive breast feeding than class 3, 4, and 5 of the socio-economic status ($p<0.01$) with an odds ratio of 1.788 (95% CI: 1.153-2.775). In addition, the prevalence of EBF was higher among the age group 25-34 years than in the aged group 15-24 years ($p<0.05$) with an odds ratio of 1.572 (95% CI: 1.021-2.421).

During the interviews, 47 (8.9%) mothers reported the problem of inverted nipple as a constraint for EBF. Seventy-seven (14.6%) mothers perceived to have the problem of low breast milk and 124 (23.5%) mothers had employment outside home. In addition, 151 (28.6%) mothers had no supportive family members at home (Table 4). It was also observed that there was a statistically significant association between perception of low breast milk and lower socio-economic status ($p<0.05$) (Table 4).

□r □□□□□□□□□□□□□□□□□□□□□□□□□r □□□□□□□d □□□□□

Breast feeding is universally recognized as the best way of feeding infants which helps in their healthy growth and development. Therefore, several countries, especially developing nations, have started implementing health promotion interventions to support successful breastfeeding by taking into account the factors influencing breast feeding outcomes. For infants till the first six months of life, the WHO strongly recommends EBF without any additional food or water. The WHO also suggests providing complementary diet at 6 months along with breast milk and sustaining breast feeding until the age of 2 years. However, whether an infant is breastfed or formula fed depends on several factors like social, psychological, and environmental scenarios.

Despite several efforts made for EBF up to six months, in our study, 42% of the mothers were still not following EBF up to six months. The mean duration of EBF was 4.52 months which is much lower than the findings reported by Chudsama et al. [5]. Infants not exclusively breast fed up to six months are at risk of higher occurrence of associated infections, malnutrition deficiencies, and under-development [10, 11]. Most of the recent studies regarding EBF come out with the similar fact that the practice of EBF tends to decline and highlight the tremendous progress in the marketing of industrial milk products as well as the lack of awareness of this serious issue among mothers.

□□□□□□□□□□□ □□□□□□□□□□□□d □□□□□□□□□□□□□□□□□□□□ □□□□□□□□□□□□□□□□□□□□ □r □□□□□□□□□d □□□□□

A significantly lower prevalence of EBF was observed among mothers with lower socio-economic status, which is controversial with the result obtained from an Ethiopian demographic health survey that explained a declining trend of EBF with the higher maternal educational and socio-economic

status [12]. Furthermore, our study found that the duration of EBF was significantly lower among mothers with lower socio-economic status. The findings of our study clearly acknowledge socio-economic status of the household as a major influencing factor for longer breastfeeding practice among mothers in a higher income bracket. In addition, we have also observed a significant association between the perception of low breast milk and lower socio-economic status. The findings clearly suggest that interventions should be tailored to target women with lower socio-economic status.

[illegible]

It was observed that age of the mother is a predictor of EBF. The mean duration of EBF was significantly lower in the age group of mothers with 15-24 years. The findings suggest that more efforts are needed to create awareness about the need for EBF in younger aged mothers.

Education and occupation of the parent's and its [illegible]

We could not find statistical significance between the father's education and increased prevalence of EBF in the multivariate analysis though we observed a statistical significance in the univariate analysis. Maternal educational status was also found statistically not significant with EBF, which is a controversial observation with the findings of the Ethiopian demographic health survey which indicated a declining trend of EBF practices with higher maternal educational status but supports the findings observed by Tesfaye Setegn et al. [10].

[illegible]

The findings clearly indicate that the interventions related to EBF up to six months of age should be targeted to women in the lower socio-economic status and at younger ages.

[illegible]

Our study relies on retrospective reporting, which may result in inaccurate recall and this can be point out as a major limitation. However, most of the recent literature also followed the similar maternal recall mode for elucidating breast-feeding practices. Since this was a hospital-based study, the study population was representative of generally higher socio-economic status and which also reflects as a limitation of our work. A community-based cross-sectional study with a large sample size can provide more light in this field. Despite these limitations, the study has several strengths. We have elicited a large number of demographic and clinical data which can influence the association of duration of EBF. The same interviewer collected all information which reduces the inter observer bias. Advanced statistical methods were employed to analyse the association of socio-demographic and clinical correlates with EBF.

[illegible]

Our results can help to create more awareness about the need for EBF in the younger age group and the mothers in lower socio-economic status.

[illegible]

To the best of our knowledge, not many studies were conducted in Tamil Nadu to examine the socio-demographic and clinical correlates of exclusive breastfeeding. Results of this study indicate a need to create awareness to mothers regarding the need of providing EBF to infants up to six months of age.

[illegible]

India has undergone a rapid transition. Contradictory to our expectations, higher socio-economic status mothers are now aware about the need for EBF. More efforts are needed for those mothers in lower socio-economic status and those at younger ages. Secondly, apart from mother's education, father's education also plays a great role in breast feeding practices. In conclusion, it was observed that lower socio-economic status and young age of the mother have negative impact on EBF for six months of age.

A Prospective Cohort Study on the Safety of Infant Pentavalent (DTwP-HBV-Hib) and Oral Polio Vaccines in Two South Indian Districts

Narendra Kumar Arora, MD, MMSc, Manoja Kumar Das, MD*, Ramesh Poluru, PhD*, Neeraj Kumar Kashyap, BIT*, Thomas Mathew, MD†, John Mathai, MD‡, Mahesh Kumar Aggarwal, MD§, Pradeep Haldar, MD§, Thomas Verstraeten, MD¶, Patrick L. F. Zuber, MD,‖ and the INCLEN Vaccine Safety Study Group***

Downloaded from https://journals.lww.com/pidj by BhDMf5ePHKav1zEoum1tQfN4a+kJLhEZgbsIHo4XMi0hCywCX1AWnYQp/IlQrHD3i3eAOwX5PbTbYmFBuQ8ZexGG8dZY9KxlZfeZ7JyEY0w= on 04/18/2020

Background: Safety of pentavalent (DTwP-HBV-Hib) vaccine has been a public concern in India and other countries. This study attempted to document the association of serious adverse events following immunization (AEFI, including hospitalizations and deaths of all causes) with the 3 doses of pentavalent and oral poliovirus (OPV) vaccines.

Methods: A cohort of 30,688 infants in 2 south Indian districts were enrolled and followed-up between October 2014 and May 2016, following their first vaccination with DTwP-HBV-Hib and OPV at public health facilities. During weekly follow-ups, by telephone or home visits, the serious AEFIs (hospitalizations and deaths) occurring any time after each vaccination until 4 weeks after third dose were documented. The incidence risk ratios (IRRs) of serious AEFIs in the first (days 0–6) and fourth weeks (days 21–27) after the vaccine doses were compared using the poisson regression analysis.

Results: Of the 30,688 infants enrolled, 30,208 received their third doses of vaccines. During the 4-week periods following each vaccination, there were 365 hospitalizations and 17 deaths. Adjusted incidence risk ratio of 3 doses combined for post-vaccination serious AEFIs during the first week compared with fourth week was 0.8 [95% confidence interval: 0.6–1.0].

Conclusions: There was no increased risk of a serious AEFIs during the first week after any of the 3 doses of pentavalent and OPV vaccination compared with the fourth week. In the absence of any temporal clustering, mortality and hospitalization rates observed in vaccinated infants probably reflects the natural occurrence of such events.

Key Words: pentavalent vaccine, oral polio vaccine, vaccine safety, serious adverse events, hospitalization, death

(*Pediatr Infect Dis J* 2020;39:389–396)

Vaccination has been one of the major success stories in global health, leading to the eradication of deadly diseases like smallpox and possibly the virtual disappearance of some diseases from several regions.[1] Over the last 25 years, effective vaccination programs have resulted in a >90% decrease in the global disease burdens for diphtheria, pertussis, and tetanus, including India.[2–4] However, in spite of the extensive evidence of their benefits, concerns and controversies about the value and safety of vaccines continue to impact adversely their acceptance in diverse contexts. Public concerns over reports linking autism with measles, mumps, and rubella vaccine in the United Kingdom had negative impact on vaccine coverage causing several disease outbreaks,[5] which spread to other countries, such as the United States, France, Italy, and the Netherlands.[6–9] This misinformation has spread globally. The rumor mongering through social media considerably affected vaccine coverage during the MR campaigns in south India.[10] The growing global challenge of vaccine hesitancy relates largely to vaccine safety concerns, leading to public confidence erosion, which in turn dampens the vaccine coverage.[11] The Global Advisory Committee on Vaccine Safety emphasized the need for thorough investigation and causality assessment of serious adverse events following immunization (AEFI) as a quality assurance mechanism for immunization programs.[12]

The decreased disease burdens in the developed countries have largely been due to the successful implementation of immunization programs using multivalent combination vaccines. The vaccines against diphtheria, tetanus, and pertussis combined (DTwP) are in use for several decades under universal immunization program. Recently the HBV and *Haemophilus influenza* type b (Hib) have been added to DTwP, known as the pentavalent (DTwP-HBV-Hib) vaccine. Over the past 15 years Global Alliance for Vaccines and Immunizations has supported the introduction of pentavalent vaccine in developing countries for protection against invasive Hib disease in universal immunization program.[13] However, there were temporary interruptions and introduction delays in Sri Lanka,

Bhutan, Vietnam[14] and Pakistan[15] during 2011–2016 due to reports of hospitalizations and deaths following vaccination after national launch of the pentavalent vaccine. Temporal association of vaccinations and sudden infant death syndrome (SIDS) has been the subject of extensive speculation, despite several studies having refuted any causal association,[16–18] particularly after the diphtheria-pertussis-tetanus immunization.[19]

In India, the reports of 32 infant deaths following the pentavalent vaccination as part of the national AEFI surveillance between 2011 and 2013 raised concerns, although no causal association could be identified.[20] Some professionals and civil society groups, however, appealed before the Supreme Court of India to ban the pentavalent vaccine.[21,22] Although the safety of pentavalent vaccine has been documented in the pre-licensure studies,[23,24] these studies were too small to identify rare adverse events. Thus, it was deemed necessary to carry out further investigations on this issue. This study was designed in consultation with all key stakeholders including the Ministry of Health and Family Welfare, Government of India and WHO (advised by Global Advisory Committee on Vaccine Safety), to assess the risk of serious AEFIs (hospitalizations and deaths) following pentavalent vaccination in an infant cohort from 2 Indian states, where pentavalent vaccine was first introduced.

MATERIALS AND METHODS

The pentavalent vaccine (manufactured by Serum Institute of India Ltd., Pune, India) was first introduced in the states of Kerala and Tamil Nadu in December 2011 with a 6, 10 and 14 weeks schedule for 3 primary doses. Both states have efficient health systems with high vaccination coverage[25] and low infant-mortality rates (IMR): 12 and 21 per 1000 live births in 2013 in Kerala and Tamil Nadu, respectively, compared with an overall IMR of 40 across India.[26] This study was conducted in 2 districts, Kollam (Kerala State) and Coimbatore (Tamil Nadu State).

Study Design

This prospective self-controlled cohort study enrolled infants who received their first dose of pentavalent and oral poliovirus (OPV) vaccine from the public health system between October 2014 and November 2015 in Kollam district, and between May 2015 and February 2016 in Coimbatore district.

Recruitment and Data Collection

Infants who received their first dose of pentavalent and OPV vaccines at all public health facilities in the 2 districts (District, Special and Taluk Hospitals, Community Health Centers, Primary Health Centers, Sub-centers) and out-reach points of rural and urban areas were traced based on the contact details recorded in the immunization registers. Home visits were made to confirm eligibility (received first dose of vaccine, expected to stay in the district for the 6 months follow-up period and contactable by telephone/mobile) and to enroll infants after obtaining informed written consent. Data on maternal care, infant gender, date of birth, birth weight, pregnancy-related and neonatal illnesses were collected at enrollment. The parent(s) were contacted weekly by telephone or home visit to document the health of the infant including any illness, hospitalization or death. The follow-up contact was continued even if the second and third vaccine doses were delayed due to any reason. Study staff confirmed receipt of the second and third vaccine doses from the vaccination card and the health facility register. If infants received their second and third vaccine doses at private facilities, a copy of the vaccination card was collected as proof of date of exposure. For each dose, the vaccine batch number, date and place of administration was documented. Recruited infants were followed up to 4 weeks after the third dose of the vaccines or death, whichever was earlier. Data were collected on tablets using a customized program developed with open source platforms (Android, PHP and MySQL version 5.1) and data including other materials uploaded, synchronized in the server and stored/deposited in a central data repository. An independent International Advisory Group (IAG) with vaccine safety experts and Brighton Collaboration representation supervised the study implementation including field visits. The IAG reanalyzed the data for validation.

Outcomes

This study captured the serious AEFIs which included both hospitalizations and deaths due to any cause during the follow-up period. The details about the events such as clinical features, diagnosis, treatment, period and place of hospitalization were captured. For hospitalizations, the study team visited the hospital for confirmation and followed till outcome to document the information. Hospitalization episodes of at least 24-hours as inpatient were further categorized as "appropriate," "inappropriate" and "indeterminate" using the Pediatric Appropriateness Evaluation Protocol–India criteria. The PAEP-India tool for child and newborn were adapted from the available tools and validated in hospitalized patients from multiple hospitals in India.[27] Each case was assessed by 2 independent pediatricians using the PAEP-India tool for child and categorized the case based on checklist criteria. A third pediatrician was consulted in cases of mismatch between the 2 reviewers. For deaths, the study confirmed the event by home visit, followed by verbal autopsy by senior investigator 4 weeks later. Causes of death were determined independently by 3 pediatricians trained in review of verbal autopsies and also referred to available hospital records.

Data Analysis

The 4 weeks following every dose of vaccination were considered to be the observation period with weekly intervals post-vaccination as separate risk periods (Figure, Supplemental Digital Content 1, http://links.lww.com/INF/D758). As almost all the serious AEFI (deaths and hospitalizations) reported in the passive national AEFI surveillance program occurred during the first week after any vaccine dose, the first week was considered as the high-risk period and the fourth week as the comparison period. It was hypothesized that, the risks of serious AEFI due to any cause, during the first and fourth weeks post-vaccination remain similar for each dose of the vaccines.

Person-time of observation was calculated based on the time from vaccine administration and the date of occurrence of an event, the date of administration of the next vaccine dose (if <28 days), the last contact date (if lost to follow-up), date of death or the first 28 days after vaccination when the next dose was delayed, according to the recommended schedule, whichever came first. Follow-up was defined by weekly risk windows after each vaccine dose split into first (0–6 days), second (7–13 days), third (14–20 days) and fourth (21–27 days) weeks. If a subsequent dose was given before the end of the fourth week, the follow-up time was censored and follow-up period was assigned to the subsequent dose. If the next dose was delayed, the person-time beyond 27 days after each dose were excluded from the analysis. Poisson regression analysis was used to estimate the incidence rates (IRs) and incidence rate ratios (IRRs) for serious AEFIs (hospitalization and all-cause deaths) during the 4-consecutive weekly risk periods after each dose separately and for all 3-doses combined. IRs were calculated by dividing the number of events by the corresponding person-time denominator and IRRs were calculated by dividing the IR in the risk period of interest by the IR in the fourth week. In a multivariate model, the IRR

© 2020 The Author(s). Published by Wolters Kluwer Health, Inc.

was adjusted for age at start of risk period (continuous, in days) and seasonality (quarterly; January–March, April–June, July–September, and October–December). To assess the potential of healthy vaccinee bias, we performed a sensitivity analysis to compare the risks in the first week after vaccination following the second and third doses with the risks in the fourth weeks of the preceding doses. All statistical analyses were performed using Stata version 15.0 (StataCorp LLC, TX). In addition, all deaths documented were reviewed by the national AEFI committee for causality assessment according to WHO published methodology.[20]

Sample Size

Considering the IMR in the study states to be 12–21 per 1000 live births and a neonatal mortality rate (0–28 days) of 6–15 per 1000 live births,[26] the post-neonatal mortality (29–365 days) was expected to be 6 per 1000 live births. This translated to ~0.125 infant deaths per 1000 live births per week. As there was no information about the hospitalization:death ratio in this age group from India, we assumed that for every infant death there would be ~4 hospitalizations. The required sample size was 27,422 infants to detect an IRR for hospitalizations and or deaths of 1.8 in the analyses pooling the different doses, assuming a 5% significance level ($\alpha = 0.05$) and 80% power ($\beta = 0.2$).[28] With the available sample (30,688), the observed results show that between the risk periods, we are able to detect a risk-ratio of 2.5 and 1.5 (at a 5% significance level and 80% power) of serious AEFIs (hospitalization and deaths), for individual doses and all 3-doses combined, respectively.

Ethical Approvals

The study protocol and related documents were approved by ethics committees of participating institutes. The infants were recruited after obtaining informed written consent from parents or legally authorized representatives. The study protocol and related documents were approved by Institute Ethics committees at The INCLEN Trust International (INCLEN) (vide IIEC-021 dated October 14, 2013), Government Medical College, Thiruvananthapuram (vide 01/01/2014 dated January 17, 2014), PSG Institute of Medical Sciences and Research, Coimbatore (vide 13/351 dated March 5, 2014) and World Health organization, Geneva (vide RPC625 dated January 22, 2014).

RESULTS

During the study period, 34,914 infants received their first dose of pentavalent and OPV vaccines at the public health facilities. Of these, 1377 (3.9%) infants could not be traced, 2818 (8.1%) were not eligible (1287 were not staying in the district for 6 months, and 1531 were from other districts) and consent was refused for 31 (0.1%) infants. Of the 30,688 infants recruited, 30,208 (98.4%) received their third vaccine dose and 29,728 (96.9%) completed the scheduled follow-up (Fig. 1). Of 479,523 scheduled weekly follow-up contacts (including the contacts during the intervals between the different vaccine doses till completion of 4 weeks after third dose), 89.9% were completed with averages of 4.4 (dose 1), 4.8 (dose 2) and 4.9 (dose 3) contacts for the vaccine doses (data not shown).

Baseline characteristics of the cohort are summarized in Table 1. No age or sex differences were observed across the districts. The Kollam population had a higher proportion of low and median socio-economic status and joint or extended families. Median ages of infants were 48, 83 and 118 days at the times of the first, second and third vaccine doses, respectively. A total of 622 hospitalizations and 32 deaths were documented during the follow-up period.

Within the 4 weeks after the 3 vaccine doses (per protocol study risk periods), a total of 365 hospitalizations (120, 137 and 108 after doses 1, 2 and 3, respectively) were documented. Of these 365 hospitalizations, 288 were classified as appropriate (96, 106 and 86 after doses 1, 2 and 3, respectively). A total of 257 hospitalizations (92, 136 and 29 after doses 1, 2 and 3, respectively) occurred after fourth weeks of the first and second doses of vaccination (Fig. 1). Pneumonia/acute respiratory infection (70.1%) was the leading cause followed by diarrhea (6.4%), fever (4.3%) and urinary tract diseases (3.1%) during the 4 week and post-4 week periods after the vaccine doses (Table, Supplemental Digital Content 2, http://links.lww.com/INF/D759).

Of the 32 total deaths observed, 17 deaths (8,7 and 2 after doses 1, 2 and 3, respectively) occurred within 4 weeks after 3 vaccine doses, while 15 deaths (11, 3 and 1 after doses 1, 2 and 3, respectively) occurred during post-4 weeks period, (Fig. 1). The leading causes of death included infections (31.3%), congenital malformations (28.1%), congenital heart diseases with infections (15.6%), SIDS (15.6%) and other causes (9.4%) (Table, Supplemental Digital Content 2, http://links.lww.com/INF/D759). Almost all congenital malformations were diagnosed prior to death. The SIDS was made based on Brighton Collaboration Criteria.[29] Causality assessment by the National AEFI committee classified all deaths as coincidental. Differentials in causes of hospitalization and death during the first 4-weeks (0–27 days) and post-4 weeks (28+ days) after vaccination were small (Table, Supplemental Digital Content 2, http://links.lww.com/INF/D759). Figures 2 and 3 show the IRs of serious AEFIs (hospitalization and deaths) by age and seasonality. Higher serious AEFI (hospitalization and deaths) rates were observed during 91 and 146 days of age (Fig. 2); between October and December, with a peak in December due to higher prevalence of respiratory illnesses (Fig. 3).

Serious AEFIs (Hospitalization and Deaths) Within 4 Risk-periods

The occurrence of serious AEFIs (hospitalization and deaths) across the risk-periods for the 3 doses are summarized in Table 2. Within the 4 weeks after the 3 vaccine doses, a total of 375 serious AEFIs (365 hospitalizations, 17 deaths and 7 hospitalization and deaths) occurred (125, 140 and 110 after doses 1, 2 and 3, respectively) (Fig. 1). For all-3 doses combined, the adjusted IRRs of serious AEFIs within the first week compared with the fourth week were 0.8 [95% confidence interval, (CI): 0.6–1.0]. Compared with the fourth week, the adjusted IRRs of serious AEFIs for the first week after first, second and third doses were 1.2 (95% CI: 0.8–1.9), 0.9 (95% CI: 0.6–1.5) and 0.5 (95% CI: 0.3–0.9), respectively. IRRs for serious AEFIs were not significantly higher in any of the other risk periods (second or third weeks) either for the 3 doses separately or for all doses pooled. Analyses of hospitalizations according to appropriateness did not show any increased risk in any week compared with the fourth week after any dose (Tables, Supplemental Digital Content 3, http://links.lww.com/INF/D760, and Supplemental Digital Content 4, http://links.lww.com/INF/D761). The sensitivity analysis comparing the rates of serious AEFI in the first week after the second or third doses with the fourth week after the first or second doses did not show any differences, suggesting the absence of a healthy vaccinee effect (Table 2).

DISCUSSION

This is the first large study to examine the association between administration of routine infant pentavalent and OPV vaccines and serious AEFIs (all-cause hospitalizations and/or deaths) in India, using a self-controlled prospective cohort design. We have shown that the unadjusted and adjusted risks of hospitalizations

*Total includes a small number of cases information missing for type of family, standard of living index (2 each in Kollam); Age of mother (20 in Kollam and 12 in Coimbatore); education of mother (14 in Kollam and 6 in Coimbatore); education of father (36 in Kollam and 16 in Coimbatore) and birth order (53 in Kollam and 40 in Coimbatore, respectively). Standard of living index (a proxy to household socio-economic status), constructed based on household assets and durable goods.

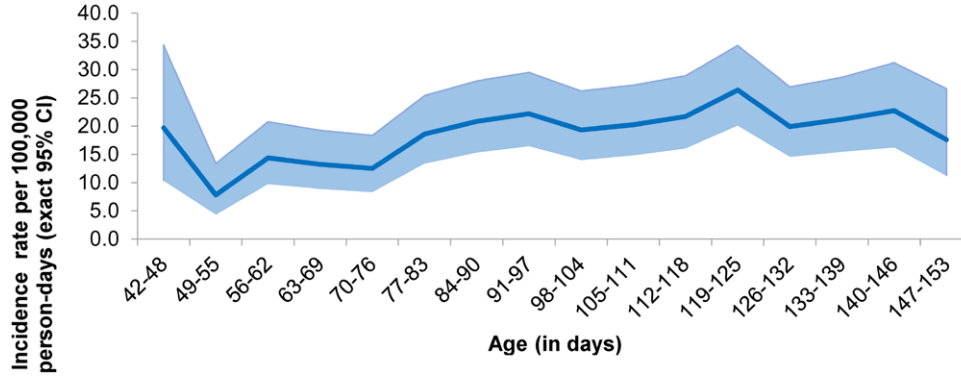

FIGURE 2. Serious AEFI (hospitalization and all-cause deaths) incidence rates (per 100,000 person-days with exact 95% CI as shaded area) by age (independent of vaccination windows). Incidence per 100,000 person-days (with exact 95% CI as shaded area); Week defined as 6-days period, starting on day-0; Person-time starts from age at first dose of vaccination and duration until the first and last day of the age period or until the Serious AEFI (hospitalization/death) events (succeeding vaccinations not considered). The hospitalization incidence presented in the figure is between 42 and 153 days of age, where 98.6% [(3,402,860/3,451,027)*100] of follow-up calls/visits were made. full color online

and deaths after any of the 3 scheduled doses of routine vaccines were similar during the first and fourth weeks post-vaccination, for either each dose separately, or all doses combined. Due to low death rates,we could not perform analyses for each individual dose but the combined analysis and analyzing the first dose only did not indicate any death clusters following vaccination.

In a highly immunized population, self-controlled study designs with defined risk windows for outcome assessment are best suited to assess possible effects during a specific time period as they are not susceptible to control selection.[30] Activation of the immune response to different vaccines occurs at different time points according to the nature of the antigen.[18,31–34] Hence, in the current study, we considered the first week after vaccination to represent the period of highest risk and the fourth week to be the comparison period. The findings of our study refute the concern of an association between serious adverse events and the pentavalent vaccine.

*Risk period corresponds to date of hospitalization (considered as at least 24-hours stay in the hospital) or all-cause death after administration of vaccination (in days); The day of vaccination defined as day-0.

†Adjusted for seasonality (January–March, April–June, July–September, October–December); age at start of risk period (in days), using Poisson regression model.

‡Twenty-one to 27 days as reference category; IR: Number of events per 100,000 person-days of follow-time, calculated as the ratio of the hospitalizations of the person-time at risk.

The main strength of the study is the representativeness of the study cohort with respect to the population in the study area due to the high rates of participation and completion of follow-up. The socioeconomic status of the population enrolled in the study was highly representative of the overall population in the 2 districts. Use of electronic data collection enabled timely follow-up and accurate data capture with real-time monitoring. Documentation of hospitalization from both participants and hospitals allowed confirmation of causes of hospitalizations and deaths. In addition, the availability of source documents and vaccination records ensured accurate confirmation of vaccine exposure.

The main limitation was possible selection bias, as infants received first vaccine dose in the private system were not represented in the study. However, according to recent National Family Health Survey (NFHS-4, 2015–2016) data, 78% and 86% of children 12–23 months of age in Kerala and Tamil Nadu, received their vaccines from a public health facility.[25] We could not trace 3.9% infants due to inaccurate address information and 8.1% could not

© 2020 The Author(s). Published by Wolters Kluwer Health, Inc.

be included due to moving out or residing outside of the 2 districts. To control for confounding by contraindication to vaccination, pre-vaccination time intervals were not included in the control periods in the main analysis. Sensitivity analyses performed to assess the potential of a healthy vaccinee bias did not suggest presence of this. The study was also limited in detecting small changes for deaths, despite the large sample size.

The study found that 128 serious adverse events (120 hospitalizations and 8 deaths) occurred among 30,000 infants during the 4 weeks after receiving their first dose of pentavalent vaccine. Calculating based on Black et al[35] and projected on a 26 million annual Indian birth cohort, it is estimated that with national coverage of 100% at a minimum 26,500 infants per year will suffer a serious health event within 1 week of receiving their first dose of pentavalent vaccine, or there will be at least 21,200 events with the current 3-dose coverage of ~80% for pentavalent vaccine. These events reflect prevailing morbidities and mortality that would have occurred regardless of vaccination as documented in 2 Indian districts with low infant mortality. Investigating these events to ensure that the vaccine product or its administration are safe remains a fundamental function of the vaccine pharmacovigilance system. This highlights the importance of continued monitoring of common serious health problems in the infant population to measure the health burden and provide new epidemiologic information on the true causes of morbidity and mortality in this group.

The study did not find any increased risk of serious AEFIs (all-cause hospitalizations or deaths) in the first week following pentavalent (and OPV) vaccination and the occurrence of these AEFIs were just coincidental. That is, in the absence of temporal clustering, mortality and hospitalization rates observed in vaccinated children reflect the natural occurrence of such events in that age range in this part of India. The study findings should help to address the vaccine safety concerns and controversies around the pentavalent vaccine in India and other low- and middle-income countries, and so boost public confidence in the program. Suspicion about a possible relationship between the vaccination and serious AEFIs among parents, communities and the health providers may not only threaten the success of immunization programs but also potentially hinder introduction of newer vaccines.

CONCLUSIONS

Close monitoring of over 30,000 infants during and after receiving their first 3 doses of DTwP-HBV-Hib and OPV did not identify any relationship between the vaccinations and the occurrence of serious AEFIs (hospitalization and/or death). The study did document the huge number of serious coincidental events that can be expected even when vaccines are properly administered. In view of the recent inclusion of several new vaccines into the immunization program in India, the findings of this study will be very useful in addressing vaccine hesitancy and safety concerns to increase public acceptance and coverage.

ACKNOWLEDGEMENTS

We express our gratitude to the district health officials and health functionaries at the public health facilities in the 2 districts for their constant support. We are highly appreciative of the parents and families of all infants for consenting to participate in this study and for their cooperation during follow-up. We thank the GAVI, the Vaccine Alliance through World Health Organization (WHO) and the patronage from Ministry of Health and Family Welfare, Government of India, New Delhi, India and the Departments of Health and Family Welfare, Government of Kerala and Tamil Nadu States for funding to conduct the study. We also acknowledge the guidance and continued support provided by the technical experts and representatives from WHO, Technical Advisory Group (TAG) members, International Advisory Group (IAG) members, officials from the Ministry of Health and Family Welfare at National and State levels. We appreciate the support from Tom Cattaert and Germano Ferreira, P95 Pharmacovigilance and Epidemiology, Heverlee, Belgium, for the validation of results, and Keith Veitch (keithveitch communication) for editorial guidance.

Abstract

Background: Congenital hypothyroidism is one of the most common preventable causes of mental retardation. The incidence and etiology of congenital hypothyroidism varies significantly across the globe.

Methods: In this retrospective observational study we aimed to find out the incidence and etiology of congenital hypothyroidism identified by neonatal screening program. We included all neonates who had their thyroid stimulating hormone screening done in a tertiary care hospital of South India between January 2014 and June 2020 and were diagnosed as a case of congenital hypothyroidism. The growth patterns, clinical features, thyroxine dose requirement during follow-up were also studied.

Results: There were 23 babies diagnosed with congenital hypothyroidism during the study period. The incidence rate was 1 in 917 live births for inborn babies, and dyshormogenesis (60%) was the most common etiology. Two babies had clinical features associated with congenital hypothyroidism. None of the babies had clinical features of congenital hypothyroidism during follow-up and their growth & development were normal for age. Babies who required dose increments of thyroxine supplement turned out to be permanent congenital hypothyroidism.

Conclusions: Incidence of congenital hypothyroidism was high in our population. Dyshormogenesis was the most common etiology. Majority of congenital hypothyroidism babies were asymptomatic at diagnosis, so screening is a vital tool for early diagnosis. Babies who required thyroxine dose increment with age tend to be permanent congenital hypothyroidism.

Keywords: Congenital hypothyroidism, Thyroid dyshormogenesis, Thyroid dysgenesis, Dose increments, Newborn screening

Introduction

Congenital hypothyroidism (CH) is an important cause of mental retardation in children.[1] With the introduction of newborn screening, most of the babies with CH are being diagnosed during the neonatal period even before the onset of symptoms. The most commonly used screening protocol is serum thyroid stimulating hormone (TSH) measurement owing to its superior sensitivity and specificity. With the increasing neonatal screening coverage all over the world, the incidence of CH is also increasing.[2]

The incidence rate of CH varies by geographic location and ethnicity.[3] There is also significant difference in the etiology of CH based on the population being studied. Our country being a mixed population with lot of inbreeding, it will be useful if the local incidence of CH and its etiology is known for better management.

Methods

We conducted this retrospective study in a tertiary level neonatal unit at PSG institute of medical science and research hospital, Coimbatore in South India. The primary

objective of the study was to find out the incidence and etiology of CH identified through newborn screening program. Our secondary objective was to follow-up the growth & development and to find out whether the dose requirement of thyroxine in these babies during follow-up can help us to differentiate permanent from transient CH cases. The study was approved by hospital ethical committee. All neonates (<30 days of life) from January 2014 to June 2020 (78 months) for whom TSH screening was done in the hospital were included in the study. We had excluded babies who were diagnosed and referred as a case of CH from other hospitals.

Serum TSH was used as screening tool for congenital hypothyroidism, which is measured by taking a venous blood, usually around 72 hours of life. In case of early discharge, samples were taken prior to discharge. Serum TSH, free T4 (fT4) and free T3 (fT3) were measured in hospital's biochemistry laboratory using sandwich electroluminescence immunoassay using cobas e601 (Roche Ltd). All neonates with TSH values <10 mIU/L were considered screen negative. If the initial TSH screening value was in the range of 10-39 mIU/L, then TSH value was repeated at around 14 days of age. All babies with serum TSH ≥40 mIU/L at any time or ≥10 mIU/L on two occasions were considered screen positive. Babies with very high TSH values were given a value of >100 mIU/L by the hospital biochemistry lab instead of absolute value.

All screen positive cases were evaluated with thyroid hormone profile, ultrasound (USG) thyroid and technetium (Tc-99m) pertechnetate thyroid scintigraphy. Etiological diagnosis was primarily based on scintigraphy results. If it shows increased tracer uptake, then it was considered to suggest organification defect and a diagnosis of dyshormogenesis was made. If there was ectopic tracer uptake, then ectopic thyroid was diagnosed and if no tracer uptake was seen then agenesis was considered. If only USG thyroid report was available, etiology of dyshormogenesis was made if the gland was present and dysgenesis was considered if it was absent. Treatment with levothyroxine was started as early as possible after evaluation. During follow-up, growth and development of these babies were monitored using World Health Organization (WHO) growth charts and Trivandrum development screening chart respectively.

Babies with CH were identified by scrutinizing the screen positive babies' case records from the medical records department. The clinical, demographic and laboratory data of these babies were obtained from the hospital's computerized database and baby's case records. Few babies had some data missing which were obtained through telephonic conversation with the parents. The follow up data including growth & development, clinical features of CH, TSH & fT4 values, the dose adjustments of thyroxine were all collected.

Data were entered in Microsoft excel and analyzed by Epi Info™ software. Results were presented as mean±SD or median with IQR for continuous variables and as percentage for discrete variables.

Results

A total of 19282 babies were born during the study period of 78 months, among them 18349 babies (95%) had their TSH screening done and 20 babies were diagnosed as CH giving an incidence rate of 1 in 917 live births. Among the 133 out-born neonates screened in our hospital, three babies were diagnosed as CH. Thus 23 babies were diagnosed as CH overall. The baseline characteristics of these babies are given in table 1.

Table 1: Baseline characteristics of the babies diagnosed with CH

Characteristics	Value
Male:Female	1:1.6
Consanguinity	3 (2,4)
Gestational age (weeks)	38.3±1.6
Birth weight (grams)	2969±449
Mode of delivery	n (%)
Vaginal	15 (65)
Caesarean	8 (35)
Family history of CH	3 (2,4)
Clinical features suggestive of CH	4 (17)
Cord TSH >200 mIU/L	3 (13)

GA – Gestational age; LBW- Low birth weight.

The clinical features, thyroid function test values, USG thyroid and Tc99 radio nucleotide isotope scan reports at diagnosis are provided (table 2). Two babies had clinical features associated with CH at presentation. One baby had Down syndrome and the other presented with delayed passage of meconium. In two babies USG thyroid report showed gland in situ but did not have scintigraphy report available and an etiological diagnosis of dyshormogenesis was made. A total of twenty babies had the etiology of CH available and among them more than half of the babies (60%) were diagnosed with dyshormogenesis. Among the babies with thyroid dysgenesis (40%), ectopic thyroid was the most common etiology and all ectopic thyroids were lingual thyroid.

Only seventeen babies had both etiological diagnosis and complete follow-up details (table 3) and among them none of the babies had any growth or developmental abnormalities. More than half of these babies (59%) did not require dose increment during follow-up and among them dyshormogenesis (90%) was the most common etiology. Those babies who required dose increments during follow-up (41%) had dysgenesis as the most common etiology (72%). Among those babies who had crossed three years of age (n=8), the thyroxine

supplements were stopped in four babies and all of them had dyshormogenesis as the etiology of CH.

Table 2: Clinical, biochemical and radiological profile of the babies with congenital hypothyroidism

Serum TSH level at diagnosis (μIU/ml)	>100		14 (61)
	40-100		4 (17)
	10-39		5 (22)
Mean serum TSH level at 21 days of life (μIU/ml)			1.1±0.6
Mean serum TSH level at 1 year of life (μIU/ml)			2.25±0.89
Goitre on USG	Absent		3 (38)
	Present		5 (63)
Tc99 scan findings	Dyshormogenesis		10 (56)
	Dysgenesis (n=8)	Agenesis	3 (17%)
		Lingual thyroid	5 (28%)
Clinical features at diagnosis	Asymptomatic		21 (91)
	delayed passage of meconium		1 (5)
	down syndrome		1 (5)

Table 3: Thyroxine dose requirement during follow-up and its association with aetiology of congenital hypothyroidism

Thyroxine dose requirement at 3 years of age	Not required dose increment (n=10)	Dyshormogenesis	9 (90)
		Dysgenesis	1 (10)
	Dose increment at least once during follow-up (n=7)	Dyshormogenesis	2 (28)
		Dysgenesis	5 (72)
Thyroxine supplements stopped at 3 years of age	Successfully stopped treatment (n=4/8)	Dyshormogenesis	4 (100)
		Dysgenesis	0
	Continued treatment (n=4/8)	Dyshormogenesis	1 (25)
		Dysgenesis	3 (75)

Discussion

In our study, the incidence of CH was 1 in 917 and dyshormogenesis was the commonest cause. Several studies have arrived at a different incidence rate for CH. In the study conducted in United States by Waller et al,4 non-Hispanic Black had lower incidence (1 in 11494) while Asian had the higher incidence (1 in 2506) of congenital hypothyroidism. Similar difference among ethnic groups were obtained in other studies.[5,6] In the study done by Arasar Seeralar et al in Chennai, the incidence rate of CH was 1.7 in 1000.[7] Similar high incidence rates were reported in other Indian studies done in different parts of the country.[8,9] High incidence rate found in population of Iran was attributed to a closed community with high inbreeding rate.[10] In India too this could be the reason for higher incidence due to marriage within the caste/community leading to inbreeding.

This study showed that, dyshormogenesis (60%) was the most common etiology of CH in our population. On the contrary, in most of the studies done in other parts of the world, dysgenesis contributed to more than 80% of the CH cases.[11] Since most of the cases of dyshormogenesis are inherited conditions, the high incidence is expected in a closed community like our population. Among those with dysgenesis, almost two third of the babies were diagnosed as Lingual thyroid, similar to the finding reported by Castanet et al.[12] This is in contrast to the study by Devi Dayal et al, where agenesis was reported more common than ectopia.[13]

Considering the clinical features at diagnosis, most of the babies were asymptomatic (91%) underscoring the importance of screening. Two babies had clinical features associated with CH, one with delayed passage of meconium and the other had Down syndrome. Though there were three babies who had neonatal jaundice requiring treatment with phototherapy, none had prolonged jaundice which is classically described in CH. Except these two babies, rest of them would have been missed otherwise and could have potentially ended up with morbidity without the screening process.

Among the babies who required thyroxine dose increment (41%) during the follow-up, dysgenesis (72%) was the most common etiology and these babies are likely to require lifelong thyroxine supplements. In those babies where thyroxine dose requirement did not increase with age (59%), dyshormogenesis (90%) was the most common etiology. All the babies in whom the thyroxine supplements were successfully stopped at 3 years of age belonged to this group. This shows that babies who don't require dose increment turn out to be transient CH and tend to be having dyshormogenesis. A similar finding was arrived in other studies where permanent CH had increased dose requirement as age increases compared to transient CH.[14,15] In our study, the etiological diagnosis of dyshormogenesis were made based on increased iodine trapping seen in the radionucleotide studies but confirmation with genetic studies could not be done. The fallacy of this approach is that there are several causes of transient CH which presents with increased thyroid trapping by scintigraphy at diagnosis. These include maternal iodine deficiency, transient dyshormogenesis due to haplodeficiency mutation affecting DUOX2 and DUOXA2 and other genes.[16-18] In developing country like

India where nutritional deficiency is very common, one can expect that a significant proportion of these babies with increased iodine trapping in radionucleotide scintigraphy may actually be having transient CH due to maternal iodine deficiency. One baby diagnosed as agenesis by scintigraphy (USG thyroid not available) had decreased dose requirement as age increased which is not expected in a case of true agenesis. The baby's mother was diagnosed as Hashimoto's thyroiditis since her adolescence. So the initial scintigraphy finding was likely due to the TSH blocking effect of trans placentally transferred maternal antibodies.[19] So in resource limited settings where genetic diagnosis could not be done, USG thyroid along with radio isotope scan will give a reliable etiological diagnosis as compared to either of it done alone.

□□□□□□□□□□

To conclude, the incidence of CH in our population was 1 in 917 live births. The most common etiology was dyshormogenesis followed by dysgenesis. Almost all the babies with CH were asymptomatic during neonatal period which makes screening a vital tool for diagnosis. Those babies who required increment in thyroxine dose as age increases tend to be permanent CH.

SCIENTIFIC LETTER

Serum Thyroid Stimulating Hormone Screening and Influence of Perinatal Factors

Sudhakar Palanisamy[1] · Ramesh Srinivasan[1] · Suvetha Kannappan[2] · JayaChandran Ganesan[3]

Received: 17 January 2020 / Accepted: 15 January 2021
© Dr. K C Chaudhuri Foundation 2021

To the Editor: Congenital hypothyroidism (CH) screening using thyroid stimulating hormone (TSH) is being done worldwide but the cutoff values vary widely in different countries and is influenced by perinatal factors [1–3]. We aimed to analyze the TSH value distribution in venous blood sampled for newborn screening and to identify the perinatal factors influencing it.

This retrospective observational study was done between January 2014 and June 2019 in south India. Newborns with their TSH screening value available were included. Babies who were < 33 wk and < 1500 g were excluded. Venous blood TSH cut-off < 10 mIU/L was considered screen negative. Institutional ethical committee approved the study.

Among a total of 15,586 babies born, analysis was done with 14,738 babies. Median gestational age and birth weight were 38 wk (37–39) and 2950 g (2670–3230), respectively. There were 51.5% male, 89.2% term babies, and 61.5% vaginally born. Median TSH value was 2.81mIU/L with 95th percentile of 11.33 mIU/L. A higher median TSH value was seen in term babies ($p < 0.001$), vaginal birth ($p < 0.001$), male gender ($p < 0.001$), birth weight ≥ 2500 g ($p < 0.004$) and babies sampled at 24–47 h of life ($p < 0.001$). Majority of population (88%) was represented by term babies between 48 and 96 h of life and this subset of population had a median TSH value of 2.85 mIU/L (1.42, 5.41) with 95th percentile being 11.33 mIU/L.

1072 (7.2%) babies were screen positive and 19 were confirmed to have CH. Since our TSH screening cutoff was < 10 mIU/L but 95th percentile in our study was 11.33 mIU/L, we followed up babies with TSH value between 10 and 11.33 mIU/L. Among 339 babies with TSH between 10 and 11.33 mIU/L, follow-up was available for 305 (90%). Repeat TSH at 2 wk of age was normal for 118 babies (34.8%). Parents were contacted for 187 babies (55.2%), aged 1–6 y and were reported to be normal.

A TSH screening cutoff of >11.33 mIU/L may be considered as an appropriate threshold for babies screened with venous blood between 48 and 96 h of age. In our study population this would have resulted in 31.6% reduction in recall rate without missing a case of CH. However a large-scale prospective population-based study is needed.

Case Report

Late-Onset Hyporegenerative Anemia in an Infant with Rhesus Isoimmunization

Saranyaa R. Velumani, Ramesh Srinivasan, Prasanna N. Kumar[1]

Departments of Pediatrics and [1]Pathology, PSG Institute of Medical Sciences and Research, Coimbatore, Tamil Nadu, India

Abstract

Late-onset anemia is a complication of hemolytic disease of fetus and newborn. It includes late hemolytic anemia and late hyporegenerative anemia. This case report is to discuss an Rh isoimmunized infant who presented with late-onset hyporegenerative anemia. The infant had low reticulocyte count, negative direct antiglobulin test, high erythropoietin, and high ferritin levels. She was treated with repeated blood transfusions and improved after 4 months of age. The follow-up of infants with Rh isoimmune hemolytic disease is needed for identification of late-onset anemia.

Introduction

Rhesus D isoimmunization is a common cause for severe hemolytic disease of fetus and newborn (HDFN). Late-onset anemia occurring after 1st week of life is found in 71%–83% of neonates with Rh hemolytic disease, and the incidence is highest among infants who received intrauterine transfusion. It commonly develops between 2 and 6 weeks after birth and usually resolves by the 3rd month of life.[1] This case report discusses an Rh isoimmunized infant who presented during the 2nd month of life with severe anemia.

Case Report

A female neonate was delivered at 35 weeks gestational age by cesarean section to a fourth gravida mother. The mother's blood group was A-negative with positive indirect antiglobulin test (IAT). Anti-D was given in the first two pregnancies but not in the third pregnancy. In the current pregnancy, antenatal ultrasound scan at 31 weeks of gestational age showed features of hydrops fetalis with ascites, pleural effusion, and hepatosplenomegaly. Intrauterine transfusion was done twice at 32 and 34 weeks of gestational age. The baby had normal transition at birth. On examination, the baby had hepatosplenomegaly but no pallor or icterus. Double-volume exchange transfusion was done at 7 h of life in view of *in utero* hydrops fetalis. Serum bilirubin sequentially monitored was not in treatment range. Packed red blood cell (PRBC) transfusion was done on day 3 of life for anemia with hemoglobin 9.1 g/dl, and the baby was discharged on day 8 of life [Table 1].

At review on day 50 of life, the infant showed adequate weight gain but had hemoglobin of 4.2 g/dl. Peripheral smear showed severe normocytic normochromic anemia with normal leukocyte and platelets. Reticulocyte count was low (0.2%). Direct antiglobulin test (DAT) was negative, but IAT was positive. Serum erythropoietin level was high. Parvovirus B19 DNA polymerase chain reaction was negative. Work-up for iron deficiency and megaloblastic anemia showed normal reports, except for increased serum ferritin level. Bone marrow study showed normoblastic erythroid hyperplasia; the myeloid series and megakaryocytes were normal. Hemoglobin electrophoresis was normal. Hence, late-onset hyporegenerative anemia of rhesus hemolytic disease was diagnosed. The baby received PRBC transfusions on day 52, 60, and 84 of life. The baby was

on folate and multivitamin supplements. Intravenous immunoglobulin (IVIg) was given on day 85 of life. At 4 months of age, the baby's hemoglobin level stabilized with increase in reticulocyte count. Liver span became normal, while spleen was not palpable. The infant did not require further transfusions. Follow-up showed hemoglobin in improving trend. At 7 months of age, IAT became negative, and DAT was positive. The Rh type that was hitherto reported as equivocal due to mixed field reaction was now reported as O-positive.

Discussion

HDFN is caused by the destruction of red blood cells (RBCs) of the fetus or newborn by maternal IgG alloantibodies that have crossed the placenta. Rh isoimmunization may lead to late hyporegenerative anemia. Pathogenesis implicated is antibody-dependent intramedullary destruction of RBCs and its precursors and bone marrow suppression by intrauterine/postnatal RBC transfusion. This anemia is characterized by normal bilirubin level and low or absent reticulocyte count. In contrast, late hemolytic anemia following Rh isoimmunization is characterized by active bone marrow erythropoiesis and elevated reticulocyte counts associated with elevated bilirubin levels.[2]

Low reticulocyte count in the peripheral smear with erythroid hyperplasia in bone marrow suggests antibody-mediated intramedullary destruction of red cell precursors. In addition, negative DAT with positive IAT in the baby suggests severe hemolysis because of the mother's Rh antibody, with the presence of free circulating maternal antibodies and absent baby's native red cells for forming antigen antibody complex.[3] Thus, the baby's circulating RBCs were probably only transfused compatible cells.

Serum erythropoietin level may be low relative to the degree of anemia in babies with late hyporegenerative anemia, but it may not be so always. Moreover, treatment with recombinant erythropoietin (rEPO) may be ineffective when anti-Rh (D) antibody titers are high. Thus, in late hyporegenerative anemia in HDFN, available data are not sufficient to support beneficial effects of rEPO.[4] Hence, erythropoietin therapy may not be essential in all such cases.

IVIg reduces the immune-mediated hemolysis by blocking Fc receptors in the reticuloendothelial system of neonate and enhances maternal antibody clearance. A meta-analysis by Louis *et al*. on the role of IVIg in isoimmune hemolytic disease of newborn showed that IVIg did not reduce the need for top-up transfusion in both Rh and ABO isoimmunization.[5] A meta-analysis by Li *et al*. has found that IVIg therapy did not cause any significant difference in the incidence of late anemia among babies with isoimmune hemolytic disease.[6] A study by Al-Alaiyan *et al*. on effects of IVIg on late hyporegenerative anemia due to rhesus HDFN has stated that there was no significant difference on the incidence of late anemia and requirement of top-up transfusion.[7] Hence, routine use of IVIg should not be encouraged in managing HDFN.

High iron storage as evidenced by increase in serum ferritin level occurs in hyporegenerative anemia due

[Downloaded free from http://www.jcnonweb.com on Thursday, May 27, 2021, IP: 103.224.34.2]

to treatment with multiple intrauterine transfusion and postnatal RBC transfusion. Rath *et al*. have reported that in neonates with red cell isoimmune hemolytic disease, iron overload occurs in 70% of neonates at birth, and the incidence of iron overload gradually decreases within the first 3 months, once the blood transfusions are discontinued.[8] Hence, iron essential for hemoglobin synthesis by erythroblast has to be supplemented only if serum ferritin levels are low or in normal range.

Conclusion

In infants with HDFN, regular follow-up of hemoglobin, reticulocyte count, and serum ferritin level are advisable till hematological parameters stabilize in normal range. Late-onset anemia can be managed with regular top-up transfusions and the role of rEPO and IVIg is to be decided on case-to-case basis.

Case Report

Unusual Presentation of Cow's Milk Protein Allergy in a Neonate

Sudhakar Palanisamy, Ramesh Srinivasan, Thirumal Perumal[1]

Departments of Pediatrics and [1]Gastroenterology, PSG Institute of Medical Sciences and Research, Coimbatore, Tamil Nadu, India

Submitted: 10-May-2021

Published: 24-Sep-2021

Abstract

Cow's milk protein allergy is the most common food protein allergy in children. We report a neonate on breast feeds and formula feeds presenting on day 9 of life with blood in stools, anemia, shock, respiratory failure with multiorgan dysfunction, and recovered with intensive care. Colonoscopy and biopsy confirmed the diagnosis as allergic colitis. Neonate improved with cow's milk protein-eliminated diet. Food protein allergy can present with protean signs and symptoms; high index of suspicion is needed for the prompt early diagnosis.

Keywords: *Colonoscopic biopsy, cow's milk protein allergy, food protein-induced allergic proctocolitis, food protein-induced enterocolitis syndrome*

Introduction

Cow's milk protein allergy (CMPA) is the most common food protein allergy in children.[1-4] Cow's milk-based infant formula is the most common allergen triggering food protein allergy in infants. Although maternal cow's milk intake can lead to secretion of cow's milk protein in breast milk, it is rarely the sole trigger for CMPA.[5] The current case report is to discuss an unusually severe presentation of CMPA in a neonate.

Case Report

A 9-day-old girl presented with blood in stools and marked pallor. She was born at term with birth weight of 2600 g. Vitamin K was given at birth. She was on breastfeeding with occasional formula feeds. She was passing small volume stools 4–5 times a day which was blood stained for the past few days. This was associated with progressive pallor in the baby. There was no significant vomiting. She had good weight gain and crossed her birth weight.

She was lethargic with poor respiratory efforts at admission and started on mechanical ventilation. She had shock requiring fluid boluses and inotrope. There was no hepatosplenomegaly or other bleeding manifestations. The perianal region was normal. Admission hemoglobin was 2.2 g/dl, and packed red blood cell (PRBC) transfusion was done. Hemolytic workup was negative. She had elevated liver enzymes, coagulopathy, thrombocytopenia, hypoglycemia, acute kidney injury, and seizures during the course of hospitalization and was managed appropriately. Her blood culture was negative. Echocardiography initially showed mild ventricular dysfunction which improved later. Ultrasound cranium and abdomen were normal. Barium study ruled out malrotation with intermittent volvulus. PRBC transfusions were repeated on days 2, 5, and 10 of hospitalization. Baby improved and was started on breast milk feeds on day 3. She was discharged on day 10 with provisional diagnosis of clinical sepsis with multiorgan dysfunction. Her discharge hemoglobin was 10.7 g/dl.

During the follow-up on day 37 of life, her weight gain was inadequate and hemoglobin was 7.6 g/dl. After 1 week, mother reported the frequent episodes of blood in stools and was continuing on formula feeds once or twice a day. She was admitted for poor weight gain with hemoglobin 5.9 g/dl and high reticulocyte count. There were no features suggestive of hemolysis. Radionucleotide scan for Meckel's diverticulum was normal. Ultrasound abdomen ruled out duplication cyst. Serum immunoglobulin E was 45 IU/ml (normal <1.5 IU/ml). Esophago-gastro-duodeno (OGD) scopy was normal. Colonoscopy showed the features

DOI: 10.4103/jcn.jcn_55_21

suggestive of severe allergic colitis. Histopathology of colonoscopic biopsy showed lymphoid hyperplasia with focal tissue eosinophilia (50/high-power field) and occasional microgranulomas suggestive of allergic colitis.

Breastfeeds were continued for the baby with dairy products eliminated from mother's diet. Mother was supplemented with calcium and Vitamin D. Elemental aminoacid-based formula was used for top up feeds. Baby was transfused PRBC on day 2 of admission and was discharged on day 8 with hemoglobin of 9 g/dl. Subsequent follow-up showed improvement in hemoglobin with adequate weight gain. Complementary feeds were started at 5 months of age. Cow's milk-related products were eliminated from baby's diet and Vitamin D with calcium supplements was added. At 10 months' follow-up, she had good weight gain and normal development.

Discussion

Food protein allergies are classified broadly into food protein-induced enterocolitis syndrome (FPIES), food protein-induced allergic protocolitis (FPIAP), food protein-induced enteropathy, and eosinophilic gastroenteritis. FPIAP seems to be the most common type of food protein allergy.[1]

FPIAP is a clinical diagnosis with predominant manifestation being blood in stools. Among infants presenting with blood in stools, 18%–65% might be having FPIAP.[2] Most of the babies appear clinically well though failure to thrive and irritability can occur rarely. Usually, they present within a few months of age and sometimes even as early as 1 week of age. Vitamin K deficiency, malrotation with volvulus, intussusception, and Meckel's diverticulum can also present with blood in stools at this early age and must be ruled out before considering allergic colitis.[6] The case reported here presented with blood in stools but also had life-threatening anemia and shock which is unusual in FPIAP.

FPIES is known to present with hemodynamic instability and hypotension in severe cases. However, as per the international consensus guidelines, the major criteria for diagnosing FPIES are vomiting within 1–4 h of ingestion of cow's milk protein. Extreme lethargy, diarrhea, pallor, hypotension, hypothermia, and need for intravenous fluid support are considered as minor criteria. The diagnosis of FPIES requires the presence of one major criterion with at least three minor criteria.[4] It is also reported that infants <2 months of age with cow's milk-related FPIES are more likely to present with diarrhea and blood in stools, whereas infants older than 2 months of age are more likely to present with vomiting.[4,7]

OGD scopy in FPIES is likely to show gastric erythema and erosion only in the presence of significant vomiting. Colonoscopy in FPIES with bloody diarrhea shows diffuse inflammation of colon. In FPIAP, colonoscopy shows focal or diffuse colitis with edema and erosion. Colonoscopic biopsy in both the conditions will show the features of inflammation with increased number of eosinophils.[8,9] Since colonoscopy and colonic biopsy findings are similar in both the conditions, clinical presentation is the main clue to the diagnosis.[10] Based on the clinical features, this baby is more likely to have FPIES even in the absence of significant vomiting. However, the management of both these pathological entities remains the same with the prescription of cow's milk protein eliminated diet.[2,4]

CMPA should be considered in the differential diagnosis of babies presenting with blood in stool, especially if they are receiving formula feeds. Response to elimination diet with recurrence of symptoms on challenge with cow's milk based diet helps in confirming the diagnosis. The prognosis is good with the early diagnosis and institution of therapeutic elimination diet.

Predisposing factors and outcome of hypernatremia in breastfed late preterm and term neonates

Received - 05 September 2017 Initial Review - 28 September 2017 Published Online - 08 November 2017

ABSTRACT

Background: Inadequate breastfeeding results in hypernatremia in otherwise healthy neonates. **Objective:** This study finds out the predisposing factors and clinical outcome of hypernatremia in breastfed late preterm and term neonates. **Materials and Methods:** A descriptive study was conducted in a tertiary hospital with retrospective data from July 2013 to June 2016. Babies with serum sodium ≥ 150 mEq/L were identified. Breastfed babies with little or no formula feeds, gestational age ≥ 34 weeks, and birth weight ≥ 2000 g were included. Babies with congenital anomalies, sepsis, prior parenteral fluid therapy and renal or endocrine diseases causing fluid and electrolyte disturbances were excluded. Total weight loss > 10% or daily weight loss > 5% from the birth weight were considered as excess weight loss. **Results:** A total of 201 babies were studied. Hypernatremia was significantly more common in babies of primiparous mothers ($p < 0.01$). There was no difference in incidence between vaginal born and cesarean-born babies. Positive correlation was seen between age at presentation, percentage of weight loss ($p = 0.001$) and serum sodium ($p = 0.01$). Significantly more cases were seen in summer season ($p < 0.01$). Excess weight loss, jaundice, fever, and dehydration were the common symptoms. Complications observed were acute kidney injury, seizures, intracranial bleed, apnea, and bradycardia. Babies with complications mostly presented after 7 days of age, had > 25% weight loss and had serum sodium ≥ 170 mEq/L. There was no death. Three babies had neurodevelopmental problems on follow-up. **Conclusion:** Breastfed babies of primiparous mothers and born in summer are predisposed to hypernatremia. Babies presenting at a later age had severe weight loss, severe hypernatremia, and complications.

Key words: *Breastfeeding, Hypernatremia, Primiparity, Summer season, Weight loss*

Exclusive breastfeeding for the first 6 months of life is recommended by the World Health Organization to optimize the growth and development of the infants [1]. Breast milk in addition to nutrients provides various immunological factors that help to reduce the diarrheal and respiratory illness in children [2]. Breastfeeding is an instinct behavior and many mother-baby dyads accomplish it successfully [3]. However, some babies may not receive enough milk from their mothers due to various reasons. If breastfeeding is inadequate, then malnutrition and hypernatremic dehydration can occur in the baby [4]. Moritz *et al*. have termed this condition as "breastfeeding associated hypernatremia" (BFAH) [5].

An increase in the incidence of BFAH in otherwise healthy neonates has been observed in the past few years [5-8]. The clinical features and complications seen in these babies have been reported in various studies [9]. It has been found that daily weighing of the babies helps in the early recognition of this illness [10,11]. Thus, the discrepancy in clinical features and complications reported in various studies were probably related to weight monitoring practices and timing of presentation of the cases [10,11]. This study was planned to find out the predisposing factors and outcome of hypernatremia in breastfed late preterm and term neonates in a hospital with regular weight monitoring practice.

MATERIALS AND METHODS

This descriptive study was done using retrospective data from July 2013 to June 2016. The study was conducted in an urban tertiary care medical college hospital with an average delivery rate of 2500 per year. Exclusive breastfeeding was promoted for all babies in the hospital. The mother-baby dyads were discharged at around 72 h after normal delivery and 120 h after cesarean delivery. As per hospital protocol, all babies were weighed daily. Excess weight loss was defined as total weight loss more than 10% from birth weight or weight loss per day more than 5% of birth weight [12]. Serum sodium level was checked for babies with excess weight loss. Hypernatremia was defined as serum sodium more than or equal to 150 mEq/L. Babies with hypernatremia were treated with liberal oral feeds, intravenous (IV) fluids, and other supportive therapies. Serum sodium <150 mEq/L was considered an end point of treatment.

The Institutional Ethics Committee approved the study. Babies admitted during the study period with hypernatremia were identified from the hospital database. Their case records were scrutinized and babies who fulfilled the following criteria were included in the study: (1) Breastfed babies with little or no formula supplementation, (2) gestational age more than or equal to 34 weeks, and (3) birth weight more than or equal to 2000 g. The babies who had major congenital anomalies, blood culture positive sepsis, received IV fluids within 48 h before diagnosis of hypernatremia and renal or endocrine disorders which may affect the fluid and electrolyte balance were excluded from the study. The following data were collected: Gestational age as completed weeks, age at diagnosis as completed days, birth weight, weight at diagnosis, maternal age, obstetric details, details about baby feeding, clinical features, treatment, complications, condition at discharge, and neurodevelopment at follow-up.

The total weight loss and weight loss per day were calculated as a percentage of the birth weight. Axillary temperature more than 38°C was considered as fever. The rate of decline in serum sodium was calculated using the sodium before and after treatment and the time taken to achieve it. Acute kidney injury (AKI) was diagnosed if serum creatinine increased by >0.3 mg/dl in 24 h or if it was >1.5 mg/dl with normal maternal renal functions [13]. Jaundice treated with phototherapy was considered as significant. At the time of discharge, babies were said to have improved if their serum sodium level was <150 mEq/L and was taking feeds well. At follow-up, their neurodevelopment was said to be normal if gross motor, fine motor, language, and social milestones were appropriate for age and had no other neurological problem.

SPSS software version 24 was used for analysis. Numerical data were presented as mean±standard deviation or median±interquartile range as appropriate. Categorical data were presented as percentages and analyzed using Chi-square test. Ordinal data were analyzed with Mann–Whitney U-test or Student's t-test. Correlation was done with Spearman rank correlation coefficient where appropriate. $p<0.05$ was considered as significant.

RESULTS

There were 213 babies with hypernatremia satisfying the inclusion criteria during the study period. 12 babies were excluded due to various reasons. The remaining 201 babies were considered for analysis (Fig. 1). During the study period, there were 7613 live births, with 4570 vaginal births, and 3043 cesarean births. There were 4463 primiparous and 3150 multiparous mothers. Hypernatremia was seen in 2.4% of vaginally born babies and 3.1% of cesarean-born babies. This difference was not statistically significant. 3.1% babies of primiparous mothers and 1.6% babies of multiparous mothers had hypernatremia, and this different was statistically significant (Chi-square 16.7, $P<0.01$). All babies were born of singleton pregnancy. Most of the (80%) mothers had no problem in breastfeeding their babies (Table 1).

Serum sodium had a negative correlation with mother's age ($r=-0.23$, $p=0.01$) and baby's gestational age ($r=-0.2$, $p=0.004$). No correlation was seen between serum sodium level and birth weight. A positive correlation was seen between age at presentation and total weight loss ($r=0.65$, $P=0.001$). Serum sodium at admission had a positive correlation with age at presentation ($r=0.704$, $p=0.01$) and percentage of total weight loss ($r=0.652$, $p=0.001$). More than 50% of the cases were seen during the summer season in this study. This seasonal variation in the incidence of cases was statistically significant (Chi-square-26.9, $p<0.01$) (Table 1).

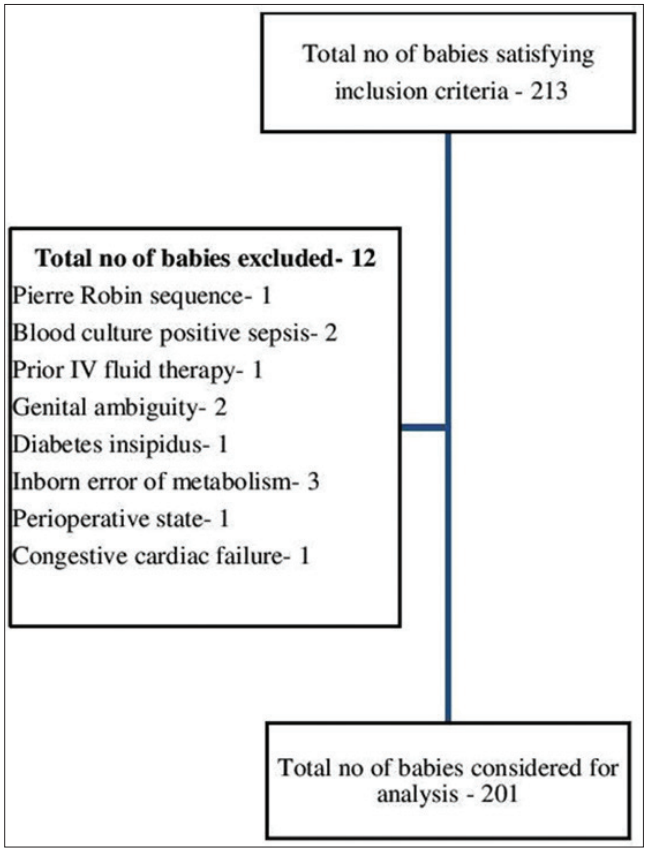

Figure 1: Flow of cases in the study

Significant jaundice was seen in 57.2% babies, but none required exchange transfusion. Phototherapy (median duration 24 h) before the onset of hypernatremia was given to 26 babies. Other common clinical findings observed were fever (33.8%) and dehydration (17.4%). No symptom other than excessive weight loss was seen in 21.4% of babies. Severe hypernatremia with serum sodium ≥170 mEq/L was seen in only five babies, and all other babies (98%) had moderate hypernatremia (serum sodium 150–169 mEq/L). About 89% of babies improved after treatment and got discharged. There was no death in the study population (Table 2). The babies who improved had a median birth weight of 3000 g (2800–3300), median admission weight of 2700 g (2460–2930), and median discharge weight of 2800 g (2540–3070).

Five babies (2.5%) had complications during the course of hypernatremia. One male baby with serum sodium of 151 mEq/L had apnea after vomiting of feeds and developed aspiration pneumonia. He improved with mechanical ventilation and antibiotics. All other four babies presented after 7 days of life

Table 1: Baseline characteristics of hypernatremic babies

Characteristics	Observation
Median maternal age (years) (n=183)*	26.9 (23-29)
Number of babies born to primiparous mothers	138/188 (73.4%)
Number of babies born to cesarean mothers	108 (53.7%)
Number of mothers reported problem in breastfeeding	42 (20.1%)
Male to female ratio	1.34:1
Median gestational age (weeks) (n=189)*	38 (37-39)
Median age at diagnosis (days)*	3 (2–18)
Number of babies presented on 2–3 days age	161 (80.1%)
Median birth weight (g)*	3080 (2810-3410)
Median weight at diagnosis (g)*	2710 (2470-3020)
Median daily weight loss (%)*	3.9 (3.3-4.7)
Median total weight loss from birth (%)*	11.3 (10-12.8)

Neurodevelopment problem at follow-up	3/154 (1.9%)

*Median (IQR). IQR: Interquartile range

with weight loss more than 25% of birth weight and severe hypernatremia (serum sodium ≥170 mEq/L). Complications observed were AKI (4), seizures (2), apnea (2), intracranial hemorrhage (1), and bradycardia (1). Peritoneal dialysis was done for one baby with AKI. No baby had peripheral or cerebral vessel thrombosis. Neurosonogram done for one baby with seizures showed increased white matter echogenicity. Another baby with seizures had normal neurosonogram. The treatment and outcome details of babies with severe hypernatremia are given in Table 3.

Follow-up details were available in 154 cases (76.6%) for a median duration of 1.5 months (0.5–11 months). Three babies had abnormal neurodevelopment. One female baby with serum sodium 150 mEq/L had a prolonged period of jaundice requiring phototherapy for 9 days. At follow-up, she had a global developmental delay with a seizure disorder. One male baby with serum sodium 150 mEq/L was found to have hyperactivity and aggressive behavior at 3 years. Neuroimaging was not available for these two babies. Another female baby had severe hypernatremia with AKI, seizures and normal neurosonogram in the neonatal period; and on follow-up at 1 year was found to have left hemiparesis and magnetic resonance imaging of the brain showed chronic infarct in right front parietal region and white matter changes in subcortical and deep cerebral white matter.

DISCUSSION

In this study, we have found BFAH to be more common among babies of primiparous mothers. Although breastfeeding is an instinct behavior, mothers have to learn the technique and need social support to successfully breastfeed their babies [3]. Systematic review on BFAH has found cesarean delivery, primiparity and absent previous breastfeeding experience as risk factors for BFAH [9]. However, there was no difference between cesarean babies and vaginally born babies in this study. Similarly, two studies had found no significant difference in mode of delivery among hypernatremic babies compared to control group [5,14].

It is stated that the parents of hypernatremic babies have poor recognition of their baby's illness [7,15]. About 80% of our baby's mothers have not felt any problem with their baby's feeding behavior. Excess weight loss gave a clue to identify these cases early. Thus, majority of our cases were identified at an early age, had less severe weight loss and less severe hypernatremia. Many studies report that babies presenting at a later age have higher weight loss and more severe hypernatremia [16,17]. Hence, daily weighing of babies along with appropriate lactation support during the first 4–5 days of life has been suggested for early detection of BFAH [10,11,18]. The seasonal variation in the incidence of hypernatremia was reported in some studies [12,19-21]. This was attributed to excess insensible water loss due to the hot climate in summer and overuse of room heaters in winter [9,21]. In this study, we have found significantly more number of cases during the summer season. This seasonal variation may be related to hot environmental temperature during summer seen in Tamil Nadu state of India where the study was done.

At admission, jaundice, fever, and dehydration were common symptoms in our study population. Lavagno *et al*. through systematic review have found jaundice, poor feeding, and dehydration each seen in about 45% of all reported cases [9]. Yang *et al*. have showed that percentage of weight loss within first 3 days of life has a positive correlation with jaundice at 72 h after birth in healthy term breastfed babies [22]. The hypernatremia and the resultant hyperosmolar state may damage the blood–brain barrier and facilitates bilirubin entry into nervous tissues at

Table 3: Clinical features and outcome of babies with severe hypernatremia

Gestational age (weeks)	Birth weight (g)	Total weight loss (%)	Day of diagnosis	Maximum Sr. sodium (mEq/L)	Complications	Treatment	Time to correct Sr. sodium (h)	Outcome at follow up

AKI: Acute kidney injury

lower serum bilirubin level [5,23]. This has to be considered in one baby with neurodevelopmental impairment in our study who had hypernatremia and prolonged jaundice. About 20% of our babies had no symptoms at admission except for excess weight loss. Similarly Uras *et al*. and Korgali *et al*. have found that 14% and 2.4% of their hypernatremic babies were asymptomatic at admission, respectively [24,25].

Four out of five babies with severe hypernatremia had neurological and/or renal complications. Similarly, Ahmed *et al*. have found that babies with AKI presented at a later age, had higher weight loss and higher serum sodium [26]. However, less number of babies in this study had complications compared other studies [5,8,9,20,25-27]. This may be due to earlier age at presentation and a lesser degree of hypernatremia seen in the large proportion of babies in our study. There was no death in our study population and on follow-up only three babies had a neurodevelopmental problem. Mortality rate of 1-5% has been reported by various authors [8,26-28]. Koklu *et al*. have reported neurodevelopmental impairment in 47.8% cases [27]. Similarly, a high rate of neurodevelopmental impairment is also reported by Bolat *et al*. and Ergenekon *et al*. [29,30]. This emphasizes the need for formal neurodevelopmental follow-up of hypernatremic babies.

In this study, we have reported the correlation of serum sodium level with various other clinical parameters in babies with BFAH. Our study has the following limitations due to retrospective nature of the study: Some data were incomplete and long-term formal neurodevelopmental assessment was not done. Our study was hospital based, and many babies had a less severe degree of hypernatremia with fewer complications. A larger scale prospective study with neurodevelopmental follow-up is needed to have a clear understanding of the risk factors, complications and long-term effects of BFAH.

CONCLUSION

Breastfed late preterm and term babies born to primiparous mothers and born in summer season have predisposition to develop hypernatremia. These babies commonly presented with excess weight loss, jaundice, fever, and dehydration. Babies presenting beyond 7 days of age and with more than 25% weight loss are likely to have severe hypernatremia. Neurological complications and AKI were common complications observed with severe hypernatremia. These babies are at risk of neurodevelopmental impairment. Prospective study with long-term follow-up is needed.

ABSTRACT

Introduction: Acute kidney injury (AKI) influences the risk of mortality in sick neonates. Predicting AKI on the basis of risk factors may help in early intervention and improved outcome. **Objective:** The aim of this study is to identify the predisposing factors, clinical features, and outcome of AKI in neonates. **Methodology:** A retrospective study was carried out from September 2011 to August 2015. AKI was diagnosed if any one of the following is present: (1) Baby's serum creatinine more than 1.5 mg/dl for at least 24–48 h with normal maternal renal function, (2) baby's serum creatinine increases by more than 0.3 mg/dl over 48 h. All babies with AKI during the study were included in the study. **Result:** Twenty-five babies with AKI were studied. Male predominance was seen. Babies presented at a median age of 3 days interquartile range ([IQR] 2–5) with the median gestational age of 36 weeks (IQR 28–40) and median birth weight of 2490 g (IQR 1885–2875). Perinatal asphyxia (44%), blood culture positive sepsis (24%) and excess weight loss due to inadequate feeds (20%) were common causes for AKI. About half of the cases have received mechanical ventilation and/or inotropes. Nephrotoxic drug exposure was seen in 44% of cases. Only one-third of the babies had oliguria. Fluid boluses, diuretics, and sodium bicarbonate to correct acidosis were commonly used for medical management. Only 12% of cases required peritoneal dialysis. One baby expired. **Conclusion:** Perinatal asphyxia, sepsis, excess weight loss, and cardiopulmonary compromise predisposes to AKI in neonates. Many babies improve with medical management.

Key words: *Acute kidney injury, Cardiopulmonary compromise, Excess weight loss, Perinatal asphyxia, Sepsis*

Acute kidney injury (AKI) is commonly seen in newborns admitted to neonatal intensive care unit. It was found to have an independent influence on the risk of mortality in sick neonates [1]. The terminology "AKI" has now replaced "acute renal failure." AKI is a disorder of renal function with clinical manifestations ranging from mild dysfunction to complete a uric kidney failure [2]. Thus, the concept of AKI includes not only established renal failure but also functional impairment relative to the physiological demand [3].

Predicting AKI on the basis of risk factors may help in prompt identification and early treatment of this condition in critically ill neonates. Jetton and Askenazi have recognized newborns with the following conditions as being at increased risk for AKI: Perinatal hypoxia, prematurity and very low birthweight (VLBW), congenital heart disease, especially requiring cardiopulmonary bypass, requiring extracorporeal membrane oxygenation, sick near-term/term infants, sepsis, and congenital anomalies of kidney and urinary tract [4]. Thus, understanding the etiological profile and outcome of AKI in our neonatal population is of utmost importance to reduce the disease burden in our country. Hence, this study was conducted to describe the predisposing factors, clinical features, and outcome of AKI in newborn babies.

MATERIALS AND METHODS

The study was done in a level 3 neonatal unit of a teaching hospital in Tamil Nadu state of India. This study was done using retrospective data from September 2011 to August 2015 over a period of 4 years. A baby was said to have AKI if any one of the following two conditions is present: (1) Baby's serum creatinine more than 1.5 mg/dl for at least 24–48 h if mother's renal function is normal, (2) baby's serum creatinine increases by more than 0.3 mg/dl over 48 h [3]. All babies admitted during the study with the diagnosis of AKI were included in the study. The study was approved by the Institutional Ethics Committee.

The babies with AKI were identified by screening the diagnosis list of cases admitted during the study. Their case records were retrieved from the medical records department and scrutinized for their eligibility. Babies who satisfied the inclusion criteria were included in the study. The following baseline data were collected as follows: gender, gestational age as completed weeks, birth weight in grams, and age at diagnosis of AKI. The presence of predisposing condition for AKI such as perinatal asphyxia, sepsis, excess weight loss, renal anomalies, exposure to nephrotoxic drugs, patent ductus arteriosus, cardiac failure, umbilical arterial line, and necrotizing enterocolitis were noted.

Clinical parameters such as hydration status, urine output, blood pressure, hemodynamic compromise, respiratory problem, and any surgical procedure done were also recorded. Laboratory data collected include maximum serum creatinine, maximum blood urea, electrolyte abnormalities, acid-base status, and blood cell count and blood culture. The following serum electrolyte values were considered as normal: Sodium 135–145 mEq/L, potassium 3.5–5.5 mEq/L, ionized calcium 1–1.4 mEq/L, and bicarbonate 20–28 mEq/L. The treatment received for AKI, duration of hospital stay, and outcome were also entered in the pro forma.

Perinatal asphyxia was defined as requirement of positive pressure ventilation at birth. Babies with microbial growth in blood culture were considered to have sepsis. Any baby with weight loss more than 10% of their birth weight was said to have excess weight loss. Aminoglycosides, vancomycin, and amphotericin were considered as nephrotoxic drugs. Oliguria was defined as urine output <1 ml/kg/h. The data were collected in the designed pro forma and entered in Microsoft Excel sheet 2007. Epi info 2017 statistical software was used for analysis. The descriptive data were presented as a median ± interquartile range (IQR), and numerical data were presented as percentage.

RESULT

During the study, there were 2876 admissions to the neonatal unit and twenty-five babies had AKI. All 25 babies were included in the study. Male predominance was seen in the study population. Median gestational age was 36 weeks (IQR 28–40), and median birth weight was 2490 g (IQR 1885–2875). One-third of the babies were born preterm. Median age at presentation with AKI was 3 days (IQR 2–5) (Table 1).

Perinatal asphyxia was the underlying cause in about half of the cases in the study population. Blood culture positive sepsis was observed in about one-fourth of the babies. One-fifth of the cases had dehydration, excess weight loss, and hypernatremia due to inadequate feeds. The renal anomaly was seen in two babies as follows: One had hypoplastic kidneys and other had medullary nephron calcinosis. Cardiac failure due to supraventricular tachycardia was seen in one baby. Exposure to nephrotoxic drugs was observed in about half of the cases. Three babies had patent ductus arteriosus and two had an umbilical arterial catheter (Table 2).

One-fourth of the cases had dehydration and 12% had edema. Almost one-third of the babies had oliguria. About 50% of the cases were on mechanical ventilator. Hemodynamic compromise requiring inotropic support was observed in about 50% of the cases. Parenteral nutrition was given for one-fourth of the cases and blood component therapy was given to about half of the babies (Table 3).

Hypocalcemia, low serum bicarbonate, metabolic acidosis, and hypernatremia each were seen in about half of the cases. About one-third of the babies had hyperkalemia. Anemia and thrombocytopenia each were seen in about 30% of the cases (Table 4). Fluid bolus (40%), diuretic therapy (36%), and sodium bicarbonate infusion (36%) for acidosis correction were commonly used as medical management. Only three babies

(12%) required peritoneal dialysis. About three-fourth of cases improved and got discharged. Seven cases left against medical advice and one expired (Table 5).

DISCUSSION

In this study, perinatal asphyxia, culture positive sepsis, and excess weight loss were the common causes for AKI in neonates. A study from Thailand has found that sepsis was the most common cause of AKI followed by hypovolemia, renal and urinary tract anomalies, congestive heart failure, and birth asphyxia [5]. In a prospective study from Egypt, Youssef *et al*. have found sepsis, respiratory distress syndrome, mechanical ventilation, perinatal asphyxia, and dehydration as the common predisposing factors for AKI in neonates [6]. Sepsis was identified as a predisposing factor in about three-fourth of the cases with AKI by Momtaz *et al*. [7]. Askenazi *et al*. have found that babies with AKI had low Apgar score at 5 min, low cord blood pH and required mechanical ventilation in delivery room [8]. Selewski *et al*. in a review on neonatal AKI has suggested that babies with birth weight <1500 g, perinatal asphyxia, low apgar scores, on extracorporeal membrane oxygenation and undergoing cardiac surgery need closer surveillance of renal function to identify AKI early [9].

About half of the babies in this study were sick requiring mechanical ventilation and/or inotropic support and 44% of the babies have been exposed to nephrotoxic drugs. Critically ill neonates are at risk of having AKI, as they are commonly exposed to nephrotoxic medications and have frequent infections that lead to multi-organ failure [2]. Youssef *et al*. have found that 51.9% of their AKI babies were on mechanical ventilator [6]. Respiratory support with high mean airway pressure and low mean arterial pressure were associated with renal failure in extremely low birthweight babies in a study by Viswanathan *et al*. [10]. Bansal *et al*. had observed an association between mortality and need for mechanical ventilation and shock in babies with AKI [11].

Male predominance observed in this study was also noted by Askenazi *et al*. and Bansal *et al.* [8,11]. Male gender was found to have statistically significant correlation with the occurrence of AKI [11]. However, Momtaz *et al*. had found female predominance in their study [7]. Oliguria was observed in only one-third of the study population. Similarly, Youssef *et al.* have found oliguria in only 29.6% of their babies [6]. Infants are commonly stated to have nonoliguric renal failure [2]. However, Momtaz *et al*. have found oliguria in 77.6% of their cases [7]. Bezerra *et al.* have observed an association between reduced urine output and mortality in neonates admitted to intensive care units [12]. Most of the cases in this study improved with conservative management which includes fluid boluses, diuretics, and sodium bicarbonate. Jetton and Askenazi state that currently there are little data on treatment options for AKI in neonates [13]. A trial of diuretics can be tried in oliguric neonates with AKI. The primary therapy for severe AKI is renal replacement therapy, and the indications are refractory acidosis, uremia, electrolyte disturbances, and fluid overload [9]. Only 12% of babies in this study required peritoneal dialysis. However, Momtaz *et al*. state that 36.7% of their babies required peritoneal dialysis [7].

Table 5: Treatment and outcome of the study population

Characteristics	Observation (%)
Treatment	
Fluid bolus	10 (40)
Diuretics	9 (36)
Sodium bicarbonate infusion	9 (36)
Peritoneal dialysis	3 (12)
Median duration of hospital stay (days)	7 (3–13)
Outcome	
Improved	18 (72)
Left against medical advice	7 (28)
Expired	1 (4)

AKI has an independent impact on survival after correction for comorbidities, complications, and severity of illness [2]. Chertow *et al*. have found that an increase of serum creatinine of >0.3 mg/dl was independently associated with mortality [14]. In a study by Vachvanichsanong *et al*., sepsis-induced AKI had the highest mortality rate with an overall mortality rate of 38.8% and nearly 14 times the risk of death compared to hypovolemia-induced AKI [5]. Among babies with perinatal asphyxia and AKI, the mortality rate was 71.4% [15]. VLBW babies with AKI had 2.4 times higher chance of death compared to those babies without AKI [16]. However, there was only one death in this study population. Premature infants who developed AKI in the neonatal period are at risk of hypertension, chronic kidney disease, and metabolic syndrome [2,17]. Thus, long-term follow-up these cases are required.

This study has identified the important predisposing factors for AKI in neonates of our geographical region. However, the study is limited by its retrospective nature and small sample size. A large-scale prospective study is needed to have a clear understanding of the epidemiology and outcome of AKI in neonates.

CONCLUSION

Perinatal asphyxia, sepsis, excess weight loss, and cardiopulmonary compromise requiring mechanical ventilation and/or inotropes were the common predisposing factors for AKI in neonates. Many babies improved with conservative medical management. Vigilant monitoring of renal function is required in babies with these predisposing factors.

ABSTRACT

Introduction: Screening for critical congenital heart diseases (CCHD) with oxygen saturation (SpO_2) by pulse oximeter often misses left-sided obstructive heart diseases. **Objective:** The role of perfusion index (PI) along with SpO_2 in CCHD screening was studied. **Methodology:** The Masimo, RADICAL-7 pulse oximeter was used to record the SpO_2 and PI in the right hand and left foot of asymptomatic babies at 24–72 h of life. Babies with SpO_2 <95% or PI <0.7 were rechecked at an hourly interval for three recordings. SpO_2 90–94% or PI <0.7 in all three recordings or SpO_2 <90% at any one recording were considered as screen positive. An echocardiogram was done for screen-positive cases. Screen negative cases were clinically followed for 6 weeks. **Result:** Of 1011 screened babies, four were screen positive. One baby had PI <0.7 and SpO_2 <90%. This baby had single ventricle, transposed great vessels, and interrupted aortic arch. Other three cases had SpO_2 between 90% and 94% in all three recordings. Echocardiogram showed severe right ventricle outflow obstruction in 2 cases and normal heart in one baby. At follow-up, no baby had CCHD. **Conclusion:** In this study with small sample size, only one baby had left-sided obstructive lesion but also had single ventricle physiology. Hence, there was no difference in the diagnostic accuracy between SpO_2 alone and SpO_2 with PI in screening for CCHD. Thus, combining PI with SpO_2 may improve CCHD screening using pulse oximeter, but large-scale study is needed.

Key words: *Critical congenital heart disease, Newborn screening, Oxygen saturation, Perfusion index, Pulse oximetry*

Congenital heart diseases (CHD) requiring intervention in the 1st month of life to ensure survival is considered as critical CHD (CCHD). CCHD has an incidence of about 170 in 100,000 live births. Early diagnosis and timely therapy are crucial to prevent acute deterioration of the affected children [1]. CHD with right-sided obstruction or well-mixing lesion present predominately with cyanosis. These cyanotic CHD initially present with faint cyanosis which may be indistinguishable clinically. Thus, the clinical examination (CE) fails to identify about 50% of CHD in the neonatal period [2]. However, these babies can be identified with low oxygen saturation (SpO_2) in the pulse oximeter. Hence, American Academy of Pediatrics (AAP) has recommended SpO_2 measurement by pulse oximeter as a screening strategy to identify cyanotic CHD [3].

However, left-sided obstructive lesions such as hypoplastic left heart syndrome, interrupted aortic arch, and coarctation of aorta present initially with poor peripheral perfusion. SpO_2 may remain within normal limits at an early stage of the disease and can be missed by pulse oximeter screening [1]. Studies have shown that more than 3% difference in saturation ($DSpO_2$) between pre-ductal and post-ductal regions may give a clue to these left-sided obstructive heart diseases [4]. Granelli and Ostman-Smith have found that peripheral perfusion index (PI) measured with new generation pulse oximeter can help in screening for left-sided obstructive lesions [5]. PI is a measure of the pulsatile blood flow in the underlying tissues and is decreased in babies with reduced peripheral tissue perfusion [6]. PI below 0.7 was suggested as a screening tool for identifying left-sided obstructive heart diseases [5].

This study was planned with a hypothesis that combining PI with SpO_2 may improve CCHD detection. The primary objective was to compare the diagnostic accuracy of SpO_2 alone, with SpO_2 and PI in screening for CCHD among asymptomatic newborn babies at 24–72 h of life. The secondary objective was to find out the diagnostic accuracy of CE in screening for CCHD either alone or in combination with SpO_2 and PI.

METHODOLOGY

This prospective study was done in a tertiary care hospital in the Tamil Nadu state of India. The study was carried out over a period of 4 months from October 2011 to January 2012. The Institutional Ethics Committee approved the study. All babies born during the study period and asymptomatic at 24–72 h of life were included in the study. Asymptomatic babies under evaluation for sepsis due to various perinatal risk factors were excluded from the study.

Parents of all babies who satisfied the inclusion criteria were approached for the study. Written informed consent was obtained from the parents and basic demographic details were collected. Babies were then clinically examined for any dysmorphic features, central cyanosis, respiratory distress, apical impulse location, femoral pulses, and grade ≥3/6 precordial murmur.

The new generation pulse oximeter with signal extraction technology (Masimo, RADICAL-7, Signal extraction pulse Co-Oximeter with rainbow technology) was used for recording functional hemoglobin SpO_2 percentage and PI. The instrument displays the pulse waveform, heart rate, SpO_2, and PI. The reusable neonatal probe was applied in the right hand (Pre-ductal area) and the left foot (Post-ductal area) serially when the baby was calm and quiet. The SpO_2 and PI were recorded, once the monitor's display panel showed regular pulse waves. The probe was cleaned with a compatible disinfectant solution between babies.

If PI was ≥0.7 with SpO_2 ≥95% in the both tested limbs and $DSpO_2$ between the two limbs was ≤3%, the screening was considered negative. If anyone of these readings was abnormal, the test was repeated after 1 h. If the second recording result remained abnormal, it was reconfirmed by repeating the test 3rd time after another hour. Babies who consistently had SpO_2 <95% or PI <0.7 or $DSpO_2$ >3% in all three recordings were declared screen positive. SpO_2 <90% in either limb at any time either in the initial recording or in the repeat recordings was immediately declared as screen positive without further testing. All babies with positive screening and those babies with abnormal clinical findings underwent echocardiography (Philips ER VISION-HD-7 with pediatric probe) by a pediatric cardiologist with 5-year experience in the field. Confirmed CCHD cases were referred to cardiothoracic surgeons for further management.

The screen negative cases were followed up clinically at 6 weeks of age when they attended the well-baby clinic for review and vaccination. Any suspicion of CHD was confirmed by echocardiography. The parents of babies who did not come for follow-up were tracked through phone about the health status of the baby. For those parents who could not be contacted by phone, a letter enquiring the health status of their baby was posted to their mailing address. The babies who could not be contacted by phone or post were considered as dropouts.

Sensitivity, specificity, positive predictive value (PPV), and negative predictive value (NPV) for SpO_2, PI, and CE were calculated individually and in combination using OpenEpi, Version 2, open source calculator for diagnostic tests. Categorical data were analyzed with two-tailed Fisher's exact test for small groups and Chi-square test for the large population using SPSS Version 16. $p<0.05$ was considered as significant.

RESULTS

A total of 1011 babies out of 1059 eligible babies were screened. 48 babies were discharged before 24 h of life due to various reasons and were not included in the study (Fig. 1).

Male to female ratio in the study population was 1.03:1. The babies were screened at a mean age of 34 h (±10.5), and their mean birth weight was 2850 g (±440) (Table 1).

Mean SpO_2 in the right hand and left foot was 97.42% (±1.35) and 97.58% (±1.44), respectively, with a mean $DSpO_2$ of 1.07% (±0.86). Mean PI in the right hand and left foot was 2.43 (±1.48) and 2.43 (±1.32), respectively (Table 2).

We had four screen positive cases: One at first recording and other three at the end of three recordings. The baby who was screen positive at first recording had SpO_2 <90% and PI< 0.7 in the right hand. This baby was antenatally diagnosed to have single ventricle. Postnatal echocardiogram of this baby showed transposition of great vessels (TGV), interrupted aortic arch, single ventricle, hypoplastic left atrioventricular valve, and patent ductus arteriosus. Three babies persistently had SpO_2 90–94%

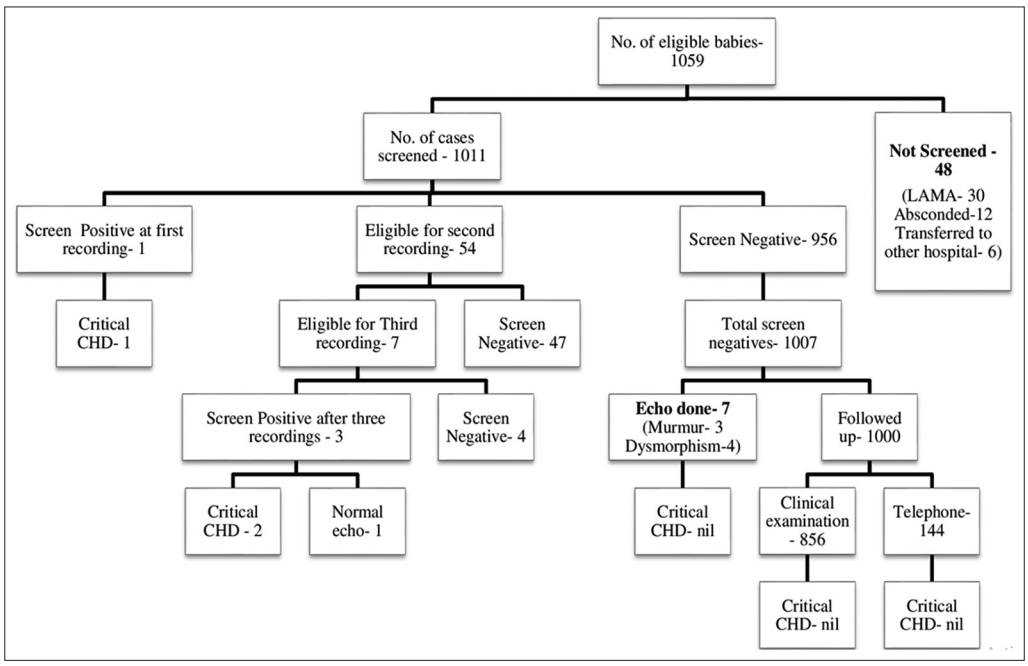

Figure 1: Flow of cases through the study

Table 1: Baseline characteristics of the study population

Characteristics	Observation
Male: female ratio	1.03:1 (p=0.687)
Mean birth weight	2850 (±440) g
Mean age at screening	34.03 (±10.5) h
Mode of delivery	Labor naturale-453; Cesarean section-532; Assisted breech-3; Outlet forceps-17; Vacuum-6

Table 2: Study results

Characteristics	Observation
Mean SpO_2 in right hand	97.42% (±1.35)
Mean SpO_2 in left foot	97.58% (±1.44)
Mean $DSpO_2$	1.07% (±0.86)
Mean PI in right hand	2.43 (±1.48)
Mean PI in left foot	2.43 (±1.32)
Number of babies with dysmorphism	4 (down syndrome-1, Preauricular skin tag-3)
Number of babies with cardiac murmur	4 (CCHD-1, VSD-3)
Number of screen positive cases	4 (Low SpO_2 and low PI-1, low SpO_2-3)
Number of confirmed CCHD	3 (Antenatally detected-2, detected by screening-1)

SpO_2: Pulse oximeter saturation, $DSpO_2$: Difference in pulse oximeter saturation between right upper limb and left lower limb, PI: Perfusion index, CCHD: Critical congenital heart disease, VSD: Ventricular septal defect

at all three recordings. Echocardiogram in these babies showed tetralogy of fallot (TOF) with severe right ventricular outlet obstruction in one baby, right ventricular dysplasia with severe right ventricular outlet obstruction in the second baby and structurally normal heart in another baby. The baby with TOF was antenatally diagnosed to have CHD and postnatally had systolic murmur by CE. The other two cases had normal antenatal scans and normal CE. The screen positive baby with normal echo subsequently had normal SpO_2 before discharge.

Thus, two babies antenatally detected to have CCHD had positive screen by pulse oximeter. Four babies had systolic murmur in CE, and this includes one screen positive baby with TOF. The other three babies with systolic murmur and negative pulse oximeter screening were found to have ventricular septal defect (VSD) by echocardiogram. In addition, four babies with dysmorphic features underwent echocardiography as a part of dysmorphology work up, and all were found to have a structurally normal heart (Table 2).

Other cases were followed up at 6 weeks of age. A total of 856 babies came for follow-up, and none had clinical features of CHD. 144 babies who did not turn for follow-up were contacted by phone and were reported to be healthy without any symptoms suggestive of CCHD. Thus, the incidence of CCHD in our population was 2.97/1000 babies, and the incidence of CHD was 5.93/1000 babies.

The diagnostic accuracy of SpO_2, PI, and CE was calculated individually and in combination. The sensitivity, specificity, PPV, and NPV of SpO_2 alone and SpO_2 with PI were similar. PI alone has low sensitivity but better PPV compared to SpO_2. If the role of PI alone in identifying left-sided obstructive lesions is considered then the sensitivity is 100% and specificity is 100%. CE has low sensitivity and PPV compared to SpO_2. When all three methods of screening are combined, i.e., SpO_2, PI, and CE the sensitivity is 100%, specificity is 99.7%, and PPV is 50% with a false positivity rate of 50% in identifying CCHD (Table 3).

DISCUSSION

In this study, an attempt was made to study the role of combined SpO_2 and PI screening in identifying the CCHD. The results are encouraging since PI has rightly identified one baby with the interrupted aortic arch. Interestingly, this baby also had SpO_2 <90% due to TGV and single ventricle. It can be assumed that even if it had been an isolated interrupted aortic arch, this case would have been picked up by pulse oximeter when both SpO_2 and PI were recorded in all babies. Thus, PI and SpO_2, each have a unique role as a screening tool for identifying left-sided obstructive heart diseases and cyanotic heart diseases, respectively.

de-Wahl Granelli *et al*. have suggested that incorporating cutoff values for PI into routine pulse oximetry screening would probably increase sensitivity for detection of the left heart obstructive disease [4]. In our study, the PI <0.7 has a sensitivity of 33.33%, specificity of 100%, and PPV of 100% in identifying all CCHD. However, it has a sensitivity of 100% and specificity of 100% in identifying CCHD with the left-sided obstructive lesion since there was only one case with the interrupted aortic arch in the study population which was identified by low PI.

de-Wahl Granelli *et al*. stated that in a complex heart disease with a combination of TGV, arch obstruction and duct dependent circulation, the post-ductal saturation may well be >95%, and hence, >3% $DSpO_2$ between pre-ductal and post-ductal regions was included as a screening tool in their study [4]. Although we had one baby with TGV and aortic arch obstruction, the $DSpO_2$ was not significant. Probably this was due to the complex nature of the defect with single ventricle physiology which resulted in SpO_2 <90% in both pre-ductal and post-ductal areas.

There were two babies in this study with antenatally detected CHD whose SpO_2 screening was positive and echo later confirmed the critical cardiac lesions. This supports Richmond *et al.*'s comment that even if the antenatal diagnosis was not made in these babies, the screening saturation measurement would have triggered the evaluation for CHD [7]. Riede *et al*. stated that in babies with the prenatal diagnosis of CCHD, if medical treatment is initiated soon after birth, SpO_2 will be spuriously high because of medical therapy [8]. Koppel *et al*. have noted that in a center where fetal echocardiography is readily accessible, many lesions will be diagnosed prenatally, and therefore, SpO_2 screening may be less useful in detecting new CCHD. However, centers, where fetal echocardiography is performed less frequently, are likely to demonstrate higher yields from pulse oximetry screening [9].

Although CE is said to miss about 50% of CHD in infants, many studies on CHD screening have included the CE in their

Table 3: Evaluation of the screening test

Variables	Sensitivity (95% CI)	Specificity (95% CI)	PPV (95% CI)	NPV (95% CI)
SpO_2	100 (43.85, 100)	99.9 (99.44, 99.98)	75 (30.06, 95.44)	100 (99.62, 100)
PI	33.33 (6.149, 79.23)	100 (99.62, 100)	100 (20.65, 100)	99.8 (99.28, 99.95)
CE	33.33 (6.149, 79.23)	99.8 (99.28, 99.95)	33.33 (6.149, 79.23)	99.8 (99.28, 99.95)
SpO_2 and PI	100 (43.85, 100)	99.9 (99.44, 99.98)	75 (30.06, 95.44)	100 (99.62, 100)
SpO_2 and CE	100 (43.85, 100)	99.7 (99.13, 99.9)	50 (18.76, 81.24)	100 (99.62,100)
SpO_2, PI and CE	100 (43.85, 100)	99.7 (99.13, 99.9)	50 (18.76, 81.24)	100 (99.62, 100)

SpO_2: Pulse oximeter saturation, PI: Perfusion index, CE: Clinical examination, CI: Confidence interval, PPV: Positive predictive value, NPV: Negative predictive value

protocol [7-10]. In this study, though CE failed to pick up two CCHD, it has identified three screen negative babies with VSD. This stresses the importance of clinical evaluation for CHD in all babies, including the screen negative babies, at least once before discharge. In developing countries, where delay in seeking medical care for sick babies is a common occurrence, early recognition of this non CCHD may also play a key role in influencing CHD related mortality.

Thangaratinam *et al*. on the basis of eight studies have found that in pulse oximeter screening, the summary estimates of sensitivity and specificity were 63% and 99.8%, respectively, yielding a false positive rate of 0.2% [2]. Valmari based on 10 studies found a high specificity (99.9–99.99%), and the overall rate of detection of 15 specified defects with pulse oximetry was 72%, which exceeds that of the CE (58%) [11]. In this study, the diagnostic value of SpO_2 in diagnosing CCHD has a sensitivity of 100%, specificity of 99.9%, and PPV of 75% with the false positivity rate of 25%.

Liske *et al*. have defined CCHD as heart diseases that require intervention or cause death within 1 month of age in contrast to AAP definition of up to 1 year of age [1,3]. The follow-up in this study was limited to 6 weeks of age, as patient compliance with long-term follow-up is poor in this study scenario. Ideally, pulse oximetry and echo have to be done for all babies [12]. However, this is not practically feasible in large community studies. Hence, in most of the studies, authors have done echo only for screen positive cases and have clinically followed the screen negative cases for manifestations of CCHD [4,8].

The study has following limitations: It is a hospital-based study done with small sample size, and clinical follow-up was not available for 15% of babies at 6 weeks of age. Hence, this may not reflect the true screening scenario at the community level. However, this study has tried to address the challenge in identifying left side obstructive heart diseases with pulse oximetry by including PI measurement in the screening protocol.

CONCLUSION

In our study, PI was low in one baby with left-sided obstructive lesion, but due to coexisting single ventricle physiology, SpO_2 was also low. Hence, in this study, there was no difference in the diagnostic accuracy between SpO_2 alone and SpO_2 with PI in screening for CCHD. However, the study was limited by small sample size. Thus, combining PI with SpO_2 may improve CCHD screening using pulse oximeter but large-scale study is needed.

[illegible]

[illegible] Coronavirus disease 2019 (COVID-19), in children has varied clinical presentations from asymptomatic infection to severe pneumonia, multi system inflammatory syndrome in children (MIS-C) and rarely death. To date, limited data has been published on the profile of COVID-19 infection among Indian children. The objective of this study was to analyze the clinical spectrum, laboratory parameters, treatment and it's outcome in children less than 15 years admitted with COVID-19 infection.

[illegible] This was a cross sectional study done in a tertiary care hospital. Children with COVID-19 infection detected by Reverse transcriptase polymerase chain reaction (RT-PCR) were included.

[illegible] Out of 167 children, 93 were males (55.6%) and median (Interquartile range- IQR) age of children admitted were 9 (4-13) years. Family cluster (71%) was the dominant source of infection. Majority were asymptomatic (60%, N=100). The predominant symptoms were fever (29%), cough (16%) and rhinorrhea (4.1%). Seven (4.1%) children had comorbidities and two (28%) among them had moderate to severe disease. Median (IQR) total leucocyte count was 7 (4-10) ×103 µl and platelet count was 390 (275-500) ×103 µl. Leukopenia was observed in 58% (N=81), lymphocytosis in 32.8% (N=46) and thrombocytopenia in 3.5% (N=5). Inflammatory markers were raised in 10-15% of children. Peri-bronchial cuffing was the common abnormality (N=14, 17.5%) in chest X-ray (CXR) and peripheral heterogeneous opacities were noted in severe disease. Children with moderate to severe symptoms were treated with remdesivir and steroids.

[illegible] COVID-19 infection in children was often benign and increased severity was noted among those with comorbidities. Leukopenia, lymphocytosis were commonly observed. High inflammatory markers were noted in severe disease. Nil fatality among our study group.

[illegible] COVID-19, Children, Chest X-ray, Leukopenia, Lymphocytosis, Laboratory profile

[illegible]

In the pre-coronavirus disease-19 (COVID-19) era human coronavirus (HCoV) was one among the causes of bronchiolitis in infants and upper respiratory infection in children.[1] Previous outbreaks of Severe acute respiratory syndrome (SARS) and Middle east respiratory syndrome (MERS) caused by coronavirus were associated with less mortality in children.[2] Similarly COVID-19 which causes severe acute respiratory syndrome (SARS-CoV2) in adults causes milder illness in children. The incidence in children is around 8.7% in below 19 years according to CDC.[3] The hypothesis behind the less severe disease in children being differences in innate and adaptive immunity, pre-existing antibodies to corona virus, more frequent respiratory infections, protective effects of other live vaccines, different expression of angiotensin converting enzyme-2 (ACE-2) receptors and less intense exposure.[4] Very rarely it may lead to Acute respiratory distress syndrome (ARDS), Multi organ dysfunction (MODS) and death. Multi system inflammatory syndrome in children (MIS-C), a post viral immune dysregulation following SARS-

CoV-2 infection is common among children and adolescents which may rarely lead to significant morbidity and mortality if not treated early.[5]

Hematological and biochemical markers of COVID-19 were well studied in adults. This cannot be extrapolated as such for children. The aim of the study was to present the detailed clinical, laboratory profile, treatment and outcome of 167 children below 15 years of age admitted with COVID-19 infection.

M□□□□□□

This was a descriptive observational study and followed the Strengthening the reporting of observational studies in epidemiology (STROBE) guideline.

This study was done at PSG Institute of Medical Sciences and Research hospital which is one of the largest designated tertiary care hospitals in Coimbatore, India which caters to patients from around 250 km radius. Institutional ethics committee approval was obtained. Informed consent was taken from parents or patients included in prospective analysis (N=107) and waiver of consent was obtained for those taken retrospectively (N=60). All children less than 15 years admitted with COVID-19 infection between March 2020 to February 2021 were included in our study. Positive cases were confirmed by Reverse Transcriptase Polymerase Chain Reaction (RT-PCR) validated as per ICMR standards. Both nasopharyngeal and oropharyngeal swabs were taken for confirmation. The severity of illness were categorized into mild, moderate, severe and critical as per the COVID-19 clinical management-Interim guidance.[6] Mild illness is defined as symptomatic COVID-19 positive patients without evidence of pneumonia, moderate as with clinical signs of pneumonia and no signs of hypoxia and severe as clinical signs of pneumonia and SpO_2<90%. Critical disease is with ARDS, sepsis or septic shock and MODS.

Fever was defined when the temperature was >38°C, the source of infection was identified by recording which family member developed the symptoms first. Basic hematological and radiological investigations were taken for most of the patients admitted except in few because of logistical issues. Investigations were repeated in patients showing persistent symptoms.

All the necessary information was collected from electronic records on the hospital database. Chest X-ray findings were analyzed and reported by a single radiologist. Information on baseline demographics, clinical features, symptoms, signs, laboratory reports, imaging, treatment and outcome were recorded. Laboratory values were interpreted with age specific reference ranges. If the patient had a serial investigation for a particular parameter, the highest value was taken into consideration. Asymptomatic and mildly symptomatic children were given supportive care. Those presented with sore throat, fever beyond 3 days, lower respiratory symptoms, pneumonia (confirmed by clinical and radiological signs) were treated with antibiotics. Steroids were used only in severe cases.

Statistical analysis

Data was entered in Microsoft excel (Microsoft corporation, Redmond, USA) sheet and analyzed using SPSS software version 24. Descriptive statistics were used to summarize the data. Continuous variables were described as median and interquartile range. Categorical variables were described as frequencies and percentages. Chi square test was used to assess the relationship between gender and incidence of COVID-19. Mann-Whitney U-test was used to assess the correlation between severity of illness and inflammatory markers. A p value of <0.05 was considered significant.

□□□□□□□

A total of 167 children admitted with COVID-19 positive reports were included in our analysis. The baseline demographic and clinical characteristics of these children are shown in Table 1.□

Demographic and clinical characteristics

The median age (IQR) of children admitted were 9 (4-13 years) and male children (N=93, 55.6%) outnumber females with a male: female ratio of 1.25:1. There was no relationship between gender and incidence of COVID infection in children (p=0.12, Chi square test). Family cluster as the source of infection was identified in 71% (N=119) (Table 1).

Fever was the predominant symptom in 29.3% (N=49) followed by cough (N=27, 16.1%) and rhinorrhea (N=7, 4.1%). Diarrhoea was noted in 3.5%, abdominal pain in 1.1% and loss of taste was present in 1.1%. Very few had fever beyond 24-48 hours after hospital admission. Among the admitted, 7 (4.1%) had preexisting comorbid conditions (Table 2). In them, a child with a germ cell tumor and a hemolytic anemia had moderate to severe illness. More than half were asymptomatic, 38% (N=64) had mild symptoms, 0.5% (N=1) had moderate symptoms and 1.1% (N=2) had severe symptoms. Out of 4 children admitted in ICU, 2 had comorbidities (hemolytic anemia and germ cell tumor) one among them required oxygen support by mask (germ cell tumor), a 2-months-old without any comorbidity had respiratory distress and hypoxemia supported by mechanical ventilation and a child with head injury was admitted for monitoring (Table 3). There was a significant association between comorbidity and severe illness (p=0.014, Fisher's exact test).

Radiological and laboratory finding

CXR was performed in 48% (N=80) of children and out of which 78% (N=63) were normal. Few had prominent

central peri bronchial cuffing (N=14, 17.5%) and peripheral heterogeneous opacities were noted in 3.7% (N=3). CT was done only in patients with moderate to severe illness which showed ground glass opacities (Table 4). On admission, the median (IQR) WBC count was 7 (4-10)×10^3/µl. Leukopenia, lymphopenia and lymphocytosis were noted in 58%, 11.4% and 32.8% respectively. Thrombocytopenia was seen only in 3.5%. Inflammatory markers IL-6, ferritin, D-dimer were raised in 10%, 6% and 13% respectively (Table 5). Moderate to severe group exhibited significantly higher IL-6, ferritin and D-dimer than milder group (p=0.04, p=0.04, p=0.06, Mann-Whitney U-test) (Figure 1-3). Hypoalbuminemia was noted in 3.5% and liver enzymes were elevated in 7-8%.

Treatment and outcome

Intravenous antibiotics and remdesivir were given in 3 children. Steroid was given only in a child with a Germ cell tumor. An infant with severe respiratory distress (0.5%) was treated with mechanical ventilatory support considering High frequency nasal cannula (HFNC) having high aerosolization risk during the initial phase of pandemic. In all others symptomatic treatment was given accordingly. Those with severe illness have recovered and discharged by 2nd to 3rd week of admission. There was nil mortality among our study group (Table 6).

Table 1: Demographic and clinical characteristics of children with COVID-19

Characteristics	n (%)
Median (IQR) age in years	9 (4-13)

□□□□ □ □□□□ □

The main focus of this study was to analyze the clinical, laboratory profile, treatment and it's outcome of 167 children admitted in the designated tertiary care COVID unit which admits children from asymptomatic infection to critical disease. When compared to adults, paediatric age groups were reported with less severe disease. As the schools were closed and outdoor activities were restricted the primary source of infection in children were household contacts. Majority of children in our cohort were asymptomatic (60%), and few had variable severity of symptoms from mild to severe. As per WHO-China joint mission on COVID-19, 2.5% of cases under 19 years had severe infection and 0.2% had critical disease.[7] A large

report from China stated that 10.6% ,7.3% and 4.2% children between 0-1, 1-5, 6-10 years had severe infection respectively.[8] High risk groups for severe infection are infants below 1 year and those with underlying medical conditions like neurological problems, metabolic disorders, congenital heart disease, diabetes, asthma, chronic lung disease, sickle cell disease and obesity.[9] Similarly, in this study a 2-months old infant and a child with comorbidity developed severe disease. Incidence of severe disease among comorbid children was high (14%) in this study. This is in accordance with a systematic review of 42 studies on severe COVID-19 infection where the clinical manifestations were severe in 5.1% of children with comorbidities and 0.2% without comorbidities.[10] Among children admitted in US and Canadian PICU with COVID-19, 83% had pre-existing comorbidities and out of which 73% had respiratory symptoms and 38% required mechanical ventilation.[11] Hence, children with comorbidities need careful monitoring during the first 2 weeks of illness.

Most common symptoms in our patients were fever, cough and rhinorrhoea followed by gastrointestinal symptoms which were consistent with previous reports.[6,12] Dermatological and neurological manifestations were not observed in our children.

Central peri bronchial cuffing was the common CXR abnormality noted in our study. 92% of them with the above finding neither had respiratory symptoms at admission nor during hospital stay. Hence, the central peri bronchial cuffing may be a nonspecific finding and further evaluation may be required only if there are worsening symptoms and signs. Another study from Spain had shown similar findings in CXR in 86% of it's patients.[13] In our study those with peripheral heterogeneous opacity in CXR had significant clinical symptoms and ground glass opacities in CT. This was identical to COVID pneumonia causing diffuse interstitial infiltrates involving the periphery of the lung.[14]

Similar to few meta-analysis and systematic review on COVID-19, leukopenia (58%) and lymphocytosis (32.8%) were most commonly observed in our study.[15] Lymphopenia (11.4%) and thrombocytopenia (3.5%) were comparable to that of study by Meena et al.[12] Though lymphopenia was frequently seen in adults with severe disease and high mortality, it was rarely observed in children. It may be because of milder illnesses in children.[16] Hence, these hematological findings along with clinical features similar to COVID should raise a strong suspicion of COVID-19 infection and it will be a useful predictor for planning treatment in children with moderate to severe illness.[12,16]

Inflammatory markers were raised in 15-25% of our children. Studies found that higher the CRP, IL-6 and ferritin more severe was the disease.[16] Liver enzymes were increased in 7-8% which is consistent with other studies and its prognostic significance is still uncertain.[17]

Children with severe infection can develop serious complications like acute respiratory distress syndrome, renal failure, myocarditis, shock, acute renal failure, coagulopathy, MODS and later MIS-C. In our study population only a single child developed respiratory failure and none had MODS. Antivirals and steroids were used in very few. Guidelines on COVID-19 treatment in children evolved only later and most were extrapolated from adult studies during our study period. Two children were readmitted with MIS-C manifestations after 3-4 weeks and both had very minimal symptoms during the 1st admission. More studies are needed to determine the children at risk for MIS-C. No mortality was encountered among the admissions in our study.

Hence our present study included the majority of asymptomatic children, these clinical and laboratory data may be helpful in supporting COVID-19 diagnosis in children when diagnostic tests are not available and it provides the true representation of disease spectrum of paediatric population. Limitations of this study was small sample size and single centre study.

□□□□□□□□□

COVID-19 infection was milder among the majority. Infants and children with comorbidities had increased risk of severe disease. Inflammatory markers were helpful in predicting the severity of illness. Antivirals and steroids were needed in very few children. Since the disease has many new variants it might present differently in future. Hence, clinicians need to have a high index of suspicion for early diagnosis and management to have a good outcome and recovery.

□□□□□□ □□□□□M□□□□□

We thank the entire COVID-19 team along with their subordinates for their effortless management and for their contribution of data and radiologist for reporting the X-ray and CT.

Clinical spectrum and short-term outcomes of multisystem inflammatory syndrome in children in a south Indian hospital

Muruganantham Balagurunathan, MD*, Thrilok Natarajan, MD, MRCPCH (UK)*, Jothilakshmi Karthikeyan, DNB, Venkateshwaran Palanisamy, MD

Department of Pediatrics, PSG Institute of Medical Sciences and Research, Tamilnadu, India

Background: Multisystem inflammatory syndrome in children (MIS-C) is a new hyperinflammatory variant that evolved during the coronavirus disease 2019 pandemic. Although the precise pathophysiology of MIS-C is uncertain, it is thought to be due to immune dysregulation occurring after recovery from acute infection.

Purpose: Our study aimed to analyze the clinical spectrum, laboratory parameters, imaging characteristics, treatment strategies, and short-term outcomes of children with a diagnosis of MIS-C.

Methods: This retrospective and prospective observational study included children less than 16 years of age who were admitted to the pediatric unit of a tertiary care teaching hospital in south India between August 2020 to January 2021 with a diagnosis of MIS-C according to World Health Organization criteria.

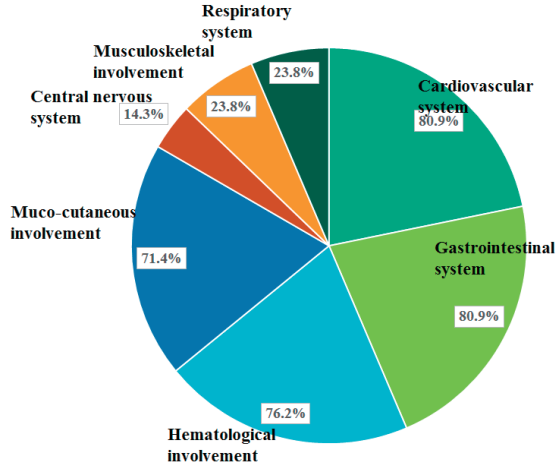
Results: Twenty-one children were included in the analysis; all had fever with variable combinations of other symptoms. The mean age was 6.9 years; 71.4% were male. Gastrointestinal (80.9%) and cardiovascular (80.9%) systems were the most commonly affected. The majority of children had elevated inflammatory markers, and 16 (76.2%) had echocardiographic abnormalities mimicking Kawasaki disease. Eleven children (52.4%) required intensive care admission, 3 (14.3%) required supplemental oxygen, and 4 (19%) required inotropes. Nine (42.9%) were treated with intravenous immunoglobulin alone, 6 (28.6%) with steroids alone, and 3 (14.3%) with steroids and immunoglobulin. The median hospital stay was 6 days; there were no fatalities. Overweight/obesity, elevated ferritin, and mucocutaneous involvement were significantly associated with a prolonged hospital stay (≥7 days). Sixteen children (76.2%) were followed up till now and all of them had no clinical concerns.

Conclusion: MIS-C is an emerging disease with variable presentation. A high index of suspicion is necessary for its early identification and appropriate management. Further research is essential for developing optimal treatment strategies.

Key words: Clinical spectrum, Coronavirus disease 2019, Kawasaki disease, Multisystem inflammatory syndrome in children

Key message

- **Question:** What are the clinical spectrum, course, and short-term outcomes of multisystem inflammatory syndrome in children (MIS-C)?
- **Finding:** MIS-C can have variable clinical manifestations. Fever is most common, followed by gastrointestinal and cardiovascular symptoms. Early identification and appropriate management lead to favorable outcomes.
- **Meaning:** MIS-C can present in a myriad of ways and severities. High suspicion is necessary to ensure its early identification and appropriate management and favorable patient outcomes.



Introduction

The coronavirus disease 2019 (COVID-19) pandemic in India is a part of the global pandemic caused by severe acute respiratory syndrome corona virus-2 (SARS-CoV-2). India is one of the countries with the highest burden of confirmed COVID-19 cases in the world and ranks second in the list of countries with a maximum number of cases.[1] Earlier reports suggested that children infected with COVID-19 were highly resilient and could present with only a mild upper respiratory illness.[2-4] But in April 2020, clinicians in the United Kingdom reported a cluster of previously healthy children presenting with shock, fever, and hyper inflammation.[5] The Royal College of Paediatrics and Child Health referred to this acute condition as pediatric inflammatory multisystem syndrome temporally associated with SARS-CoV-2.[6] As the pandemic progressed and the number of such cases increased globally the illness was labelled as multisystem inflammatory syndrome in children (MIS-C) by the Centers for Disease Control and Prevention and

Graphical abstract

the World Health Organization (WHO).[7,8] Although the exact pathophysiology of MIS-C is uncertain, it is thought to be due to immune dysregulation occurring after recovery from acute infection. As the burden of COVID-19 infection is increasing in India, more children are being recognized with this condition. Although many articles are reported from western countries there is a dearth of published reports from Asian countries.

Our study aimed at analyzing the clinical spectrum, laboratory parameters, and imaging characteristics of children less than 16 years admitted with a diagnosis of MIS-C. In addition, this study aimed to analyze the treatment strategies and short-term outcomes.

Methods

1. Study design and setting

This study was a partly retrospective and partly prospective observational study done in children admitted with a diagnosis of MIS-C in a tertiary care teaching hospital in south India from August 2020 to January 2021. The hospital is one of the largest COVID-19 care centers in south India and receives referrals from a radius of 200 kilometers. The study was approved by the Institutional Human Ethics Committee of PSGIMS&R (project No. 20/262 dated 27th November, 2020). Informed written consent was obtained from parents prior to the inclusion of children in the prospective part of the study. Waiver of consent was obtained for the retrospective collection of data.

2. Participants

Children less than 16 years of age diagnosed with MIS-C as per WHO criteria were included in the study. The following parameters were considered for diagnosis: (1) fever ≥3 days, (2) 2 of the following: a) rash or bilateral nonpurulent conjunctivitis or mucocutaneous inflammation signs (oral mucosa, hands, or feet), b) hypotension or shock, c) features of myocardial dysfunction, pericarditis, valvulitis, or coronary abnormalities (including echocardiography findings or elevated troponin/N-terminal pro-B-type natriuretic peptide [NT-proBNP]), d) evidence of coagulopathy (by prothrombin time, partial thromboplastin time, elevated D-dimers), e) Acute gastrointestinal problems [diarrhea, vomiting, or abdominal pain], (3) elevated markers of inflammation such as erythrocyte sedimentation rate, C-reactive protein, or procalcitonin, (4) no other obvious microbial cause of inflammation, including bacterial sepsis, staphylococcal or streptococcal toxic shock syndromes, (5) evidence of COVID-19 (real-time reverse transcription polymerase chain reaction [RT-PCR], antigen test or serology positive), or likely contact with patients with COVID-19.

3. Data collection

Data on demographics, clinical features, laboratory results, imaging studies, treatment details, outcomes, and follow-up were collected. All the investigations and treatment were carried out as per institutional protocol and treating physician's discretion.

COVID-19 infection was confirmed by testing for SARS-CoV-2 antibody by chemiluminescence immunoassay (VITROS 3600 immunodiagnostic system, Ortho Clinical Diagnostics, Raritan, NJ, USA) and/or RT-PCR as recommended by Indian Council of Medical Research. The laboratory values were interpreted as either increased or decreased based on the age-specific normal reference ranges. Organ system involvement was described based on clinical features, laboratory reports, and imaging studies. Echocardiography was performed in all children by the pediatric cardiologist to identify the following abnormalities; (a) left ventricular dysfunction (ejection fraction

less than 55%), (b) pericarditis or pericardial effusion, (c) coronary artery abnormalities (dilatation, aneurysm, or irregular nontapering coronary arteries), or (d) valvular regurgitation. The dimension of the coronary artery was measured as per standard criteria and a coronary z score above 2 was reported as dilated. Other imaging studies were done as clinically indicated.

4. Statistical analysis

Data analysis was done using Microsoft Excel 2019 (Microsoft Corp., Redmond, WA, USA). Descriptive statistics were used to summarize population characteristics. Categorical variables were expressed as frequency or percentage and continuous variables were expressed as mean with standard deviation or median with interquartile range. IBM SPSS Statistics ver. 26.0 (IBM Co., Armonk, NY, USA) was used to perform univariate analysis and a *P* value of <0.05 was considered significant.

Results

From August 2020 to January 2021, twenty-one children met the WHO MIS-C criteria and were included in the analysis. Among them, only 2 children were admitted with active coronavirus-2 infection and were subsequently diagnosed as MIS-C. The demographic and clinical characteristics of the study population are mentioned in Table 1. The mean age of the study population was 6.9 years and 71.4% were male. All children were previously healthy and 9.5% were either obese or overweight.

All patients had fever with a variable combination of other symptoms. Gastrointestinal symptoms like abdominal pain, diarrhea, and vomiting were the most common presenting symptoms. The mean duration of symptoms prior to admission was 4.8 days and the mean total duration of fever was 7.9 days. The majority of children in this series had multiorgan involvement. Gastrointestinal (80.9%) and cardiovascular (80.9 %) systems were the most commonly affected organ systems. This was followed by hematological (76.2%), mucocutaneous (71.4%), and central nervous system (14.2%) involvement. None of the children had acute kidney injury in this series. Two children in this series had been treated for COVID-19 3 weeks prior to the diagnosis of MIS-C, and 5 children had history of confirmed exposure to COVID-19 patients in the preceding 3 to 4 weeks. In other children, no history associated with COVID-19 was revealed.

In the study population, 19 children (90.4%) had positive COVID-19 antibody tests, 1 (4.8%) had positive COVID-19 RT-PCR test, and another (4.8%) had both positive COVID-19 RT-PCR and antibody tests. The results of laboratory tests and imaging studies are summarized in Tables 2 and 3. Lymphopenia and thrombocytopenia were seen in 47.6% and 38.1% of cases, respectively. Inflammatory markers were elevated in the majority of cases. Specifically, D-dimer and interleukin 6 (IL-6) were elevated in 95.2% and 90.5% of cases, respectively. Children with cardiovascular system involvement showed elevation of

Thrombocytosis	6/21 (28.6)	Platelet >500×10^3 cells/mm^3
Inflammatory markers		
Elevated ESR	17/20 (85)	≥40 mm/hr
Elevated CRP	20/20 (100)	≥0.6 mg/dL
Elevated procalcitonin	5/5 (100)	≥0.5 ng/mL
Elevated ferritin	9/21 (42.9)	>500 ng/mL
Elevated IL-6	19/21 (90.5)	≥7 pg/mL
Elevated LDH	11/16 (68.8)	LDH >300 U/L
Electrolytes		
Hyponatremia	12/17 (70.6)	Sodium <135 mEq/L
Hypokalemia	8/17 (47.1)	Potassium <3.5 mEq/L
Liver function test		
Elevated AST	6/17 (35.3)	AST >40 U/L
Elevated ALT	5/17 (29.4)	ALT >40 U/L
Hypoalbuminemia	9/17 (52.9)	Albumin <3 g/dL
Cardiac biomarkers		
Elevated troponin-T	4/13 (30.8)	≥14 pg/mL
Elevated NT-proBNP	12/15 (80)	>450 pg/mL
Coagulation profile		
Elevated D-dimer	20/21 (95.2)	≥0.5 mg/L FEU
Deranged coagulation	2/8 (25)	INR ≥1.2

Hb, hemoglobin; ANC, absolute neutrophil counts; ALC, absolute lymphocyte counts; ESR, erythrocyte sedimentation rate; CRP, C-reactive protein; IL, interleukin; LDH, lactate dehydrogenase; AST, aspartate aminotransferase; ALT, alanine aminotransferase; NT-proBNP, N-terminal prohormone of brain natriuretic peptide; FEU, fibrinogen equivalent units; INR, international normalized ratio.

cardiac biomarkers, and NT-proBNP (80%) was found to be more commonly elevated than troponin-T (30.8%). Electrolyte imbalances like hyponatremia and hypokalemia were seen in 70.6% and 47.1% of cases, respectively, which were managed appropriately.

Echocardiography was performed in all the children, and abnormality was noted in 16 children (76.2%). A greater number of children had a combination of abnormalities rather than a single abnormal finding. Coronary artery abnormality (57.1%) was the most common finding, followed by pericardial effusion (52.4%), left ventricular dysfunction (23.8%), and mitral regurgitation (23.8%). Gastrointestinal imaging studies like x-ray, ultrasound, and computed tomography were done as indicated, and ascites (50%) was the most common abnormality, followed by dilated bowel loops (35.7%), and mesenteric lymphadenitis (35.7%). Of the 17 patients who underwent chest imaging (x-ray or computed tomography), pleural effusion and lung infiltrates were observed in 3 (17.6%) and 1 patient (5.9%),

PICU, pediatric intensive care unit; IQR, interquartile range.

respectively. Of the 3 children with central nervous system involvement, 1 had encephalopathy with features of cerebellar involvement, 1 had seizures, and another had headache with bilateral papilledema. All 3 children with central nervous system involvement showed normal neuroimaging. Two children underwent cerebrospinal fluid analysis, and findings of aseptic meningitis were seen in the patient who presented with encephalopathy.

Treatment details and outcomes are summarized in Table 4. Eleven children (52.4%) required pediatric intensive care unit (PICU) admission and the mean duration of PICU stay was 74.8 hours. Three children (14.3%) required supplemental oxygen, and none of the children required mechanical ventilation. Four children (19%) required inotropic support for hemodynamic instability, and the mean duration of inotrope requirement was 37 hours. Nine children (42.9%) were treated with intravenous immunoglobulin (IVIG) alone, 6 (28.6%) were treated with steroids alone and 3 (14.3%) were treated with both IVIG and steroids. None of the cases required other immunomodulators for treatment.

An 8-year-old girl presented with features of acute appendicitis, and an emergency surgery was done, which revealed a perforated appendix with abscess collection. She was subsequently diagnosed as MIS-C and was treated with IVIG.

The median length of hospitalization was 6 days in this series. Table 5 shows the results of univariate analysis for prolonged hospital stay (≥7 days). Children who were either overweight or obese (P=0.035), had elevated ferritin (P=0.019), or had mucocutaneous involvement (P=0.040) were found to be significantly associated with prolonged hospital stay. Further extensive analysis could not be performed due to small sample size. There was no mortality in patients of our study, and all patients were discharged home. At the time of writing this article, 16 patients (76.2%) had attended follow-up visits.

Table 5. Results of univariate analysis of factors associated with prolonged hospital stay (n=21)

Variable	Hospital stay<7 days (n=14), n (%)	Hospital stay≥7 days (n=7), n (%)	*P* value	OR (95% CI)

Table 6. Common clinical characteristics in our study versus those of other studies

Clinical feature	Our study (n=21)	Whittaker et al.[10] (n=58)	Dhanalakshmi et al.[11] (n=19)
Fever	21 (100)	58 (100)	19 (100)
Vomiting	12 (57.1)	26 (45)	6 (31.5)
Abdominal pain	11 (52.4)	31 (53)	8 (42)
Diarrhea	11 (52.4)	30 (52)	3 (15.8)
Rash	8 (38.1)	30 (52)	12 (63.2)
Bilateral conjunctival congestion	12 (57.1)	26 (45)	9 (47.4)
Cervical lymphadenopathy	3 (14.3)	9 (16)	6 (31.5)
Strawberry tongue±cracked lips	7 (33.3)	17 (29)	9 (47.4)
Oedema/erythema of hands and feet	6 (28.6)	9 (16)	10 (52.6)

Values are presented as number (%).

Among them, 11 children (52.4%) had attended one follow-up visit, and 5 (23.8%) had attended 2 follow-up visits, all of whom had no clinical concerns. Among 16 children with abnormal echocardiography, 12 (75%) underwent follow-up echocardiography, and their cardiac imaging showed partial or complete resolution of previous abnormalities. Further follow-up echocardiography was recommended to some of them.

Discussion

MIS-C is an evolving concept of disease and its exact incidences in different geographic areas are uncertain. The focus of this study was to analyze the clinical spectrum and short-term outcomes of children with MIS-C managed in a tertiary care teaching hospital in south India. We described 21 children under the age of 16 years with MIS-C associated with SARS-CoV-2 infection. All these children had evidences of previous or active COVID-19 infection. The spectrum of clinical presentations in our study was broadly consistent with available literatures. The mean age of children in this study was 6.9 years, and 61.9% of affected children were above 5 years, which was similar to studies by Kaushik et al.,[9] Whittaker et al.,[10] and Dhanalakshmi et al.[11] The male preponderance in this study was also identical to previous reports by Kaushik et al.,[9] Whittaker et al.,[10] and Gupta et al.[12] Table 6 shows the comparison between common clinical features of children in this study and 2 previous studies.[10,11] Concordant to previous reports, a greater number of children in our series had multiorgan involvement with gastrointestinal and cardiovascular systems being the most commonly affected systems.[11,13-15]

The incidence of hematological abnormalities like lymphopenia (47.6%) and thrombocytopenia (38.1%) in our study was in agreement with previous reports.[11,14,16] The majority of children in this study had raised inflammatory markers, which was similar to previous reports by Kaushik et al.,[9] Dhanalakshmi et al.,[11] Feldstein et al.,[13] and Mamishi et al.[16] In contrast to previous studies by Dhanalakshmi et al.,[11] Feldstein et al.,[13] Toubiana et al.,[15] and Miller et al.,[17] none of the children in this series had acute kidney injury. The incidence of hyponatremia (70.6%) in this study was higher than in previous reports by Dhanalakshmi et al.[1] and Mamishi et al.[16] Hypokalemia was found in 47.1% of children, and it was more common in children with gastrointestinal manifestations, which was not reported in any previous studies. Hypoalbuminemia was noted in 52.9% of children in this study, which was almost similar to previous reports by Dhanalakshmi et al.[1] and Mamishi et al.[16] The elevation of cardiac biomarkers was also concordant to previous reports by Whittaker et al.[10] and Mamishi et al.[16] The incidence of echocardiographic abnormalities in this study was comparable to previous reports by Ramcharan et al.[15] and Toubiana et al.[18] The abnormalities seen in gastrointestinal imaging studies in this study were comparable to the previous report by Miller et al.[17]

Since MIS-C is an emerging disease, guidelines regarding the management are still evolving and there is a lack of consistency in management. The majority of patients in our study were treated with either IVIG, steroids, or a combination of both and, none required other immunomodulators. The treatment decision for the patients in our study was made based on severity of the illness and the treating physician's discretion. Significant differences in treatment strategies were noted among studies from different parts of the world, which could be due to lack of standard treatment protocols in the initial phase of disease evolution.[9-11,14,16] However, a considerable number of studies would be required for developing standard treatment protocols. Concordant to previous reports by Torres et al.[14] and Dhanalakshmi et al.,[11] 52.4% of children in this series required PICU admission. The median length of hospital stay was 6 days which was comparable to previous reports.[9,14,15] Although previous studies showed variable rates of mortality, no death was reported in this study.[11,14,15,17] The follow-up rate in this study was 76.2%. All children had no health concerns at the time of follow-up, and most echocardiographic abnormalities had resolved. However, these children should be followed up at regular intervals to know the long-term consequences of the disease.

A major limitation of this study is that it was conducted in a single center over a limited period of time, and has a small sample size. Another limitation is that this study only included children under the age of 16 years, because our institutional policy defined children under 16 years to be admitted to the pediatric department. It might have missed MIS-C patients older than 16

years of age.

In conclusion, MIS-C is a novel disease that can present in a myriad of ways with variable severity, and a high index of suspicion is necessary in this era of COVID-19 pandemic for early identification, appropriate management, and favorable outcomes of patients. Further research is essential to develop optimal treatment strategies.

Sublingual Ulceration Due to Natal Tooth – Riga – Fedes Disease.

KEYWORDS: Riga – Fede's disease, natal tooth, sublingual ulceration

P VENKATESHWARAN	Dr.N.T.Rajesh	Dr.Pavai Arunachalam
Associate Professor of Pediatrics, PSG Institute of Medical Sciences and Research, Peelamedu, Coimbatore-641004	Associate Professor of Pediatrics, PSG Institute of Medical Sciences and Research, Peelamedu, Coimbatore-641004	Professor of Pediatrics, PSG Institute of Medical Sciences and Research, Peelamedu, Coimbatore-641004

INTRODUCTION :

Ulceration on ventral surface of the tongue in newborn is most commonly associated with trauma by Natal (or) Neonatal tooth.[1,2] It is due to forward and backward movement of the tongue over the primary teeth. In older children ulceration occurs after eruption of primary lower incisors with repetitive tongue thrusting habits.[3] Neurological disorders like familial dysautonomia (insensitive to pain)[4] will also be associated with above such lesions.

The lesion usually begins as ulceration on ventral surface of tongue with repeated trauma. It may progress to fibrous enlarged ulcerative granulomatous mass. But its nature is relatively benign and seldom requires histopathological examination. It will be brought to the Pediatrician's attention since it interferes with sucking,feeding leading on to nutritional deficiency risk for the neonate.

This case is reported to recognize this entity to prevent unnecessary workups and invasive procedures.

Case report:

A 22–days-old term neonate was brought with complaints of difficulty and excessive irritability while breast feeding. The mother noticed an ulcer beneath the tongue (figure -1) for the past 3 days before she came to us and can't able to feed her baby properly. On examination there was a sharp natal tooth in the place of mandibular central incisor ,whitish in colour causing a deep ulceration 20 x 10 mm in the ventral aspect of the tongue extending from anterior border to frenulum with white fibrinopurulent membrane and surrounding erythema(figure 2). Tenderness was noted on gentle digital palpation. There was no other intraoral mucosal lesions. There was no family history of such lesions and was negative of congenital syndromes, neurological disorders and disorders in development .

A diagnosis of Riga – Fedes disease (RFD) was made and the tooth was extracted under topical local anesthesia. The ulcer has healed remarkably well after 3 weeks of extraction and the feeding was reestablished.

Discussion :

Teeth eruption at birth was reported age old in many medical as well as dental literature.[5] These entities have been coined as 'Natal teeth', 'Neonatal teeth', 'congenital teeth' (or) Precocious dentition by Mayhall and Baderhoff.[6,7] The most accepted terminology in present literature has been defined by Massler and Savara.[8] Natal teeth indicates the teeth present in oral cavity at birth and 'neonatal teeth' those which erupt during the neonatal period ie from birth to thirtieth day of life.

RFD is observed in 6 to 10 percent of neonates with natal tooth and it is most commonly with its sharp nature. These ulcerations interfere with proper suckling and feeding and put the neonates at risk for nutritional deficiencies resulting in failure to thrive.

This lesion was first described by Antonio Riga, an Italian Physician in 1881 and Fede, an Italian Pediatrician published its histopathological studies in 1890 [3] and subsequently it has been known as " Riga-Fedes disease".

Another entity described by Elzay in 1983, ' traumatic ulcerative granuloma with stromal eosinophilia' (TUGSE) with similar histopathological features like RigaFedes disease[9].TUGSE is reported mostly in late adulthood and not restricted only to tongue also to buccal mucosa , vestibule, gingiva (or) palate. But Riga Fedes disease has been reported as exclusively restricted to the tongue. In our case, the lesion is restricted mainly to tongue and no other mucosal lesions anywhere.

Neurological disorder association has been described by Domingues - Cruz et al classifying it into " Precocious Riga Fede disease" in first 6 months with no neurological disorders and "late Riga Fede disease "after 6-8 months after primary dentition with possible relationship to neurologic disease.

Treatment modalities of Riga- Fedes has varied over years from extraction of the tooth and curettage of underlying Dental papilla which is the standard way of care to other conservative therapeutic options like Grinding (or) discing the sharp edges (or) coverage of the tooth with light-cured composite resin.[10,11]

In our case, since the ulcer area was large and denuded and interferes with suckling & feeding the tooth has been extracted.

On follow up the lesion has healed well and the feeding was normally established.

Antibiotic Prophylaxis and Surgical Site Infection

S. Karthikeyan*, Priya**, Vimal Raj**, Sivaprasanna***, Akash***

*Professor **Assistant Professor ***Resident, Dept. of General Surgery, PSG Hospitals, Coimbatore.

Abstract

Background: Surgical Site Infection rate is an important health care index. Prophylactic antibiotics have been used to prevent surgical site infections. A continuous surveillance is called for to keep a check on the resistance pattern of microbes to the prophylactic antibiotic.

Objectives:

1. To estimate the Rate of Surgical Site Infections in the years 2014 and 2015 with reference to CDC guidelines at a tertiary care hospital (PSGIMS&R) located in Tamil Nadu, Southern India
2. To estimate the frequency of various organisms causing Surgical Site Infections
3. To study the antibiotic resistance pattern to the prophylactic antibiotic used.

Type of Study: Retrospective Observational study

Period of Study: January 2014 – December 2015

Methodology: The present study was conducted in PSG Institute of Medical Sciences & Research, Coimbatore. We did a thorough retrospective analysis of case files of 467patients reported to have culture positive SSI. SSI was established using clinical and Standard microbiological testing.

Results: The outcome of this study is that the SSI rate of 4.9% reported in our hospital is consistent with or less than the rates reported in other parts of the country. Diabetes is a very important comorbidity which makes the person significantly vulnerable to SSI. In culture positive cases 24.4% of SSI showed resistance to the prophylactic antibiotic used.

Conclusion: There is a significant rise in incidence of organisms exhibiting resistance to the prophylactic antibiotic and a constant surveillance with feedback to the surgeons and strict adherence to antibiotic policies is essential.

Keywords: Surgical Site Infection Rate; Prophylactic Antibiotics; Diabetes Mellitus; Surveillance.

Introduction

Surgical Site Infections (SSI) are those which occur in the wound created by invasive surgical procedures. Historically they were called 'Irritative Fevers' [1] before the era of antisepsis brought about by Joseph Lister. These 'fevers' were uniformly lethal and so dreaded by all surgeons. They are an important cause of Healthcare associated infections. They continue to be an important health hazard even in hospitals with standard protocols of preoperative preparation and prophylactic antibiotic usage. Their prevalence is usually underestimated [2] owing to the occurrence of many of these infections after the patient has been discharged from the hospital. The spectrum of SSI can range from a simple wound discharge to life threatening sepsis. The incidence of SSI in India is estimated [3] to be around 11% at tertiary care centers.

The present study was aimed at obtaining theincidence of surgical site infections and determining the role of Diabetes Mellitus as an

ABSTRACT

Background: Since a long time, skin incisions have routinely been made with scalpels. Now a days there is a shift in trend from this method to electrosurgical skin incisions. However, fear of bad scars and improper wound healing has prevented its wide spread use. The aim of the study was to compare the Diathermy versus Scalpel skin incision in elective hernia surgeries with regards to post-operative pain, post-operative wound infection rate and wound healing.
Methods: A total of 200 patients were taken for this study. 100 patients underwent diathermy incision (group A) who were compared with 100 scalpel incision patients (group B). Variables used in this study were postoperative pain, wound infection and scar.
Results: Patients with diathermy skin incision were having less post-operative pain which was assessed by visual analogue scale when compared with scalpel incision since the p value was 0.01 which is significant (<0.05). The postoperative infection rate and scar were comparable in both the groups since the p-value is >0.05 in each which is insignificant.
Conclusions: Diathermy incisions are therefore less harmful to the skin. It has got more advantages than scalpel incisions like less postoperative pain.

Keywords: Electrosurgery, ESU, Monopolar, Surgical site infections, Visual analogue scale

INTRODUCTION

Surgical incisions are usually made with scalpel. Usage of scalpel, usually results in skin bleeding which obscure the operating field resulting in wastage of operating time. Other alternative in making surgical incision is diathermy. Diathermy is mainly used for tissue dissection and hemostasis.[1] Usually skin incision by diathermy is avoided due to fear of deeps burn, poor wound healing and excessive scarring. These presumptions stem from experimental and clinical studies that yielded varied reports.[2,3] Modern electrosurgical units capable of delivering pure sinusoidal currents have evolved a change in this concept. The advantages are rapid hemostasis, faster dissection, and a reduced overall operative blood loss.[4,5] Majority of studies had compared electrocautery and scalpel incision in terms of wound infection, postoperative pain, blood loss, duration of healing and postoperative wound complication in only selected groups of patients with the exclusion of patients with medical co-morbidities.

No single study to date has focused on diathermy incisions in elective surgical cases exclusively so as to figure out the post-operative wound infection rate. This study was conducted to compare diathermy and scalpel incisions in terms of postoperative pain, wound healing i.e. scar character and postoperative wound infection.

ABSTRACT

Background: Lateral internal sphincterotomy is the only choice in the treatment of the fissure in ano. Complete and partial sphincterotomy was followed in variable individuals. But post-operative complication like incontinence, early mobilization and early recovery is to be made into account for best results among these patients.
Methods: This study is made in 2015-2016 period among 52 patients with chronic fissure in ano, partial sphincterotomy i.e., division of internal sphincter below the dentate line was performed. Post-operative follows up and symptoms were recorded, in such cases treated adequately. The period of revisit was decided according to patient compliance 1 month, 3months, 6 months. The data was collected prospectively and recorded in view of change in the treatment.
Results: 47 of the patients were pain free within first 5 days of surgery. Remaining 5 patients required further division for pain relief due to persistent pain after 3 weeks. The associated post-operative complication among these patients was itching due to burning sensation in and around the anus which resolved later. None among these patients developed fecal incontinence.
Conclusions: Among all age group of the patients included in this study were subjected to same type of the procedure and results were recorded to give better prognosis with lowest degree of recurrence for which repeat of the same procedure gave the complete relief. Lateral internal partial sphincterotomy is an effective technique for complete relief of pain in chronic fissure in ano.

Keywords: Chronic fissure in ano, Earlymobilisation, Lateral internal partial sphincterotomy

INTRODUCTION

Chronic fissure in ano is very common in all age group of people due to present days hi-fi method of food habits, modified life style and inborn errors of health conscience. The present generation is more moribund on the development of technology and work styles of these techis are tedious. Requirement of the remedies are long standing, permanent and symptom or complication free. Early mobilization after any procedure is the only way out for earned population. In the development of the internet medicine access leads to the attitude of clearance of the physician doubts. Based on the above wide range of criteria among these lies the choice of the treatment to be very selective and preferably high in placement of the best treatment for them.

Lateral internal sphincterotomy is the only choice in the treatment of the fissure in ano. Complete Sphincterotomy and partial sphincterotomy was followed in variable individuals.[1,2] But post-operative complication like incontinence is to be made into account for the follow up

Abstract
Aim: *To identify the various clinical presentations and the complications of upper 1/3rd Ureteric calculus, To study the most common type of stone in upper 1/3rd ureter(stone analysis). To study the difference and relative advantage of different treatment modalities so that an appropriate treatment regimen can be instituted for the patient and further complications may be prevented.*
Materials and Methods: *Prospective study of 100 patients diagnosed to have upper ureteric calculi at Kempegowda Institute Of Medical Sciences Hospital, Bangalore from October 2014 to August 2016 and of them 74 underwent operative procedure for upper ureteric calculi. Data was analysed using descriptive statistics and chi-square test.*
Results: *Results were analysed among who underwent operative procedure in different ascepts like, Age (mean age=43.59), Incidence (M>F), dietary habits (mixed diet> veg diet), site of pain (U/L>B/L), complications, need for ESWL(19), different operatives modalities followed by stone analysis.*
Conclusion: *the incidence of urolithiasis has increased drastically, probably due to modern lifestyle and dietary habits and shift in the age distribution of Urolithiasis in recent times. There is an increased number of patients suffering fromthis condition in younger age group. Shift in gender distribution of urolithiasis with age, especially in females in post-menopausal period.*

Introduction

Urolithiasis is one of the common cause for morbidity in modern society. The lifetime prevalence of kidney stone disease is estimated at 1% to 15%, varying according to age, gender, race, and geographic location with the most recent prevalence estimate of 8.8%.[1] It has been suggested that the rise in stone incidence and prevalence seen in the worldwide can be attributed in part to a rise in the detection of asymptomatic calculi through increased utilization of radiographic imaging, particularly computed tomography.[2,3] Edvardsson and colleagues (2013) found that the annual incidence of symptomatic stones did not increase significantly, despite significant increases in the incidence of asymptomatic stones in both genders (from 7 to 24 per 100,000 in men, P < .001, and from 7 to 21 per 100,000 in women< .001).

Manikandan Kathirvel, Ajay Sivakumar, Jayalakshmi Jayarajan et al. Diabetic Foot Ulcer and Multidrug-Resistant Organisms: Prevalence and Bacteriological Profile. New Indian J Surg. 2018;9(4):455-58.

Abstract

Aim: To study the prevalence and bacteriological profile of multi-drug resistant organism (MDRO) infection in diabetic foot ulcers. *Methods:* 150 Diabetic patients with foot ulcer were prospectively studied. Detailed clinical history and clinical examination of the ulcer were done for all patients. The microbiological profile was analysed, in detail, for each patient. The multi-drug resistant organisms (MDRO) were identified, using internationally accepted criteria. *Results:* 153 MDROs were isolated, out of a total of 279 organisms (54.8%). These were isolated from 99 out of 150 patients (66%). The commonest MDRO isolated was *Escherechia coli*, followed by *Pseudomonas aeruginosa*. *Conclusion:* The prevalence of MDRO is alarmingly high in infected diabetic foot ulcers.

Keywords: Diabetic Foot Ulcer; Multi-Drug Resistant Organisms (MDRO).

Introduction

Foot ulceration is a major cause of morbidity in diabetes mellitus. It is said that a sixth of all patients with diabetes mellitus develop foot ulcers at some point in their lifetime [1]. Infections in diabetic foot ulcers have become increasingly difficult to treat, because of the emergence of multi drug resistant organisms (MDRO). In the past, the problem of MDRO was less well understood, because of a lack of uniform définition of MDRO. This study was done, as very few studies have been done in India to analyse the prevalence of MDRO in diabetic foot ulcers.

Patients and Methods

Conducted between January 2011 and July 2012 at PSG Institute of Medical Sciences & Research, Coimbatore, India, this is a prospective observational study to find the prevalence of MDRO in diabetic foot ulcers. Prior approval from the institution review board was obtained. 150 diabetic patients with foot lesions were included in the study. Written informed consents were obtained from the patients. Detailed clinical history of the patient and other relevant data were collected using structured case report forms.

Wound swabs were obtained from the floor of the ulcer, before starting on empirical antibiotic therapy. Direct microscopic examination and aerobic cultures were done by standard methods. The bacteriological spectrum and the sensitive antibiotics were noted for each patient. MDROs were identified using the ECDC and CDC criteria [2].

Results

Seventy Eight percent (78%) of the patients were 51 years or older, with the average age being 58.21. 74.6% of the patients were males. Almost all the patients had Type II diabetes, with only 4% of them having Type I. Only 19.33% of patients had a good glycaemic control, with HbA1c 6–7%. 40 % of patients with foot ulcer had diabetes for less than 5 yrs.

Sixty eight percent (68%) of patients had ulcers of less than one month duration. Most of the patients had Wagner's grade II, III, or IV ulcers. There were very few

S. Karthikeyan, Subbaiah S., Vimal Raj et al. Analysis of Antibiotic Therapy in Acute Severe Pancreatitis. New Indian J Surg. 2018;9(3):323-27.

Abstract

Background: Acute Pancreatitis is a common surgical entity that is increasing in incidence. Gallstones and alcohol consumption remain the major contributors of Acute pancreatitis. The disease usually follows a prolonged course with increased hospital stay, early and late complications contributing to increased patient morbidity and mortality. Traditionally the role of antibiotics is usually limited to severe necrotising pancreatitis. There is however increasing evidence to prove the role of antibiotic therapy in reducing mortality and long term morbidity in acute pancreatitis patients.

Objectives:

1. To retrospectively analyse antibiotic therapy in patients with Acute severe pancreatitis in the years 2014 - 2017 in the tertiary care hospital PSG IMSR located in Coimbatore, Tamilnadu, India
2. To analyse the role of antibiotics in patient prognosis and outcome

Type of study: Retrospective Observational study. *Duration of study*: January 2014-January 2017. *Methodology:* The present study was conducted in PSG Institute of Medical Sciences & Research, Coimbatore. We did a thorough retrospective analysis of case files of 900 patients with acute severe pancreatitis. Analysing the available data from case files. *Results*: Of 900 patients, 411satisfied the inclusion criteris, of these 63% (n=258) of patients were started antibiotics within 48 hrs of hospital admission. The first choice antibiotics were Piperacillin tazobactum and metronidazole in 45% of cases, Fluoroquinolones and metronidazole in 12% of cases and Cefaperazone sulbactum ± metronidazole in 14% of cases. In 26% of cases a combination of imipenem + Cilastatin was used. Antibiotic use did not improve survival, nor was there any observed survival benefit when the different antibiotic agents were compared (p = 0.7 and 0.4 respectively). The timing of antibiotic use also does not appear to confer a survival benefit (p = 0.5). All patients with proven pancreatic infection died, there was not a significant difference in survival in those with extra-pancreatic infections (p = 0.2).

Keywords: Acute Pancreatitis; Necrotising Pancreatitis; Severe Acute Pancreatitis; Antibiotic Prophylaxis; Retrospective Analysis.

Introduction

Acute pancreatitis is a common gastrointestinal emergency. Its incidence varies from 5 to 80 cases per 100,000 inhabitants per year, with an overall mortality rate of 10–15% [1]. More than two-thirds of patients will recover within 1 week, however the remaining one-third will experience multiple systemic and/or local complications, with a high mortality rate of 10–30%, 80% of deaths are due to infectious complications [2-3].

The use and efficacy of prophylactic antibiotic therapy in acute pancreatitis has long been debated. The role of prophylactic antibiotics to prevent infection and reduce mortality in pancreatitis was first evaluated in the 1970s, where several randomised controlled trials (RCTs) had been conducted and concluded that prophylactic antibiotics were effective in preventing secondary pancreatic infections and therefore in

ABSTRACT

BACKGROUND

In the modern medical era, laparoscopic approach to surgical conditions has reached to a height that it is performed even for malignant conditions. The minimal access surgery which has grown up from minimally invasive surgery has given us the faith that nearly all surgeries can be done by laparoscopy. The first laparoscopic cholecystectomy was done by Prof. Dr. Med Erich Muhe of Germany in the year 1985. About ten lakh cholecystectomies are performed ever year, of which 96% are done by laparoscopic method. Laparoscopic cholecystectomy is the most common laparoscopic procedure. By number of studies and research works, it is stated that laparoscopic cholecystectomy is superior to conventional open method because of its advantages like smaller incisions, early recovery, less post-operative pain and hospital stay with better cosmesis. However, laparoscopic cholecystectomy also has got its own disadvantages and complications. In 1992, an NIH consensus conference held in Bethesda approved laparoscopic cholecystectomy as the treatment of choice for symptomatic cholelithiasis. Conversion to open technique is a major morbidity of laparoscopy, as it loses its supremacy over open technique once the conversion takes place. With growing experience of laparoscopic cholecystectomy and completion of the learning curve, the indications for laparoscopic cholecystectomy have been extended approaching that of open cholecystectomy. Complications of laparoscopic cholecystectomy have been minimised to as low as 2 - 6%. However, a substantial proportion of patients had to be converted to open surgery because of technical difficulties or intraoperative complications. Conversion rates of 2.6% to 14% had been described in different studies. The factor to be considered with conversion is that it should never be considered a complication, but rather a correct judgement by the surgeon.

The aims of the present study are:

1. To study the incidence of conversion of laparoscopic cholecystectomy.
2. To analyse the reasons for the conversion of laparoscopic cholecystectomy owing to per operative complications like-
   a) Arterial injury,
   b) Hepatobiliary tract injury,
   c) Dense adhesions,
   d) Aberrant anatomy,
   e) Technical issues.

MATERIALS AND METHODS

This prospective observational study was conducted in patients who underwent laparoscopic cholecystectomy from November 2016 to November 2017 in the Department of General Surgery, Karpagam Faculty of Medical Sciences and Research, Coimbatore. There were totally 98 patients, of which 36 were males and 62 were females. The study has been done after the patient's informed consent. All these patients were evaluated in a proper manner as given in the proforma and had been assessed pre-operatively and operated under perfect anaesthetic fitness. This study mainly focussed on the patients who had been converted to open method. They were analysed further regarding the reasons for conversion to open method due to per-operative complications.

RESULTS

From November 2016 - November 2017, a total of 98 patients had undergone laparoscopic cholecystectomy in the Department of General Surgery, Karpagam Faculty of Medical Sciences and Research, Coimbatore. Out of 98 patients who underwent laparoscopic cholecystectomy, 13 patients (13.26%) were converted to open cholecystectomy owing to per-operative complications. All patients underwent cholecystectomy as an elective case. Though some morbidity was there in terms of post-operative complications, which we are not analysing, no mortality was reported.

CONCLUSION

After analysing the results of our study, we conclude that the incidence of conversion of laparoscopic cholecystectomy is 13.26%. The reasons for conversion in descending order of frequency are: 1. Dense adhesions (5.1%), 2. Difficult anatomy around Calot's triangle (3.06%), 3. Arterial injury (3.06%), 4. Hepatobiliary injury (1.02%) and 5. Technical issues (1.02%).

Abstract

Background: *In the modern surgical practice, Hernioplasty remains the commonest surgical procedure in general surgery. Though most of the patient recovers completely without complications, certain number of patients experience a stormy and complicated post-operative period in terms of seroma, infection, pain and last but not the least mesh reaction which is a rare but serious complication. Current day practice involves hernioplasty with polypropylene mesh rather than herniorraphy in most surgical centres, hence every effort should be made to reduce mesh related complications. Mesh reactions are more common in patients with preexisting allergic diseases like atopic dermatitis, asthma, allergic rhinitis, seasonal urticarial and also in patients with elevated serum IgE levels. This retrospective observational study was conducted in patients who underwent open inguinal and ventral hernioplastyfrom March 2010 to Feb 2017 in the Department of General Surgery, Coimbatore medical college hospital, Coimbatore. This study focuses mainly on patients who developed mesh reaction in the post-operative period particularly in patients who have existing atopic manifestations. After analyzing the results of our study, we conclude that IgE antibodies estimation pre-operatively in patients with existing allergic diseases can be used as a predictor for assessing mesh related reactions in the post-operative period. In this continuation we are planning immuno-electrophoresis to pinpoint the gamma globulin associated with mesh reaction.*

Abstract
Preoperative prediction of morbidity in colorectal cancer (CRC) surgery helps to optimize the surgical outcome. In this study, we aim to develop a dedicated equation for predicting operative morbidity using colorectal possum scoring system and also to validate the predictive accuracy of CR-POSSUM scoring system in prognosticating actual complications. We did a retrospective analysis of 322 patients undergoing colorectal cancer surgery from a single centre in South India from 2004 to 2016. Mortality and morbidity risk factors as defined by CR POSSUM were collected from 322 patients who underwent CRC surgery and were used to derive equations to predict morbidity, and the results were compared with the observed morbidity. Logistic regression analysis was used to derive the equation. The model fit and model discrimination were analysed using the Hosmer-Lemeshow statistical test for goodness of fit, the Nagelkerke R^2 and area under the receiver operating characteristic (ROC) curve respectively. Out of 322 patients, 103 (32%) patients developed complications and 10 (3%) died due to complications. The regression equation we derived has an overall correct classification of about 70% ($P < 0.01$) with positive and negative predictive value of 60% and 73% respectively. The Hosmer-Lemeshow goodness of fit was 3.147 ($P = 0.829$), and the Nagelkerke R^2 was 17% and area under ROC as model discrimination was 71.6%. Hence, CR-POSSUM scoring which was originally used for predicting mortality risk can also be extrapolated to predict morbidity.

Keywords Colorectal POSSUM · POSSUM · Colorectal surgery · SSI · Morbidity and mortality · Prediction model

Introduction

Colorectal malignancy is the third most common malignancy among men and the second most common among women around the world [1]. Fortunately, in India, the incidence is not too high. However, the incidence has been found to be rising, with the AAR (adjusted annual incidence rate) for colon cancer in men and women being 4.4 and 3.9 per 100,000, respectively [2]. Being in a country, where people living with poor access to quality healthcare, extreme presentation like advanced stage and perforation are common in tertiary care centres [3, 4]. In such scenarios, the mortality and morbidity for the patients undergoing surgery are relatively high [5]. Complications following major surgeries will proportionately increase the hospital cost and duration of hospital stay [6]. Apart from such hardships, complications also had an adverse impact on long-term survival [7]. So in a country like India, where the spending on health by the government is low and health insurance is under-penetrated, morbidity following a major surgical procedure will further drain the already constrained resources [8]. The complication rates are not uniform and cannot be generalised, as there are certain factors, such as age, patients' co-morbidity and operative severity, influencing the outcome of surgery [9]. So, putting together these factors and assessing the postoperative outcome preoperatively will help in optimizing the available resources. In such cases, the predictive scoring has to be more accurate, and its predictive ability should

Key message: CR-Possum can be used to predict morbidity in patient undergoing colorectal cancer surgery.

A CADAVERIC STUDY OF THE MYOCARDIAL BRIDGES

Suganya Saminathan[1], Vishnuvarthan Selvaraj[2]

[1]Assistant Professor, Department of Anatomy, Karpagam Faculty of Medical Sciences and Research, Coimbatore, Tamilnadu, India.
[2]Associate Professor, Department of General Surgery, Karpagam Faculty of Medical Sciences and Research, Coimbatore, Tamilnadu, India.

ABSTRACT

BACKGROUND

Myocardial bridging is a congenital anomaly, where a segment of an epicardial coronary artery is undercover of myocardial fibres for a variable distance and the underlying arterial segment is described as a mural coronary artery or a tunnelled artery. The history of myocardial bridges dates back to 1737 when it was first recognized by Reyman and then by Black in 1805. The first detailed post mortem examination of myocardial bridges was done by Geiringer in 1951 and the first radiological description was given by Portmann and Iwig in 1960. The bridged segment of the coronary artery is susceptible to various pathophysiological mechanisms leading to myocardial ischemia, especially when associated with other cardiovascular diseases. The myocardial bridges were initially thought to be innocent bystanders in the development of acute coronary syndromes. But in the last two decades, the outlook has changed with the increasing incidence of sudden cardiac deaths in young athletes, where myocardial bridges were the only finding at autopsy. The mechanism by which the myocardial bridges induce clinical symptoms is uncertain, but among the proposed are vasospasm, thrombus formation, endothelial dysfunction and impaired coronary flow reserve. Most important of these is the dynamic systolic compression of the tunnelled artery with sustained early diastolic diameter reduction.

The aim of this study is to provide more information on the incidence of myocardial bridges, arterial preponderance for myocardial bridging, the length of the bridged segment and multiple bridging.

MATERIALS AND METHODS

A descriptive study of fifty formalin fixed hearts from the department of anatomy were dissected by conventional dissection methods as guided by Cunningham.

RESULTS

Myocardial bridges were found in 18 (36%) hearts with a total of about 28 bridges. Most common artery involved was the anterior inter ventricular artery (66.6%), which even had multiple bridges over it. The mean length of the bridges was 26.54 mm.

CONCLUSION

From the present study, we infer that the presence of myocardial bridges in an unsuspected population is relatively higher. The definitive role of these bridges in acute coronary syndromes is yet uncertain. But owing to its higher rate of detection in those with myocardial ischemia, it is better to screen for the bridges along with other aetiological factors and treat the patients prophylactically. Of the imaging modalities, CT Coronary Angiography is found to be the investigation of choice. In the near future, holistic studies involving cadaveric, radiologic and clinical data are mandatory in researching the myocardial bridges.

BACKGROUND

Myocardial bridging is a congenital anomaly, in which an epicardial coronary artery lies in the myocardium for part of its course. The bridged segment of the coronary artery is susceptible to various pathophysiological mechanisms leading to myocardial ischemia, especially when associated with other cardio vascular diseases. Recently, myocardial bridges have become a main topic of interest owing to its probable causation of sudden cardiac death in young athletes.

The aim of this study is to provide more information on the arteries with myocardial bridges. Of the fifty formalin fixed hearts dissected, myocardial bridges were found in 18 (36%) hearts with a total of about 28 bridges. Most common artery involved was the anterior inter ventricular artery, which even had multiple bridges over a single artery. The mean length of the bridges was 26.54 mm.

Myocardial bridging is a congenital anomaly, where a segment of an epicardial coronary artery is undercover of myocardial fibres for a variable distance and the underlying arterial segment is described as a mural coronary artery or a tunnelled artery.[1] (Fig. 1).

S.V. Arun Prasath, Vinoth D, Rajesh Kumar. Monitoring Postoperative Pain Management in General Surgical Wards: A Clinical Audit of Feedback Pain Protocol in Our Institution. New Indian J Surg. 2019;10(4):389-392.

Abstract

"Pain" is defined by the International Association for the Study of Pain as an unpleasant sensory and emotional experience arising from actual or potential tissue damage or described in terms of such damage. There is both the physiologic and affective nature of the pain experience. Inadequate pain control, apart from being inhumane, may result in increased morbidity or mortality. Despite this overwhelming rationale for effective postoperative pain control, the clinical reality is unfortunately, still far from satisfactory. As the importance of postoperative pain relief is undebated, there is a need for an effective protocol in the care of all postoperative patients. In our hospital, we follow a "feedback" pain protocol, in which the VAS pain scale is used to record pain at least once a day, or more depending on the analgesia frequency, with a follow-up after 15 to 45 min to see the level of pain relief, and to receive drug orders for further analgesia if the pain relief is not adequate. The aim of this audit is to find the level of compliance to this protocol, and its effectiveness. The main reason being that there is no standard protocol for postoperative pain management widely being practiced. The surgeons are the ones who are managing the postoperative pain. This audit will determine the effectiveness, and the adherence to protocol, which will suggest whether there is a need for a change in the protocol, or adherence. Objectives being to ensure that the analgesia protocol is followed in all postoperative patients and to ensure that atleast 95% of those who receive the analgesia protocol, has a VAS score of less than 3 in their first two postoperative days.

Keywords: Postoperative pain; Pain protocol; Feedback protocol; Institution.

Introduction

"Pain" is defined by the International Association for the Study of Pain as an unpleasant sensory and emotional experience arising from actual or potential tissue damage or described in terms of such damage[1]. Although this is a technical description of pain, it recognizes both the physiologic and affective nature of the pain experience. Inadequate pain control, apart from being inhumane, may result in increased morbidity or mortality. Acute pain following surgery, can activate the sympathetic branch of the autonomic nervous system and produce such responses as hypertension, tachycardia, diaphoresis, shallow respiration, restlessness, facial grimacing, guarding behavior, pallor, and pupil dilation. Although pain in response to tissue damage is a normal phenomenon, it may be associated with significant, unnecessary physical, psychological, and emotional distress. Inadequate relief of acute pain can contribute to hypercoagulability and impaired immunity, leading to such complications as venous thromboembolic disease and infections.

Vijay Muthuraman, SV Arun Prasath, S Rajesh Kumar *et al.* Acetic Acid Based Dressings on *Pseudomonas aeruginosa* Infected Diabetic Ulcers: A Randomized Controlled Study. New Indian J Surg. 2019;10(5):532-535.

Abstract

Wound infections had increased the risk of amputations in Diabetic patients by 90 times. *Pseudomonas aeruginosa*, has been a local deterrant to wound healing by its various properties of biofilm formation, increased virulence and multi drug resistance by various methods. Unfortunately, due to its resistance to first generation spectrum of antibiotics, and its gradual increase in resistance to third generation cephalosporins, aminoglycosides etc, the need for alternative methodologies arise. Acetic acid helps in local control of the microbe by reducing the wound pH to acidic. This was an Open labelled prospective randomized control trial. Totally 80 patients with diabetic foot ulcers with culture proven *Pseudomonas aeruginosa* positive status were included, and non diabetic ulcers were excluded. Two groups based on simple randomization into test and control groups each containing 40 patients. The control group received traditional saline dressings. The test variables and the control variables were tabulated and compared using Chi square test. The efficacy of 3% Acetic acid in eradication of *Pseudomonas aeruginosa* infected diabetic ulcers was assessed. $p<0.01$ was considered to be statistically significant. At the end of the study, it was seen that there was complete eradication of *Pseudomonas aeruginosa* in 87.5% of the individuals in the test group and 62.5% of the individuals in the control group which was statistically significant ($p = 0.009$). Thus, in conclusion, Acetic-acid based dressings are effective for management of diabetic foot.

Keywords: Acetic acid; Pseudomonas; Dressing.

Introduction

Diabetes mellitus is a disorder characterized by uncontrolled sugar levels in the blood and its various manifestations to the human body. Diabetic foot and diabetic foot ulcers occurs as a complication of its sequelae. Foster et al discovered in 1997 that nearly 30 percent of patients with diabetes mellitus have increased risk of developing foot ulcers. 15% of diabetics developing foot ulcers, accounting for 30% of the hospital admissions with the hospital stay of those patients being 60% longer than the rest of the patients. These high risk patients had an increased risk of amputations[1]. The overall healing period of the diabetic ulcer was estimated to be 3 months with persistence of a small ulcer for more than a year[2]. Various management methodologies have been implemented in treating diabetic wounds including Debridement, Dressings, Infection control, Amputation, correcting vasculopathies, Off-loading. Wound infection deters the healing process of the diabetic ulcer and leads to amputations. It was seen wound infections had increased the risk of amputations by 90 times to that of a non-infected wound[4]. It has been seen that the following microbial organisms are more

ABSTRACT

Intussusception is the telescoping of one segment of the gastrointestinal tract into an adjacent one. Adult intussusception is less than 0.1% of all hospital admissions. Non-specific symptoms often delay the diagnosis with most cases diagnosed only after emergency laparotomy, hence the need for imaging as a screening investigation. The gold standard is computed tomography with the limitations of cost, radiation and contrast hazards. Our suggested initial screening tool is ultrasound. the aim of this study was to evaluate the sensitivity of ultrasound in diagnosing this rare entity. Thirteen patients (2013 to 2019) in a single tertiary care hospital diagnosed as "intussusception" were analysed. They were initially diagnosed by ultrasound and confirmed by CT or intra-op as needed. There were no exclusion criteria. The mean age was 50. There were 6 males and 7 females. Ultrasound sensitivity was 72%. Symptoms were variable. 100% had abdominal pain (1 day to 2 years duration). 69% had Intestinal obstruction. The most common type of adult intussusception observed was ileo-ileal (39%). The least common noted was gastro-jejunal (8%). The most common treatment was resection and anastomosis (77%). 3 cases were managed conservatively successfully. The biopsy was mostly benign (54%), 3 were malignant (23%) and 3 were unknown as they were not operated (23%). Our suggested initial screening is ultrasound with a fairly good sensitivity (72%). The upcoming improvement in technology can raise this sensitivity even further. The management protocols, biopsy findings, and clinical findings are however subjected to discretion.

Keywords: Adult, Intussusception, Ultrasound, Diagnosis

INTRODUCTION

Intussusception is the telescoping of one segment of the gastrointestinal tract into an adjacent one.[1] Any focus of an intraluminal irritant such as inflamed mucosa or a mass lesion may act as a lead point and the resulting hyperperistaltic activity causes a segment of bowel (intussusceptum) possibly along with its mesentery to telescope into the adjacent distal bowel lumen (intussuscipiens).[2] Adult intussusception is classified according the location of the lead point as entero-enteric, ileocolic, ileocecal, and colo-colic.

Paediatric intussusception is more common and they are easily identified because they present typically with intermittent colicky pain, abdominal mass and passage of dark clots mixed with mucus.[3] Intussusception, compared to the paediatric population, is an infrequent cause of bowel obstruction in adults, with only two to three cases occurring in a population of 1,000,000 per annum, accounting for less than 0.1% of all adult hospital admissions.[4-6] There is thus a low suspicion of intussusception due to vague range of acute to longstanding or intermittent non-specific symptoms which delays the diagnosis.[3,7] Most cases are diagnosed only after emergency laparotomy.[8] In non-emergency

Abraham Benjamin Muthunayagam, Chitra R, Muruganand Myilsamy et al. Comparison of CTSI and BISAP Scoring in the Assessment of Severity and Mortality in Cases of Acute Pancreatitis. New Indian J Surg. 2019;10(5):559-566.

Abstract

Background: Acute pancreatitis is a disease where earlier initiation of treatment in case of complication gives a better prognosis to the patient. It has been firmly established that the BISAP scoring system is superior to the other clinical scoring system and the superiority of the CTSI scoring has been established for almost a decade. Yet, there are very few studies that directly compare these two scores directly. Hence, such a study is of utmost importance at this time as it can decrease the financial burden for the patient as well as provide a simple scoring system for the surgeon. This study compares CTSI and BISAP scoring in the assessment of severity and mortality of acute pancreatitis, and assess the validity, the specificity and the sensitivity of both the scoring systems.

Methodology: In 35 patients diagnosed with acute pancreatitis, the BISAP score was calculated, and after 48 hours of onset of symptoms, CTSI scoring done. The data was then analyzed with STATA statistical software.

Results: BISAP score showed a sensitivity of 100% and specificity of 36.8% in establishing the mortality of acute pancreatitis with cut-off value taken as > 1. If the cut-off value is taken as > 2, the sensitivity became 56.3% and specificity became 79%. CTSI score showed a sensitivity of 64% and specificity of 100% in establishing the onset of complications in cases of acute pancreatitis.

Conclusion: Our study showed that BISAP score is comparable to CTSI in predicting the prognosis and mortality of cases of acute pancreatitis but does not compare with CTSI in establishing degree of necrosis. Hence, BISAP score is a simple, cost-effective scoring system that can be implemented in tertiary and even most primary healthcare centres.

Keywords: BISAP; CTSI; Acute pancreatitis; Predicting morbidity; Complications of acute pancreatitis; Pancreatic necrosis BISAP; CTSI; Acute pancreatitis; Predicting morbidity; Complications of acute pancreatitis; Pancreatic necrosis.

Introduction

Acute inflammation of pancreas named acute pancreatitis, is becoming common abdominal disease posing some major challenge to general and intestinal surgeons around the world.[1,2] It is one of the most challenging disease that leads to various local and systemic complications. Acute pancreatitis presents with the hallmark features of acute pancreatic inflammation which is associated with little or no fibrosis. The presentation of acute pancreatitis may range from a pancreatic inflammation that is mild and self-limiting to life threatening pancreatic necrosis with secondary infection and multi-organ failure.[3] The acute pancreatitis incidence world wide varies from 5 to 80 per 1, 00,000 acute population. Finland and United States of America records the highest incidence of acute pancreatitis worldwide.[4] The incidence of acute pancreatitis varies among different racial and ethnic group. Alcohol consumption without moderation is an important cause for acute pancreatitis in India, with smoking being an independent risk for developing acute pancreatitis.[5] Acute pancreatitis can be classified,

J Vaishnavi, R Chitra, S Rajeshkumar, et al. Retrospective Study on Patients Undergoing Laparotomy to Assess the Risk Factors of Re-Laparotomy. New Indian J Surg. 2020;11(2):230–236.

Abstract

Introduction: Abdominal surgery that has to be redone in association with initial surgery is referred to as re laparotomy. Re-laparotomy is associated with 22 to 513% morbidity and mortality, therefore it's the final choice of surgery. The main aim of this study was to find out the incidence of re- laparotomy and to identify the risk factors i.e. predictors of re laparotomy in patients undergoing general surgery operations.

Materials and Methodology: This was a retrospective study involving 100 patients, done from 1st Jan 2016 till 1st June 2017 Patients with age more than 18 years, those requiring laparotomy for both general and trauma surgery were included. Those with initial laparostomy, with only flank drain placement, any Laparotomies during colostomy or ileostomy closure, those with Initial laparoscopic procedure, minimal invasive procedure like ultrasound guided drainage etc. Were excluded. Data was analyzed using SPSS Software. The Results were expressed in percentage. Associations were analyzed using chi-square or 't' test depending on outcome variables.

Results: The incidence of revision laparotomy in this study was 7% and the incidence of second revision laparotomy was 1%. The indications for relaparotomy were anastamotic leak 2/7 (20%), burst abdomen 2/7 (20%), pancreatic injury 1/7 (10%), bladder injury 1/7 (10%), negative laparotomy 1/7 (10%), anastamotic leak and burst abdomen. The variables with significant *p*-value are systemic hypertension, COPD, CAD, intra-op and post-op inotoropic support, wound infection, wound dehiscence and intra-abdominal abscess. These data can thus be used in future to formulate a prediction scoring system.

Keywords: Laparotomy; Re-lapaprotomy; Post-op peritonitis; Burst abdomen.

Introduction

Laparotomy is the surgical incision into the abdominal cavity, for diagnosis or in preparation for major surgery. From its origins in a private house in the backwoods of Kentucky in 1807, a large number of patients undergo various operative procedures every day, out of which laparotomy forms a major proportion.

Abdominal surgery that has to be re-done in association with initial surgery is referred to as re laparotomy. Laparotomy has to be re done due to complications like biliary peritonitis, faecal fistula, anastamotic leak, burst abdomen etc. Of these, post-operative peritonitis and intra abdominalsepsis[1] are the most common cause. Clinical and haematological parameters and radiological evidence form the basis of re laparotomy. Incidence of relaparotomy differs accordingto patient characteristics, initial surgery and post-op care. The surgeon factors include hesitation to decide on second surgery, focus more on conservative treatment. Need for supervision under a qualified surgeon.[2] Despite

ABSTRACT

Neuropathic ulcers pose a global burden carrying a risk of amputation of 15-46 times especially in developing countries. These ulcers are mainly managed with offloading techniques. In this study we share our experience of using an easy to use, cost effective method the Suvidha offloading dressings in terms of its acceptability and effectiveness in managing these cases. A prospective case series of 83 patients with mean age 58 years, managed with Suvidha offloading dressing in our institution from 2016 till 2019, excluding patients with ABI less than 0.4 and Wagner 4 and 5. They were reviewed after 6 months/SOS. Ulcer measured 1×1 to 4×4 cm, was present most commonly in the mid foot and least commonly in the lateral aspect of the foot. 53 cases were Wagner grade 2 and 9 cases Wagner grade 3. Forty cases were initially infected, 29 cases had a deformed foot, 5 cases needed interval wound debridement. The duration of ulcer healing was 2 weeks for 1×1 cm great toe ulcer, to 12 weeks for the 4×4 cm mid foot ulcer. All 83 patients were followed up for 6 months. 5 ulcers recurred. The patient satisfaction was measured by a 5-points Likert scale with a mean value of 17.4 out of 20. The Suvidha offloading footwear is a cost effective, easily replicable and efficient dressing requiring only the readily available dressing materials, with good healing rates, good patient satisfaction and adapted for developing countries. The results are comparable with other methods of offloading practiced worldwide.

INTRODUCTION

Ulceration of the lower limb affects 1% of the adult population and 3.6% of people older than 65 years. Leg ulcers are debilitating and painful. They greatly reduce patient's quality of life. Ulcer healing has been shown to restore quality of life. Lower limb ulceration tends to be recurrent and the total annual cost of treating leg ulcers to the NHS has been estimated at £400m.[1] Chronic ulcers ruin the life of patients and increases the burden on health care as a whole. Neuropathic ulcers are formed due to undue pressure leading to breakdown of skin. Various causes are implicated, but diabetes is the most common cause. The number of diabetics worldwide was estimated at 131 million in 2000. It is projected to increase to 366 million by 2030. Diabetic patients have up to 25% lifetime risk of developing foot ulcers. The annual incidence of diabetic foot ulcers is ~3%.[2] The worldwide prevalence rate of diabetic foot ulcer (DFU) was 6.3%. North America showed the highest prevalence rate of 13.0% compared with Oceania with prevalence rate of 3.0%. Africa showed a prevalence rate of 7.2% which is higher than Asia 5.5%. Europe showed a prevalence rate of 5.1%, Australia has prevalence rate of 1.5%.[3] Belgium

ABSTRACT

Background: Colorectal cancer, a formidable health problem worldwide has upto 8% synchronous peritoneal carcinomatosis. As only diagnostic laparoscopy can identify them, in countries with economic burden, selection of patients for laparoscopy is ideal. Our aim is to evaluate whether the already done baseline carcinoembryonic antigen (CEA) is a good selection tool.

Methods: A retrospective study of 125 patients, who were diagnosed to have colorectal malignancy (any stage) and underwent elective surgery at our institution from 2012 till 2019 were included. The baseline serum CEA was compared with the intraoperative findings. The threshold levels of serum CEA compared were 6.5 and 100 ng/dl. The sensitivity, specificity, positive predictive value and negative predictive value for both thresholds were compared in 3 categories of patients, namely peritoneal metastasis (9 cases), metastasis in other organs (36 cases) and cases with no metastasis either in peritoneum or other organs (85 cases). The results were analysed using SPSS software.

Results: The mean age was 65, sex ratio was 72:53. The sensitivity, specificity, positive predictive value, negative predictive value (NPV) for CEA threshold of 6.5 ng/dL was 44.44%, 60.34%, 8% and 93.33% for category 1. For CEA threshold of 100 ng/dl, it was 33.33%, 97.41%, 50% and 94.95% for category 1. NPV was 96.55% for category 3 (the highest value).

Conclusions: We can be 96.55% sure that if baseline CEA is less than 100 ng/dl, we don't need a diagnostic laparoscopy. This hopefully will cut down the cost of unnecessary diagnostic laparoscopies, and reduce the morbidity of unnecessary laparotomies.

INTRODUCTION

Colorectal cancer (CRC) is a formidable health problem worldwide. It is the third most common cancer in men (663000 cases, 10.0% of all cancer cases) and the second most common in women (571000 cases, 9.4% of all cancer cases).[1] Almost 60% of cases are encountered in developed countries. The number of CRC-related deaths is estimated to be approximately 608,000 worldwide, accounting for 8% of all cancer deaths and making CRC the fourth most common cause of death due to cancer. In India, the annual incidence rates (AARs) or colon cancer and rectal cancer in men are 4.4 and 4.1 per 100000, respectively. The AAR for colon cancer in women is 3.9 per 100000. Colon cancer ranks 8th and rectal cancer ranks 9th among men. For women, rectal cancer does not figure in the top 10 cancers, whereas colon cancer ranks 9th.[2] Usually the patients have a favourable prognosis when diagnosed at an early stage: 70-80% are eligible for curative-intent surgery, with a 5 years survival of 72-93% for stages I-II.[3] Approximately 25% of the remaining

A single-blind, randomized controlled study to compare Desarda technique with Lichtenstein technique by evaluating short- and long-term outcomes after 3 years of follow-up in primary inguinal hernias

Hemanth Vupputuri, Satish Kumar R, Priya Subramani, Venugopal K

Abstract:

BACKGROUND: Lichtenstein tension-free repair is associated with postoperative complications and dysfunctions; hence, there is a need to look for a new hernia repair techniques while retaining its advantages. Desarda technique is a physiologic repair and essentially restores physiology of the inguinal canal. This single-blind, randomized controlled study was conducted to compare Desarda with Lichtenstein technique evaluating short- and long-term outcomes after 3 years of follow-up in primary inguinal hernias.

MATERIALS AND METHODS: One hundred and twenty-three adult male patients with primary inguinal hernia (both direct and indirect) were randomly allocated intraoperatively to Lichtenstein repair, Mesh (M) Group or Desarda repair, nonmesh (NM) Group. Baseline characteristics were recorded before the surgery. Short- and long-term outcomes and patients responses on patient global impression of change (PGIC) and Prolo scale after surgery were recorded.

RESULTS: Sixty-two patients were assigned to NM and 61 to M group. Surgery time was significantly higher for M group ($P < 0.001$) in M than NM group whereas complications were comparable. The total mean duration of follow-up for M was 35.2 months while for NM was 35.7 months. The recurrence rate was not significantly different; however, chronic groin pain was significantly higher in M compared to NM ($P = 0.05$). After surgery, PGIC score was consistently higher in NM group with better functionality in NM group.

CONCLUSIONS: After 3 years of follow-up, Lichtenstein technique and Desarda technique results were similar. After considering the pros and cons of both the methods, a tailor-made approach is required while choosing a procedure for hernia repair.

Introduction

Inguinal hernias comprise about 96% of all groin hernias.[1] About 27% of men and 3% of women ranged between 1 and 85 years are at risk of developing an inguinal hernia, and around 20 million hernias are estimated to be repaired every year. It ultimately raises the healthcare cost and resource

Abstract

Aim: To compare the efficacy of autologous platelet-rich fibrin (PRF) over moist sterile saline/povidone-iodine dressing in diabetic foot ulcers.

Objective: To compare the mean reduction in ulcer area at the end of 4 weeks of dressings.

Methodology: 60 diabetic patients with foot ulcers from the department of general surgery, general medicine, endocrinology, and cardiology were prospectively studied. Detailed clinical history was obtained, the ulcer was evaluated and the presence of wound infection was assessed for all the patients. Patients were randomised into two groups of 30 patients each. While one group received PRF dressings, the other received saline/povidone-iodine dressings. The wound healing was then compared in the two groups. The efficacy of platelet-rich fibrin dressing over moist saline/povidone-iodine dressings was assessed by comparing the percentage reduction of the ulcer area, at the end of four weeks, using chi-square test and A NOVA test.

Results: It was found that there was a better reduction in the area of the ulcer at the end of four weeks in patients who received platelet-rich fibrin dressings than in moist saline/povidone-iodine dressings.

Conclusion: PRF dressing was superior to moist saline/povidone-iodine dressings.

Keywords: Diabetes; Foot ulcer; PRF.

Introduction

Foot ulcer is a devastating complication of diabetes mellitus, particularly in the elderly. The majority of diabetic foot ulcers may heal, whereas a smaller percentage will remain active and finally lead to gangrene and amputation of the limb.[1,2] With increasing duration of the ulcer and the increasing age of the patient, the risk of amputation also rises. Thus early prevention plays a vital role.

Wound dressings constitute a major part of the management of diabetic foot ulceration. An ideal dressing will have to reduce the symptoms, give adequate protection of the wound and promote good healing. Platelet-rich fibrin (PRF) prepared from the patient's own blood is used in the fields of orthopedics and dentistry to promote wound healing. PRF transfers growth factors to the wound surface. The use of autologous preparation reduces the risk of allergic reactions. There are very few studies comparing the efficacy of PRF with other dressing materials. This study compare the efficacy of PRF dressing with moist saline/povidone-iodine dressing in diabetic foot ulcers.

Materials and Methods

The period of study was between February 2015 and February 2016. It was an open-labeled

Accepted 13 October 2021

SUMMARY

A 60-year-old man presented with severe abdominal pain, two episodes of massive haematemesis and chest discomfort. CT angiography showed a saccular aneurysm of the juxtaphrenic aorta with possible oesophageal erosion. Upper GI endoscopy revealed external compression of the lower oesophagus—near total luminal obstruction with impending rupture of the aortic aneurysm. Emergency aneurysmal repair by interposition grafting using 20 mm Dacron graft with oesophageal–gastric reconstruction done. Postoperative period was uneventful

BACKGROUND

This report describes the management of a life threatening rare vascular emergency of aneurysm of the juxtaphrenic aorta with oesophageal erosion leading to formation of aorto-oesophageal fistula complicated with acute dissection. The presentation was inevitable for cardiovascular collapse in the absence of timely surgical intervention. The aneurysm being located in the descending thoracic aorta, the repair requires a left atrium-to-femoral bypass to maintain perfusion to the abdominal viscera and lower extremities. During the repair, the brain and the spinal cord is protected by cerebrospinal fluid drainage.

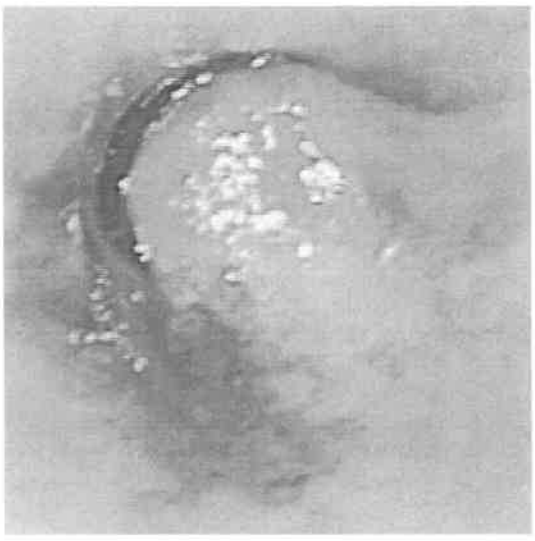

Figure 1 Upper gastrointestinal endoscopy – lower oesophageal external compression – near total luminal obstruction with impending rupture/ leaking nature of aortic aneurysm with mucosal ulceration of oesophagus covered with blood clot, eroding the distal oesophagus just above the oesophageal hiatus of the diaphragm.

Figure 2 CT angiogram.

CASE PRESENTATION

A moderately built 60-year-old man, habitual smoker for 40 years with recently diagnosed hypertension not on medications was admitted with severe abdominal pain, two episodes of massive haematemesis and chest discomfort for the last 2 days. The abdominal pain was sudden in onset, gradual in progression, localised to the epigastric region.

On examination, he was conscious, oriented, afebrile, pallor present with pulse rate of 86/min, blood pressure 100/80 mm Hg and respiratory rate of 30/min. On cardiovascular system examination, S1, S2 heard in the mitral, tricuspid, aortic and pulmonary area with no murmur. Respiratory system examination, normal vesicular breath sounds heard with equal bilateral air entry, no added sounds. On abdomen examination, soft, non tender with no organomegaly. On central nervous system examination, clinically normal with no focal neurological deficits.

INVESTIGATIONS

Routine investigations revealed haemoglobin of 90 g/L, blood group O negative, bleeding parameters

Figure 3 CT angiogram: large saccular aneurysm of juxtaphrenic aorta with large intramural thrombus and sign of impending rupture.

S Karthikeyan, DG Manoj Prabhakar, Guhan Ramasamy *et al.* Vacuum Assisted Closure Versus Conventional Wound Therapy in the Management of Diabetic Wounds. New Indian J Surg. 2019;10(5):501-506.

Abstract

Background: Diabetic foot ulcers are a major cause of hospitalization which increases hospital stay because of multiple surgical procedures. The objective of this study is to compare Vacuum Assisted Closure and the conventional therapy for diabetic wounds with respect to time and wound healing and to prove the efficacy of one method over the other by appropriate statistical methods at the end of data collection.

Methods: A retrospective randomized hospital based observational study of 40 patients was conducted at PSGIMSR, Coimbatore, Tamilnadu, India for a period of 24 months (January 2017–December 2018). All these 40 patients were studied and the data was statistically evaluated to determine the efficacy of vacuum assisted closure in healing of diabetic wounds and to compare it with the conventional method of treatment of diabetic wounds. The patients were divided into 2 groups, Group-A which consisted of 20 patients who received vacuum therapy (VAC), Group-B which consisted of 20 patients who received conventional dressings.

Results: The patients on VAC had early appearance of granulation tissue (90% vs 60% at the end of Day 3), increased percentage of decrease in wound depth (53% vs 25% at the end of day 9) as compared to patients treated by conventional dressing. All patients developed granulation tissue by the end of Day 9.

Conclusion: We thus conclude that VAC appears to be superior in the treatment of diabetic foot ulcers in terms of early appearance of granulation tissue and decrease in wound depth when compared to conventional dressings.

Keywords: VAC; DFU; Wagners classification.

Introduction

Acute and chronic wounds are a major cause of morbidity and reduced quality of life, they affect atleast 1% of the population and present as a risk factor for hospitalization, amputation, sepsis and even death.[4]

Foot ulcers are a major cause of hospitalization in patients with diabetes mellitus which increases hospital stay because of multiple surgical procedures, prolonged length of stay. Diabetics have 25% risk of developing foot ulcers which preceeds amputation in about 85% of cases.[3]

A main stay of diabetic foot ulcer (DFU) therapy is debridement of all necrotic, callus and fibrous tissue with a primary goal to obtain wound closure. The management of DFU is determined by its severity (grade) vascularity of the limb and presence of infection.[3]

Wound healing is a complex and dynamic process that begins with removal of debris,

control of infection, clearance of inflammation, angiogenesis, deposition of granulation tissue, contraction, remodeling of the connective tissue matrix and maturation.[2]

Saline moistened gauze has been the standard method, however, it has been difficult to continuously maintain a moist wound environment with these wound dressings. Subsequently various hydrocolloid wound gels, growth factors, hyperbaric oxygen therapy and other wound therapies have been advocated. All of these therapies are associated with increased cost and are being utilized without adequate scientific evidence favouring their efficacy.[1]

Vacuum assisted wound closure (VAC) is a wound management technique that exposes wound bed to negative pressure and provides a moist wound healing environment. VAC promotes wound healing by removing fluid from open wounds, preparing the wound bed for closure, reducing oedema and promoting formation and perfusion of granulation tissue.

This study is being done to compare the effectiveness of VAC with conventional dressings in the healing of DFU, in terms of healing rate: early appearance of granulation tissue and percentage decrease in wound depth.

Materials and Methods

A hospital based retrospective randomized control trial was conducted in the Department of Surgery, PSGIMSR, Coimbatore.

The study period was 2 years in total and both methods were tested out over a period of one and a half weeks.

All the eligible subjects fulfilling the inclusion and exclusion criteria were included in the study (sample size: 40).

Group A: Patients treated with VAC.

Group B: Patients treated with conventional dressings.

Inclusion criteria

- Above 18 years of age.
- Patients with diabetic foot ulcer more than 4 cm square.

Exclusion criteria

- Patients age less than 18 or more than 70 years
- Pregnant and nursing mothers.
- Patients on medications such as corticosteroids, immunosuppressive agents.
- Patients with severe wound ischemia and severe neuropathy.
- Deep infections such as osteomyelitis and septic arthritis.
- Patients were divided into Group-A (treated with VAC) and Group-B treated with conventional dressings, with an equal number of patients in each group. For each patient, ulcers were treated till wound closure, either spontaneously or surgically.

Patients were assessed by the following methods:

- % decrease in the wound depth.
- Early appearance of granulation tissue.

Treatment Schedule

Group A

Patients treated with vacuum assisted closure. Dressings were regularly changed every 3 days. Wound tracing and photos were taken every 3 days. Ulcers were followed up until wound closure, either spontaneously or surgically.

In patients undergoing VAC therapy, foam was autoclaved and was cut according to the shape of the wound and ryles tube placed between the two layers of the foam. Adhesive plaster applied around the foam airtight. Ryles tube connected to the wall suction using tubings. Negative pressure set to 125 mmHg. Negative pressure applied for 72 hours continuously, patient was taught to detach the tubing when ambulating. Dressing opened after 72 hours.

Group B

Patients treated with conventional dressings. Daily dressings were done. Wound tracing and photos were taken every 3 days. Ulcers were followed up until wound closure, either spontaneously or surgically.

In patients undergoing Conventional dressings, after wound wash, povidone soaked gauze pieces were used for initial 72 hours followed by dressings of normal saline soaked gauze pieces for twice daily.

Patients in both groups were insulin therapy according to blood levels and antibiotics started empirically initially and then according to culture sensitivity reports. Necessary debridement and wound toilet done before application of dressings.

Treatment outcome was assessed in terms of time taken for the appearance of granulation tissue and measurement of wound depth and area at subsequent follow up. Wound depth was measured using a sterile thread vertically in the deepest part of the wound crater to the skin surface level.

Results

Statistics

All the collected data was entered in Microsoft Excel Sheet. All the quantitative data was presented as Mean and Standard Deviation and compared using student's T-test.

Qualitative data was presented as Frequency and percentage and analysed using chi-square test. P-value of less than 0.05 was considered as significant.

Distribution of Patients based on age group

Mean age of study subjects was 51.2 and 50.4 years in conventional and VAC group respectively (Fig 1).

Distribution of Patients based on gender

Male preponderance was observed in both the groups (80% in conventional and 85% in VAC group respectively) (Fig. 2).

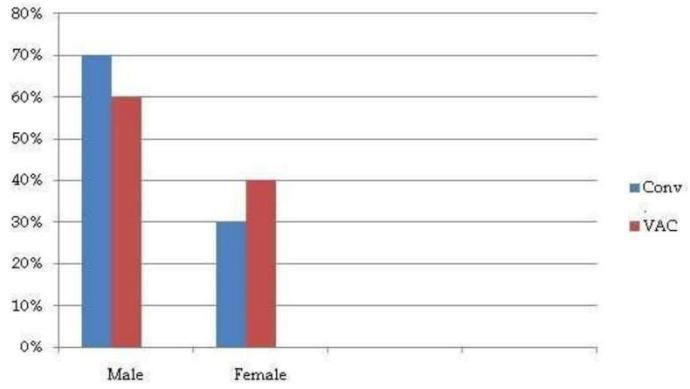

Fig. 1: Distribution graph of patients based on age.

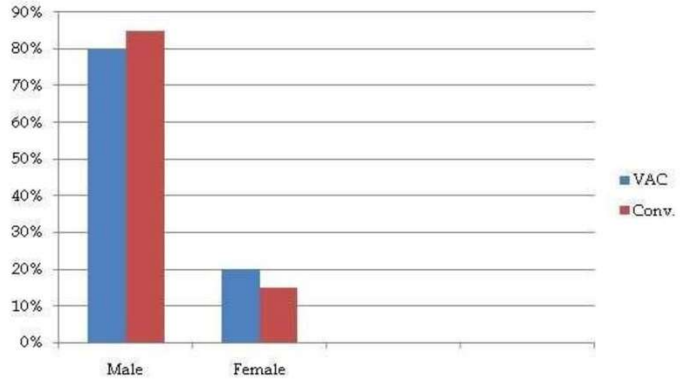

Fig. 2: Distribution graph of patients based on gender.

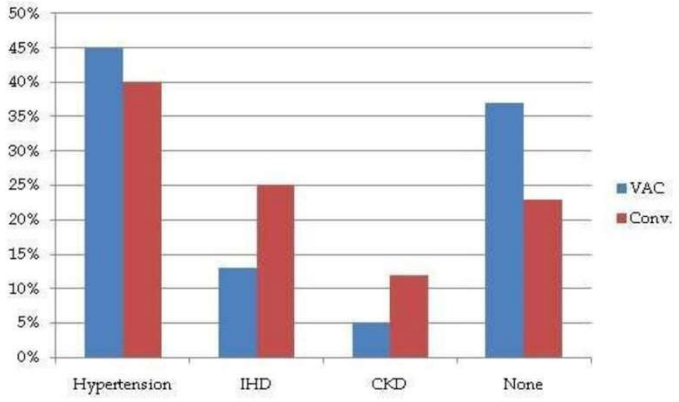

Fig. 3: Distribution of patients based on co-morbidities.

Distribution of patients based on co-morbidities

Hypertension was the most common co-morbidity observed in study subjects (40% and 45% in Conventional and VAC Groups respectively) followed by ischemic heart disease (25% vs. 13% in both the groups respectively) (Fig. 3).

Distribution of patients based on wound depth

The percentage decrease in the wound depth was more in the VAC group than conventional dressing at the end of Day 9 (53% vs 25% at the end of day 9) (Table 1).

Table 1: Distribution of patients based on wound depth.

Wound Depth	Group	N	Mean	SD	P-value
Before debridement	VAC	20	2.50	1.27	0.172
	Conv	20	2.00	0.97	
After debridement	VAC	20	4.30	1.17	0.023
	Conv	20	3.50	0.94	
Day 3	VAC	20	3.10	1.02	0.285
	Conv	20	2.75	1.01	
Day 6	VAC	20	2.38	0.86	0.812
	Conv	20	2.31	0.97	
Day 9	VAC	20	1.17	0.60	0.006
	Conv	20	1.90	0.92	

Distribution of patients based on granulation tissue

The patients on VAC therapy had early appearance of granulation tissue as compared to patients treated by conventional dressing (90% vs. 60% at the end of Day 3). All patients developed granulation tissue by the end of Day 9 (Table 2).

Table 2: Distribution of patients based on granulation tissue

Granulation tissue	Group		Total
	Conv	VAC	
Day 3	12	18	30
	60%	90%	75%
Day 6	19	18	37
	95%	90%	92.5%
Day 9	20	20	40
	100%	100%	100%

Discussion

Vacuum assisted closure has been recommended as a novel method in the healing of diabetic foot ulcers by stimulating the chronic wound environment in such a way that it reduces the bacterial burden and chronic interstitial wound fluid, increases vascularity and cytokine expression.

Application of negative pressure over the wound bec allows arterioles to dilate, increasing the effectiveness of local circulation, promoting angiogenesis which assists in the proliferation of the granulation tissue.

We observed that the patients on VAC therapy had an early appearance of granulation tissue as compared to patients treated by conventional

dressing (90% vs 60% at the end of Day 3). All patients developed granulation tissue by the end of Day 9.

The percentage decrease in wound depth was more in VAC group than conventional dressing at the end of Day 9 (53% vs 25% at the end of day 9).

In a study by Lone *et al.*, granulation tissue appeared in 26 (92.85%) patients by the end of week 2 in VAC group in contrast to 15 (53.57%) patients by that time in conventional group.

In a study by Eginton *et al.*, rate of wound healing with VAC was compared with conventional moist dressings in the treatment of large diabetic foot wounds. VAC dressings decreased the wound volume and depth significantly more than moist gauze dressings (59% vs. 0% and 49% vs. 8% respectively).

Priyatham K *et al.*, in a prospective study, assessed the efficacy of Vacuum assisted closure with conventional moist wound dressing in improving the healing process in chronic diabetic wounds. Shorter duration of hospital stay and better graft uptake was observed in the Vacuum dressing group.

Outcome

The primary end point in this study was a granulated wound or a wound ready for skin grafting or healing by secondary intention. Primary closure of the wound or split thickness skin grafting was done in patients of conventional and VAC group respectively.

Lone *et al.* observed that in 86.4% of patients, wounds were closed by a split thickness skin graft in VAC group as compared to 90.9% of patients in conventional.

Conclusion

Rate of granulation tissue formation, overall graft survival and patient compliance was better in VAC group as compared to conventional dressing group. It was also seen that the overall hospital stay and post operative complications were less in VAC group.

A retrospective randomized control trial was conducted for a period of 2 years in the Department of Surgery, PSGIMSR with the aim of studying the efficacy of VAC in healing of diabetic foot ulcers and to compare it with the conventional wound dressing.

A total of 40 patients with Grade 2 to 3 diabetic foot ulcers (Wagners classification) were randomly divided into 2 Groups. Group-A: Vacuum assisted closure and Group-B : Conventional dressing.

Following observations were made during the study:

- Hypertension was the most common co-morbidity observed in study subjects (40% and 45% in Conventional and VAC Groups respectively) affecting the wound healing time.
- The percentage decrease in wound depth was more in VAC group than conventional dressing at the end of day 9. (53% vs 25% at the end of day 9).
- The patients on VAC therapy had early appearance of granulation tissue as compared to patients on conventional dressing (90% vs 60% at the end of day 3). All patients developed granulation tissue at the end of day 9.

We thus conclude that VAC appears to be superior compared to conventional dressings in the treatment of diabetic foot ulcers in terms of early appearance of granulation tissue and decrease in wound depth.

Funding: No funding sources

Conflict of interest: None

Ethical Approval: The study was approved by the Institutional Ethics Committee.

S. Karthikeyan, Subbaiah S., Vimal Raj et al. Analysis of Antibiotic Therapy in Acute Severe Pancreatitis. New Indian J Surg. 2018;9(3):323-27.

Abstract

Background: Acute Pancreatitis is a common surgical entity that is increasing in incidence. Gallstones and alcohol consumption remain the major contributors of Acute pancreatitis. The disease usually follows a prolonged course with increased hospital stay, early and late complications contributing to increased patient morbidity and mortality. Traditionally the role of antibiotics is usually limited to severe necrotising pancreatitis. There is however increasing evidence to prove the role of antibiotic therapy in reducing mortality and long term morbidity in acute pancreatitis patients.

Objectives:

1. To retrospectively analyse antibiotic therapy in patients with Acute severe pancreatitis in the years 2014 - 2017 in the tertiary care hospital PSG IMSR located in Coimbatore, Tamilnadu, India
2. To analyse the role of antibiotics in patient prognosis and outcome

Type of study: Retrospective Observational study. *Duration of study:* January 2014-January 2017. *Methodology:* The present study was conducted in PSG Institute of Medical Sciences & Research, Coimbatore. We did a thorough retrospective analysis of case files of 900 patients with acute severe pancreatitis. Analysing the available data from case files. *Results:* Of 900 patients, 411satisfied the inclusion criteris, of these 63% (n=258) of patients were started antibiotics within 48 hrs of hospital admission. The first choice antibiotics were Piperacillin tazobactum and metronidazole in 45% of cases, Fluoroquinolones and metronidazole in 12% of cases and Cefaperazone sulbactum ± metronidazole in 14% of cases. In 26% of cases a combination of imipenem + Cilastatin was used. Antibiotic use did not improve survival, nor was there any observed survival benefit when the different antibiotic agents were compared (p = 0.7 and 0.4 respectively). The timing of antibiotic use also does not appear to confer a survival benefit (p = 0.5). All patients with proven pancreatic infection died, there was not a significant difference in survival in those with extra-pancreatic infections (p = 0.2).

Keywords: Acute Pancreatitis; Necrotising Pancreatitis; Severe Acute Pancreatitis; Antibiotic Prophylaxis; Retrospective Analysis.

Introduction

Acute pancreatitis is a common gastrointestinal emergency. Its incidence varies from 5 to 80 cases per 100,000 inhabitants per year, with an overall mortality rate of 10–15% [1]. More than two-thirds of patients will recover within 1 week, however the remaining one-third will experience multiple systemic and/or local complications, with a high mortality rate of 10–30%, 80% of deaths are due to infectious complications [2-3].

The use and efficacy of prophylactic antibiotic therapy in acute pancreatitis has long been debated. The role of prophylactic antibiotics to prevent infection and reduce mortality in pancreatitis was first evaluated in the 1970s, where several randomised controlled trials (RCTs) had been conducted and concluded that prophylactic antibiotics were effective in preventing secondary pancreatic infections and therefore in

© Redflower Publication Pvt. Ltd.

reducing the related mortality[4-6]. However, in recent studies, there have been multiple large controlled trials, with conflicting results [7-9], different consensuses reached and differing guidelines for the use of prophylactic antibiotics [10].

Acute Pancreatitis and its Management

Acute pancreatitis is complex disease. It ranges from a mild degree inflammation that lasts for few days to severe pancreatitis, which can lead to mortality, especially in the presence of multiple organ failure or severe pancreatic infections.

Severe pancreatitis progresses in two phases [11-12]. The early stage – the first 14 days from the onset of the disease – is characterised by a systemic inflammatory response syndrome (SIRS), which may be complicated by multiple organ dysfunction syndrome (MODS). In 15–20% of cases, this may be followed by a stage of secondary bacterial infection within the inflamed pancreas, typically 2–3 weeks from the onset of pancreatitis [13].

Pathogenesis of secondary bacterial pancreatic infection is still debated. Pathogens can reach the pancreas through the haematogenous pathway, the biliary system, ascending from the duodenum via the main pancreatic duct, or through transmural colonic migration via translocation of the colonic bacteria to the lymphatics. Most pathogens in pancreatic infection are gastrointestinal Gram-negative bacteria (Escherichia coli, Pseudomonas, Proteus, Klebsiella), which occur via disruption of the intestinal flora and damage to the bowel mucosa. Impaired body defences predispose to translocation of the gastrointestinal organisms and toxins with subsequent secondary pancreatic infection. But Gram-positive bacteria (Staphylococcus aureus, Streptococcus faecalis, Enterococcus), anaerobes and, occasionally, fungi have also been found [14-16]. Infection of sterile necrosis is attributed to bacteria of gut origin in up to 70% of cases [17].

Assessment of Severity and Prognosis

Tools have been developed to predict the severity of pancreatitis and the likelihood of complications and mortality. They have been shown to be superior to clinical judgment alone, and should be used in conjunction with typical clinical criteria, such as presence of comorbid conditions, age, and first episode of pancreatitis.

The Atlanta criteria use early prognostic signs, organ failure, and local complications to define disease severity [18-19] (Figure 1). Early prognostic signs include a Ranson score of 3 or greater, or an acute physiology and chronic health evaluation (APACHE II) score of 8 or greater. Organ failure is defined as shock, hypoxemia (partial arterial oxygen tension of 60 mm Hg or less), creatinine level greater than 2 mg per dL (177 μmol per L), or gastrointestinal bleeding (greater than 500 mL per 24 hours). Local complications include necrosis, abscess, or pseudocyst [20].

The Ranson score evaluates 11 factors within 48 hours of hospital admission to predict severity of pancreatitis and risk of mortality. However, the sensitivity for predicting poor outcome is only 70% [21]. The APACHE II scoring system uses 12 criteria to predict the severity of pancreatitis, with the risk of death increasing as the score increases. The CT severity index is based on CT findings at admission and evaluates for the presence of peripancreatic inflammation , phlegmon, and, if present, the amount of pancreatic necrosis. A total score of 5 or greater is associated with a statistically significant increase in morbidity and mortality.

Severity	*Criteria*
Mild	No organ failure
	No local complications (e.g., peripancreatic fluid collections, pancreatic necrosis, peripancreatic necrosis)
	No systemic complications
	Typically resolves in first week
Moderate	Transient organ failure (≤ 48 hours)
	or
	Local complications
	or
	Exacerbation of comorbid disease
Severe	Persistent organ failure (> 48 hours)

Fig. 1: Modified Atlanta Classification for acute pancreatitis (Column width)

Antibiotic Therapy in Acute Pancreatitis

The ideal drug to use should:

1. Have specific activity against the bacteria responsible for pancreatic infections
2. Be able to penetrate the pancreatic tissue, pancreatic exocrine secretions, and peri-pancreatic fluid/ exudates at therapeutic mean inhibitory concentrations
3. Be able to penetrate the pancreas during acute pancreatitis; and
4. Have a clear-cut clinical capacity to reduce the development of infected necrosis [22].

There is no evidence to support the previous criteria of ideal antibiotics, and physicians should realise that pancreatic infection normally starts in necrotic tissue. No antibiotics effectively penetrate necrotic tissue without blood supply, which makes pancreatic infections sometimes very resistant to antibiotics.

Imipenem, clindamycin, piperacillin, fluoroquinolones and metronidazole are known to have adequate tissue penetration and bactericidal properties in infected pancreatic necrosis, in contrast to penicillins, first-generation cephalosporins, aminoglycosides and tetracyclines, which are ineffective in acute pancreatitis [22]. Meropenem is shown to have as wide a spectrum as imipenem in preventing septic complications in acute pancreatitis [23]. The use of systemic antibiotics in pancreatic infections must be accompanied with drainage, either surgical or percutaneous.

One of the main problems of prolonged administration of antibiotics in severe acute pancreatitis is the development of multidrug resistance bacterial and fungal infection, which is associated with long hospital stay and poor outcome [24]. Hence, each case should be individually evaluated, weighing the benefits of antibiotics against the significant adverse events associated with their use, including increased bacterial resistance and fungal infections. Microbiologists with a specific interest in pancreatitis should be involved in such decisions, and blood culture is highly suggested as this might detect bloodstream infections associated with pancreatitis [25-26].

Objectives

1. To retrospectively analyse antibiotic therapy in patients with Acute severe pancreatitis in the years 2014 - 2017 in the tertiary care hospital PSG IMSR located in Coimbatore, Tamilnadu, India.
2. To analyse the role of antibiotics in patient prognosis and outcome.

Type of Study

Retrospective Observational study

Duration of Study

January 2014 - January 2017

Inclusion Criteria

1. Patient admitted in PSG hospitals coimbatore with the diagnosis of Acute pancreatitis (alcoholic and biliary) graded as Severe by Modified Atlanta classification.
2. Antibiotic therapy for the patients instituted within 48 hours

Exclusion Criteria

1. Post ERCP/Post operative pancreatitis
2. Non alcoholic non biliary pancreatitis
3. Mild and moderate pancreatitis

Methodology

The study was conducted in PSG IMS & R a tertiary care centre in southern India. There have been 900 patients admitted with the diagnosis of Acute Pancreatitis in the four year period considered for this study.

Among this the total number of cases that had Acute severe pancreatitis and had been given antibiotics wishing 48 hours were 411. These fit into the inclusion and exclusion criteria. Their data was analysed with their age , sex, alcoholic and gall stone pancreatitis, antibiotic instituted, duration if antibiotic and mortality.

The data was analyzed using Microsoft Excel

Results

Of 900 patients surveyed, 500 fit the inclusion and exclusion criteria. Of which 411 received antibiotics. 63% (n = 259) of patients were started antibiotics within 48 hrs of hospital admission. 37% (n=152) did not receive any antibiotics (Figure 2).

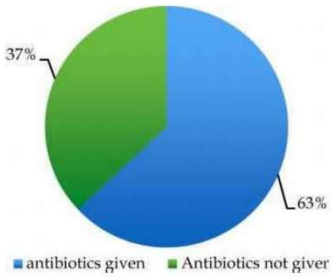

Fig. 2: Chart showing percentage of patients started on antibiotics vs Patients who did not receive antibiotics (Column width)

The first choice antibiotics were Piperacillin tazobactum and metronidazole in 45% of cases, Fluoroquinolones and metronidazole in 12% of cases and Cefaperazone sulbactum ± metronidazole in 14% of cases. In 26% of cases a combination of imipenem + Cilastatin was used (Figure 3).

Total mortality was 11 due to various complications negative bacilli as a causative organism.Antibiotic use did not improve survival, nor was there any observed survival benefit when the different antibiotic agents were compared (p = 0.7 and 0.4 respectively). The timing of antibiotic use also does not appear to confer a survival benefit (p = 0.5). It was, however, associated with a statistically significant reduction in hospital stay (p = 0.040). All patients with proven pancreatic infection died, there was not a significant difference in survival in those with extra-pancreatic infections (p = 0.2).

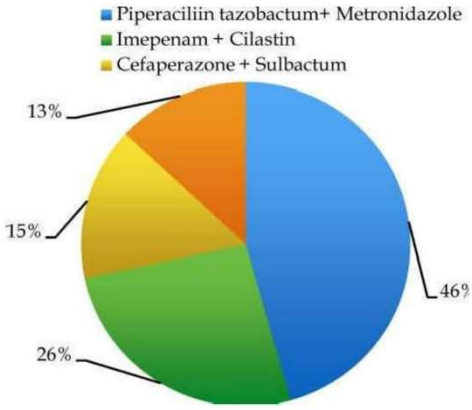

Fig. 3: Chart showing percentage of antibiotics used

Discussion

Antibiotic prophylaxis in the setting of pancreatic necrosis refers to the use of antibiotics to avoid infection in severe AP. This issue has remained controversial for the last four decades. The most important questions raise dare about antibiotic indications, antibiotic selection and length of treatment. Inappropriately selected or distributed over time antibiotics may carry complications such as anaphylaxis and selection of resistant bacteria [27-28]. The latter affects not only the patient, but also the hospital bacterial flora and the population around the hospital. The same subjects may be applied to the treatment of fungal infections. Available studies are not conclusive although some have shown benefit from antibiotic prophylaxis. These last studies used different antibiotic drugs, different selection criteria, and different length of treatment [29-31].

Also, definitions of severe disease varied between trials although in each the aim was to deliver antimicrobial prophylaxis to patients with severe AP and evidence of pancreatic necrosis. Duration of prophylaxis was relatively long (up to 14 days) [25-30].

The studies do not specify an appropriate antibiotic or duration protocol common to all. In our study we have found that while antibiotic use did not alter the mortality or survival benefit, it did alter the length of hospital stay and ICU admissions.

Conclusion

Evidence is accumulating to suggest that prophylactic antibiotics in patients with acute pancreatitis is not associated with a significant decrease in secondary pancreatic infection and mortality. We do not therefore recommend routine prophylactic antibiotic therapy for all patients with acute pancreatitis.

Table 1: Table showing patients surveyed in the year 2014 – 2017

Year	Total cases analysed (n=411)	Antibiotics given (n=259)	Antibiotics not given	Mortality
2014	126	80	46	3
2015	129	97	32	2
2016	130	71	59	4
2017	26	11	15	0

Table 2: Table showing sex, mean duration of antibiotics and mean duration of hospital stay in both groups and mortality in both groups

Patients surveyed (n=411)	Male (n=266)	Female (n=145)	Mean duration of antibiotics	Mortality
Patients who received antibiotics (n=259)	172	87	10	11
Patients who did not receive antibiotics (n=152)	94	58	Not applicable	0

Conversely, the prompt use of prophylactic antibiotics once a physician detects early markers associated with high risk of pancreatic infection is mandatory. These subset of patients with proven evidence of infection may benefit from easy antibiotic prophylaxis. Being able to identify biomarkers indicating pancreatic infection and whether they predict responsiveness to antibiotics would significantly enhance the clinical management of acute pancreatitis.

The Characteristics of routine Histopathological Examination of Appendicectomy Specimen: A Study from a Tertiary Care Centre

S. Karthikeyan[a], Raja S.R.[b],Vimal Raj[b], Priya[b], Sivaprasanna K.[c], Vijay Muthukumaran[c]

[a]Professor [b]Assistant Professor [c]Resident, Dept. of General Surgery, PSG Institute of Medical Sciences & Research & PSG Hospitals, Coimbatore-641004, Tamil Nadu, India.

Abstract

Acute appendicitis is one of the most common diseases, needing surgical intervention at its time of presentation. A histologic basis on diagnosis is essential in further workup and management of the patient in view of prognosis of the patient. Resection of the appendix whether via an open or laparoscopic approach is a very common procedure. Patients who were clinically and sonologically diagnosed with acute appendicitis, were taken up for this study. The resected specimen is sent for routine Histopathological Examination(HPE). The Histopathologic data of such patients were studied in PSG hospitals from the period of January 2015 to December 2016. 158 appendicectomy specimens were recovered of the said duration and amongst which 85(53.79%) werefrom males and 73(46.2%) from females. Perforated appendix(0.6%), lymphoid hyperplastic changes (52.38%) was seen at the maximum in the age group of 20 and below and maximum features of acute appendicitis (53.12%) was seen in the age group of 21- 40 years.

Keywords: Acute Appendicitis; Histopathology; Lymphoid Hyperplasia.

Introduction

Acute appendicitis is the most common disease of surgical field in worldwide and affects about seven percent of the population [1]. Surgeons have many challenges in the diagnosis of this common condition. Diagnosis of acute appendicitis is made primarily on the basis of the history and the physical examination, with additional assistance from laboratory and radiographic findings [7-9]. However histopathologic studies are routinely done after surgery for acute appendicitis. This makes the appendix one of the more commonly received specimens at pathology department. Histopathologic features of appendicitis are myriad. A great number of patients are operated but the specimen may or may not portrayevidence of severe involvement [17-19]. This study aims to find the value of routine Histopathological Examination in post operative course of the patient, and estimates the frequency of various histopathological findings in patients diagnosed with acute appendicitis [24,25].

Objectives

1. To find the value of routine Histopathological Examination of Appendicectomy specimen in the postoperative course of the patient.
2. To estimate the frequency of various Histopathological findings in the setting of appendicitis

Materials and Methodology

This is a retrospective analysis of appendectomies carried out in a single center (PSG IMSR) between January 2015 and December 2016. Specimens were collected from the patients, keeping in mind the inclusion and exclusion criteria mentioned below.

Inclusion Criteria

- Patient admitted in PSG Hospitals who have undergone appendicectomy (laparoscopic or open) diagnosed clinically and sonologically and confirmed with blood tests

Exclusion Criteria

- Incidental appendicectomies (Appendicectomies done during other procedures)

The Histopathology reports of appendectomy specimens were retrieved and all specimens had been Formalin-fixed, Paraffin-based and at least reviewed by two pathologists. A total of 158 appendicectomy specimens were received, and analysed based on the prevalence in different sexes, age groups andhistopathological feature of the specimens, namely:

- Acute appendicitis
- Perforated appendix
- Lymphoid hyperplasia
- Acute appendicitis with periappendicular inflammation
- Normal appendix

The various histopathological findings in the appendicectomy specimen will be studied and was correlated with the demographic data and the clinical benefit of doing routine Histopathological examination of appendicectomy specimen will be studied.

Results

Based on the Gender Predilection

85 males and 73 females underwent laparoscopic appendectomy with a prevalence of 53.79% and 46.2% respectively.

A total of 158 appendix specimens were retrieved from the patients operated from January 2015 to December 2016, amongst which, the following were the histopathological findings.

Table 1:

Histopathology Finding	No. of Specimens
Normal Appendix	3
Acute Appendicitis	69
Acute Appendicitis With Periappendicitis	32
Lymphoid Hyperplasia	53
Perforated Appendix	1
Total	158

Prevalence Between Sexes

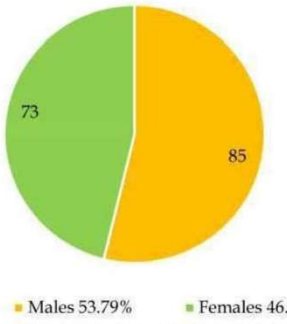

Fig. 1: Based on the gender predilection

Table 2: Histopathological findings in different age groups

	Normal Appendix	Acute Appendicitis	Acute Appendicitis with Periappendicitis	Lymphoid Hyperplasia	Perforated Appendix
20 yrs. and Below	0	25	5	33	0
21 – 40 yrs.					
More than 40 yrs.	2	34	12	16	0
	1	10	15	4	1

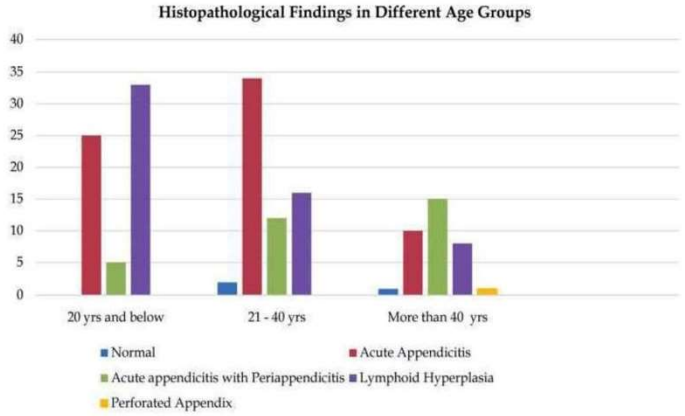

Fig. 2: Based on the histopathological findings in different age groups

Discussion

In the 1st group of patients aged 20 yrs and below, amongst the 63 patients, 25 patients (39.68%) had features suggestive of acute appendicitis, 5 patients (7.93%) had features suggestive of acute appendicitis with periappendicular inflammation and 33 patients (52.38%) had lymphoid hyperplasia. The second group of patients aged 21 to 40 years, amongst 64 patients, 2 specimens (3.12%) received were of normal histological findings, 34 patients (53.12%) had features suggestive of Acute Appendicitis, 12 patients (18.75%) had features suggestive of acute appendicitis with pariappendicular inflammation, 16 patients (25%) had features suggestive of lymphoid hyperplasia. In the third group of patients more than 40 yrs, amongst 31 patients, one specimen (3.2%) received had perforation at the tip, one specimen (3.2%) had features suggestive of normal Histology, 10 patients (32.26%) had features suggestive of acute appendicitis, 15 patients (48.39%) with features suggestive of acute appendicitis with periappendicular inflammation and 4 patients (12.9%) with feature of lymphoid hyperplasia

A perforated appendix of 0.6% was seen in the above study. Predominant lymphoid hyperplasia changes were seen in the age group of 20 years and below. Age specific incidence of acute appendicitis followed a similar pattern for males and females, with an increased predominance over the age groups of less than 40 years. Histopathological features of appendix are very difficult to diagnose the stage of appendicitis and may need new cuts and slides as needed for the patient's prognosis and outcome.

Antibiotic Prophylaxis and Surgical Site Infection

S. Karthikeyan*, Priya, Vimal Raj**, Sivaprasanna***, Akash*****

*Professor **Assistant Professor ***Resident, Dept. of General Surgery, PSG Hospitals, Coimbatore.

Abstract

Background: Surgical Site Infection rate is an important health care index. Prophylactic antibiotics have been used to prevent surgical site infections. A continuous surveillance is called for to keep a check on the resistance pattern of microbes to the prophylactic antibiotic.

Objectives:

1. To estimate the Rate of Surgical Site Infections in the years 2014 and 2015 with reference to CDC guidelines at a tertiary care hospital (PSGIMS&R) located in Tamil Nadu, Southern India
2. To estimate the frequency of various organisms causing Surgical Site Infections
3. To study the antibiotic resistance pattern to the prophylactic antibiotic used.

Type of Study: Retrospective Observational study

Period of Study: January 2014 - December 2015

Methodology: The present study was conducted in PSG Institute of Medical Sciences & Research, Coimbatore. We did a thorough retrospective analysis of case files of 467patients reported to have culture positive SSI. SSI was established using clinical and Standard microbiological testing.

Results: The outcome of this study is that the SSI rate of 4.9% reported in our hospital is consistent with or less than the rates reported in other parts of the country. Diabetes is a very important comorbidity which makes the person significantly vulnerable to SSI. In culture positive cases 24.4% of SSI showed resistance to the prophylactic antibiotic used.

Conclusion: There is a significant rise in incidence of organisms exhibiting resistance to the prophylactic antibiotic and a constant surveillance with feedback to the surgeons and strict adherence to antibiotic policies is essential.

Keywords: Surgical Site Infection Rate; Prophylactic Antibiotics; Diabetes Mellitus; Surveillance.

Introduction

Surgical Site Infections (SSI) are those which occur in the wound created by invasive surgical procedures. Historically they were called 'Irritative Fevers' [1] before the era of antisepsis brought about by Joseph Lister. These 'fevers' were uniformly lethal and so dreaded by all surgeons. They are an important cause of Healthcare associated infections. They continue to be an important health hazard even in hospitals with standard protocols of preoperative preparation and prophylactic antibiotic usage. Their prevalence is usually underestimated [2] owing to the occurrence of many of these infections after the patient has been discharged from the hospital. The spectrum of SSI can range from a simple wound discharge to life threatening sepsis. The incidence of SSI in India is estimated [3] to be around 11% at tertiary care centers.

The present study was aimed at obtaining theincidence of surgical site infections and determining the role of Diabetes Mellitus as an

important risk factor for the development of SSI. The Study also aims at determining the percentage of SSI that were resistant to the prophylactic antibiotic

Defining a SSI should involve : 1. Demonstration of signs & symptoms of Inflammation 2. Microbiological evidence of infection. The skin is colonized by a wide range of microbes and clinical evidence of inflammation is mandatory to establish a diagnosis if SSI.

The CDC definition [4] describes three levels of SSI:

superficial incisional, involves the skin and subcutaneous tissue. These infections may be indicated by Celsian signs of localized inflammation such as redness, pain, heat or swelling at the site of the incision or by the drainage of pus.

Deep Incisional involves the fascial and muscle layers. These infections may be indicated by the presence of pus or an abscess, fever with tenderness of the wound, or a separation of the edges of the incision exposing the deeper tissues.

Organ or Space Infection involves any part of the anatomy other than the incision that is opened or manipulated during the surgical procedure, for example joint or peritoneum. These infections may be indicated by the drainage of pus or the formation of an abscess detected by histopathological or radiological examination or during re-operation

Time period: The majority of SSIs become apparent within 30 days of an operative procedure and most often between the 5th and 10th postoperative days. However, where a prosthetic implant is used, SSIs affecting the deeper tissues may occur several months after the operation

Superficial Incisional SSI Infection occurs within 30 days after the operation and infection involves only skin or subcutaneous tissue of the incision and at least one of the following:

1. Purulent drainage, with or without laboratory confirmation, from the superficial incision.
2. Organisms isolated from an aseptically obtained culture of fluid or tissue from the superficial incision.
3. At least one of the following signs or symptoms of infection: pain or tenderness, localized swelling, redness, or heat and superficial incision is deliberately opened by surgeon, unless incision is culture-negative.
4. Diagnosis of superficial incisional SSI by the surgeon or attending physician.

Deep Incisional SSI Infection occurs within 30 days after the operation if no implant† is left in place or within 1 year if implant is in place and the infection appears to be related to the operation and infection involves deep soft tissues (e.g., fascial and muscle layers) of the incision and at least one of the following:

1. Purulent drainage from the deep incision but not from the organ/space component of the surgical site.
2. A deep incision spontaneously dehisces or is deliberately opened by a surgeon when the patient has at least one of the following signs orsymptoms: fever (>38°C), localized pain, or tenderness, unless site is culture-negative.
3. An abscess or other evidence of infection involving the deep incision is found on direct examination, during reoperation, or by histopathologic or radiologic examination.
4. Diagnosis of a deep incisional SSI by a surgeon or attending physician.

Organ/Space SSI Infection occurs within 30 days after the operation if no implant† is left in place or within 1 year if implant is in place and the infection appears to be related to the operation and infection involves any part of the anatomy (e.g.,

organs or spaces), other than the incision, which was opened or manipulated during an operation and at least one of the following:

1. Purulent drainage from a drain that is placed through a stab wound‡ into the organ/space.
2. Organisms isolated from an aseptically obtained culture of fluid or tissue in the organ/space.
3. An abscess or other evidence of infection involving the organ/space that is found on direct examination, during reoperation, or by histopathologic or radiologic examination.
4. Diagnosis of an organ/space SSI by a surgeon or physician

Objectives

1. To estimate the rate of Surgical Site Infections in our hospital separately for the years 2014 & 2015.
2. To estimate the frequency of various organisms causing SSI.
3. To study the antibiotic resistance pattern to the prophylactic antibiotic used.

Type of Study

Retrospective Observational Study

Period of Study

January 2014 - December 2015

Inclusion Criteria

1. Patient admitted in PSG Hospitals who have undergone surgeries here in and reported to have SSI. The definitions were based on CDC guidelines.
2. The patients should have microbial growth on wound swab culture.
3. Prophylactic Antibiotic should have been used in all cases.
4. The SSI should have been reported within 30 days of the Surgery.

Exclusion Criteria

1. Patients operated in other hospitals but presenting with SSI.
2. Swab cultures from other centers.
3. Preop antibiotics not used or not tested for sensitivity in microbiology.

Methodology

The study was conducted in PSG IMS&R a tertiary care center in southern India. There have been 9470 surgeries performed in the two year period considered for this study. These include surgeries performed in the departments of General surgery, Urology, Pediatric surgery, Cardiothoracic and Vascular surgery, Neuro surgery, HepatoPancreaticobiliary, Plastic surgery, Obstetrics & Gynecology and Orthopedics.

Among this the total number of cases that had SSI was 467. These cases met the CDC definition and fit into the inclusion and exclusion criteria. They were diagnosed using wound swabs that were processed using standard microbiological methods

The data was analyzed using Microsoft Excel

Results

Our SSI rate is estimated to be 4.92% for the year 2014 and 4.95% for the year 2015

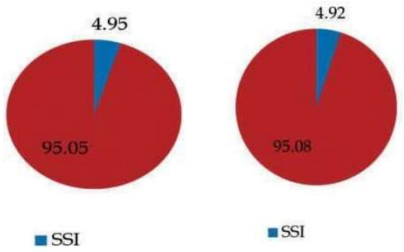

Fig. 2: SSI 2014

The most common antibiotic used preoperatively was IV Cefazolin and this was in accordace with our institution antibiotic policy

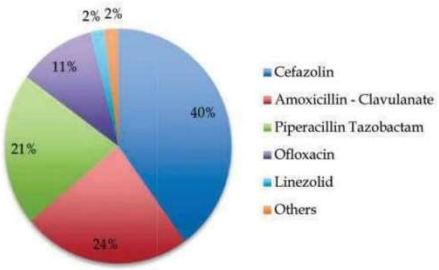

Fig. 3: Antibiotic usage

The commonest organism that showed up in wound swab culture was Escherichia Coli followed by Klebsiella pneumonia

Table 1: SSI rates for the years 2014 & 2015

Year	Total cases	SSI	SSI rate
2014	4719	232	4.92%
2015	4751	235	4.95%

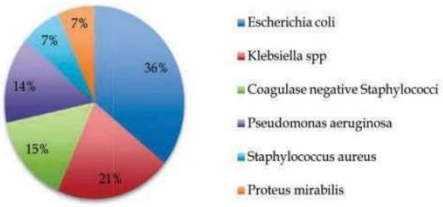

Fig. 4: Organisms grown in culture

Our study showed a predominance of SSI in Diabetics - 27.62%(n=129)

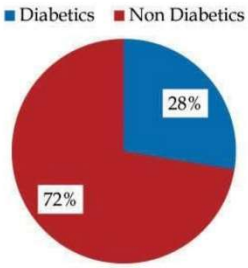

Fig. 5: Incidence of SSI in Diabetics

Resistance to the antibiotic used prophylactically was noticed in - 24.41%(n=114)

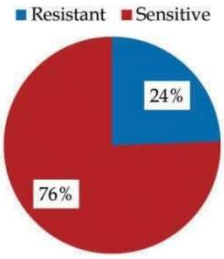

Fig. 6: Resistance to prophylactic antibiotic

Discussion

Surgical site infections are an important cause of Health Care Associated Infections (HCAI). They stand second only to Urinary Tract Infections as a significant cause of morbidity and occasional mortality in operated patients. This rate is widely variable among institutions. The rate of SSI is significantly higher in abdominal than extra abdominal procedures.

The rate of SSI varies greatly worldwide and from hospital to hospital. The rate of SSI varies from 2.5% to 41.9% as per different studies [13,14]. Thepresent study shows SSI rate 4.9% which isless than the rate of SSI reported by other authors in India.

National Academy of Science reported [15] higher rate of infection in patients with Diabetes Mellitus which is similar to our study Microbes that cause SSI are acquired either endogenously from the patient's own flora orexogenously from contact with the environment. However, theperiod of greatest risk remains the time betweenopening and closing the operating site [16].

Prophylactic antibiotics play a major role in the prevention of SSI. But a significant number of culture positive SSI show resistance to the prophylactic antibiotic.

Conclusion

All hospitals should aim at keeping a check on Surgical Site Infections. Special consideration should be given to Diabetics as this population is at a very great risk of developing SSI. Periodic surveillance and feedback to the surgeons is essential to monitor the rise of antibiotic resistant SSI.

Predictors of Major Lower Limb Amputation among Type II Diabetic Patients

S. Karthikeyan*, Priya, Vimal Raj**, Akash*****

*Professor, **Assistant Professor, ***Resident, Dept. of General Surgery, PSG Hospitals, Coimbatore.

Abstract

Diabetes mellitus (DM) is the most common cause of amputations. This study aimed toidentify the predictive factors for major lower limb amputation among patients with type 2 DM (T2DM) who were admitted to our hospital, in order to reduce its likelihood. *Methods:* This study involved 218 patients with T2DM who were admitted for diabetic foot problems from January 2015 to July 2016. A form was developed to document the patients' profiles, comorbidities, complications, investigations, treatment and clinical outcomes. The predictors for major lower limb amputations were determined using univariate and stepwise analysis. *Results:* A total of 31 patients underwent major lower limb amputations (25 transtibial, 6 transfemoral). The followingfactors were found to be associated with the incidence of major lower limb amputations: T2DM duration ≥ 10 years, diabetic neuropathy, diabetic nephropathy, presentation with gangrene, diabetic foot conditions of Wagner grade 4 or 5, and necrotising fasciitis. Patients who underwent major amputations had significantly lower haemoglobin and albumin levels, and higher total white blood cell counts, erythrocyte sedimentation rates, and C-reactive protein, urea and creatinine levels. However, only T2DM duration ≥ 10 years, positive bacterial culture and albumin levels were significant on stepwise analysis. *Conclusion:* T2DM duration ≥ 10 years, positive bacterial culture and low albumin levels were found to be significantpredictive factors for major lower limb amputation among patients with T2DM admitted for diabetic foot problems.

Introduction

Diabetes is fast gaining the status of a potential epidemic in India with more than 62 million diabetic individuals currently diagnosed with the disease. In 2000, India (31.7 million) topped the world with the highest number of people with diabetes mellitus followed by China (20.8 million) with the United States (17.7 million) in second and third place respectively. According to Wild et al, the prevalence of diabetes is predicted to double globally from 171 million in 2000 to 366 million in 2030 with a maximum increase in India. It is predicted that by 2030 diabetes mellitus may afflict up to 79.4 million individuals in India, while China (42.3 million) and the United States (30.3 million) will also see significant increases in those affected by the disease.

The Average amputations performed were related to Patients with diabetic foot problems were also found to have a poorer health-related quality of life, especially in terms of physicality Given the abundant problems related to amputations and prostheses, it would be beneficial to reduce the amputation rate due to DM. The present study sought to determine predictive factors for major lower limb amputations

Methods

This study involving 218 patients who were

admitted PSH IMSR and Hospitals from January 2015 to 2016 with type 2 DM (T2DM) were included in the study. A case record form was developed for the documentation of data prior to the commencement of this study. The following predictive factors were analysed: age, gender, marital status, duration of T2DM, smoking habits, alcohol consumption, hypertension, ischaemic heart disease, neuropathy, peripheral vascular disease, hyperlipidaemia, glycated haemoglobin level, renal profile, total white blood cell count, and erythrocyte sedimentation rate (ESR).

Peripheral Vascular Assessment was Done Using a Doppler Ultrasound

Other information that was documented included the type of diabetic foot problems (i.e. abscess, osteomyelitis, gangrene, ulcers, cellulitis, necrotising fasciitis and/or charcotosteoarthropathy). Foot conditions were graded according to the Wagner classification (grade 0: high-risk foot; grade 1: superficial ulcer; grade 2: deep ulcer, penetrating tendon, bone or joint; grade 3: deep ulcer with abscess or osteomyelitis; grade 4: localised toe, forefoot or heel gangrene; grade 5: hindfoot gangrene). Patients who underwent below- or above-knee (i.e. transtibial or transfemoral, respectively) amputations were considered to have had a major lower limb amputation.

Minor lower limb amputation was defined as an amputation distal to the ankle joint. The decision to amputate was made by the general surgeons.

Duration of ten years and above was chosen as it yielded about 80% sensitivity and specificity for having a major lower limb amputation. Demographics as well as clinical and laboratory variables of the minor and major amputation groups were compared. Unless stated otherwise, numerical data was described using mean ± standard deviation, while categorical data was described using percentages. The statistical differences of the variables for minor and major amputations were tested using independent sample *t*-tests for numerical variables and chi-square tests for categorical variables. Important variables were modelled with logistic regression to determine significant predictors.

Results

Of the 218 patients included in the present study, 147 were male and 71 were female. Their mean age was 60.97 (range 36–98) years About half (n = 131, 60.1%) of the patients had hyperlipidaemia and 183 (83.9%) had hypertension; 79 (36.2%) patients were obese and 86 (39.4%) were smokers.

Nearly 60% of the patients (n = 130) were on oral hypoglycaemic agents and 88 (40.4%) patients were on insulin therapy. In terms of follow-up location, 143 (65.6%) patients were followed up at government health clinics, 57 (26.1%) at tertiary government hospitals and 18 (8.3%) at general practitioner. Retinopathy was observed in 62 (28.4%) patients, neuropathy in 94 (43.1%) patients, nephropathy in 65 (29.8%) patients, and peripheral vascular disease in 80 (36.7%) patients. 15 (6.9%) patients had a history of cerebrovascular accidents and 55 (25.2%) had underlying coronary heart disease. The most common presentation was abscesses (n = 68, 31.2%), followed by osteomyelitis (n = 56, 25.7%), cellulitis (n = 45, 20.6%), gangrene (n = 30, 13.8%), necrotising fasciitis (n = 19, 8.7%), charcotosteoarthropathy (n = 2, 0.9%) and ulcers (n = 1, 0.5%). When the foot conditions were categorised according to the Wagner classification (n = 203), 27 (13.3%) were grade 1, 19 (9.4%) were grade 2, 114 (56.2%) were grade 3, 19 (9.4%) were grade 4 and 24 (11.8%) were grade 5. Among the 218 patients, 31 (14.2%) underwent major lower limb amputation – 6 (2.8%) were transfemoral amputations, while 25 (11.5%) were transtibial amputations.

We found that age, gender, ethnicity, monthly income, dependency on family, smoking status, obesity, hyperlipidaemia, hypertension and history of ischaemic heart disease were not associated with major lower limb amputation (Table 1). The factors associated with major lower limb amputations included T2DM duration of ≥ 10 years, higher or tertiary education level, diabetic neuropathy, presentation with gangrene, diabetic foot condition of Wagner grade 4 or 5, and necrotising fasciitis (Table 2). Coronary heart disease, abscesses, osteomyelitis, ulcers and cellulitis were not significant factors for major lower limb amputation. Gangrene was a significant factor because 12 (40%) patients with gangrene underwent major lower limb amputation compared to 19 (10.1%) patients without gangrene.

Compared to those who underwent minor lower limb amputations, the patients who underwent major lower limb amputations were found to have significantly lower haemoglobin and albumin levels, higher white blood cell count, ESR, and, urea and creatinine levels. A significantly higher number of patients who underwent major amputations also had a positive bacterial culture result, compared to those who underwent minor amputations (Table 3).

To determine the significant predictors for major

lower limb amputation, we included those variables that we considered to be clinically important. The variables were duration of T2DM(< 10 years vs. ≥ 10 years), Wagner classification (grade 1–3 vs. grade 4–5), positive bacterial culture (regardless of type of bacterial specimen cultured) and plasma albumin level.

A stepwise logistic regression was performed and the final model consisted of: duration of T2DM, positive bacterial culture and. Based on a 95% confidence interval level, the independent significant predictive factors for major lower limb amputations among our patients were duration of T2DM of ≥10 years, positive bacterial culture and low albumin levels).

Table 1: Characteristics of the patients with type 2 diabetes mellitus

Gender	Minor lower limb amputation (n = 187)	No. (%)	Major lower limb amputation (n = 31)
Female (n = 71)	60 (84.5)	11	(15.5)
Male (n = 147)	127 (86.4)	20	(13.6)
Age (yr)			
< 60 (n = 96)	84 (87.5)	12	(12.5)
≥ 60 (n = 122)	103 (84.4)	19	(15.6)
Comorbidity

Table 3: Vital signs and investigation results of the patients during admission (n = 218)

Vital sign/investigation result	Mean ± standard deviation			
	Minor lower limb amputation (n = 187)		Major lower limb amputation (n = 31)	
Systolic blood pressure (mmHg)	151	± 23	110	± 25
Diastolic blood pressure (mmHg)	91	± 13	62	± 13
Pulse (bpm)	84	± 13	112	± 13
Temperature (°C)	37.7	± 1.1	38.5	± 0.6
Haemoglobin level (g/dL)	10.7	± 1.7	9.3	± 1.7
Total white blood cell count (× 10^9/L)	13.4	± 3.1	18.4	± 4.3
Erythrocyte sedimentation rate (mm/hr)	68.9	± 25.8	84.8	± 21.0
C-reactive protein level (mg/dL)	35.8	± 36.2	105.5	± 23.4
Glycated haemoglobin level (%)	8.0	± 1.4	8.1	± 0.4
Urea level (mmol/L)	8.4	± 2.8	14.7	± 4.3
Creatinine level (mmol/L)	111.2	± 36.2	231.9	± 104.5
Albumin level (g/L)	35.3	± 5.7	23.2	± 4.4
Positive bacterial culture*	88 (80.7)		21 (19.3)	
Negative bacterial culture*	99 (90.8)		10 (9.2)	

Discussion & Conclusion

The rate of major lower limb amputations for diabetic foot problems in the present study (14.2%) is lower than the ratesreported by other studies.These differences in the rates of major lower limb amputation could be due to poor acceptance of amputations as a means of diabetic foot management among our study population. In the present study, duration of T2DM of ≥ 10 years was found to be a significant independent predictive factor for major lower limb amputation and age was not found to be a significant predictive factor for major lower limb amputation. While neuropathy was found to be associated with major lower limb amputation in the present study, it was not a significant independent predictive factor. Necrotising fasciitis was found to be associated with major lower limb amputation, following stepwise logistic regression, only a positive bacterial culture result was

found to be a significant independent predictive factor for major lower limb amputation. Abscess, osteomyelitis, ulcers and cellulitis were not significant factors for major lower limb amputation, suggesting that they could be treated with minor limb amputation. In the present study, total white blood cell count, ESR and Albumin were dependent factors for major lower limb amputation. While major lower limb amputation was not significantly associated with peripheral vascular disease. It was significantly associated with gangrene at presentation anddiabetic foot conditions. Albumin level was found to be an independent predictive factor for major lower limb amputation. Nephropathy and high levels of urea and creatinine were also found to be associated with major lower limb amputation. A low albumin level indicates poor nutritional and renal function. Low albumin levels were also found to be associated with poor wound healing after Syme amputations, leading to major lower limb amputation in patients with DM. In conclusion, the present study showed that a duration of T2DM ≥ 10 years, positive bacterial culture and low serum albumin levels were predictors for major lower limb amputation in patients admitted with diabetic foot problems. Hence, we recommend early aggressive treatment for infections in patients with a long history of T2DM who are admitted for diabetic foot problems, without neglecting their clinical management and nutritional support.

To Operate or not to Operate, That is the Question! Review of Management of Splenic Trauma in our Institution over the Past 15 Years

S. Karthikeyan*, Hemachandran, Adharsh Kumar M.***, Bichu Joseph Maliakal*****

*Professor, **Assistant Professor, ***Resident, Dept. of General Surgery, PSG IMSR & Hospital, Coimbatore.

Abstract

Objectives: To review the management of Splenic trauma (operative vs conservative management) and our outcomes. *Type of Study:* Retrospective observational study. *Period of Study:* 2000-2015. *Methodology:* There have been 36 cases who were admitted with splenic trauma in our institution over the last 15 yrs. ICD-10 Code S36.0 was used to identify these patients. A thorough review of their files was undertaken. *Results:* AAST Grading for splenic injury was done for these cases and there were 3 cases of grade 1, 6 cases of grade 2, 13 cases of grade 3, 12 cases of grade 4 and 2 cases of grade 5.

Of these, both cases of Grade 5 injury were operated immediately, while 4 out of 12 cases of grade 4 injury were operated immediately. Of the 8 cases of grade 4 injury which were managed conservatively, One case needed to be operated at a later date, which is our only case of failure of conservative management.

Usion criteria. One case of grade 3 injury was operated, while all cases of grade 1 and 2 were managed conservatively.

We had 7 cases of Operative management (OM), 28 cases of Successful conservative management (CM) and 1 case of Failure of conservative management (FOC). *Conclusion:* The goal of this study was to evaluate the success of the various strategies (conservative vs surgical) and their outcome. Our study shows that conservative management has a major role to play in hemodynamically stable patients even if their AAST grading of Splenic injury was 4. But these patients who are managed conservatively, need to be monitored closely and the surgeon should be ready to take the patient up for emergency surgery if any signs of worsening are evident.

The failure of non-operative management can be life-threatening and even fatal if the deterioration is not picked up immediately.

Keywords: Splenic Trauma; Splenic Injury; Conservative Management; Non-Operative Management; Splenectomy; AAST Grading.

Introduction

Historically, patients presenting with splenic trauma were taken up for emergency splenectomy. But due to advances in Imaging and ICU care, a conservative approach is presently in vogue. Patients who are managed conservatively tend to have shorter hospital stay, have lesser blood transfusions and avoid risk of long term infectious complications.

But patients who are managed conservatively require very close monitoring as failure of conservative management can be a life threatening event if the deterioration is not picked up early and the patient is not operated immediately.

Failure of conservative management can be due to missed injury, delayed splenic rupture, splenic artery pseudoaneurysm or spontaneous haemorrhage.

AAST Grading for splenic injury is a useful tool to assess necessity for surgery in these cases. Historically, Grade 4 and Grade 5 were taken up for immediate surgery. However, we are now attempting to manage Grade 4 splenic injury patients, who are hemodynamically stable, with conservative management.

Aast Grading for Splenic Injury

Grade*	Injury type	Description of injury
I	Hematoma	Subcapsular, <10% surface area
	Laceration	Capsular tear, <1cmparenchymal depth
II	Hematoma	Subcapsular, 10%-50% surface area intraparenchymal, <5 cm in diameter
	Laceration	Capsular tear, 1-3cm parenchymal depth that does not involve a trabecular vessel
III	Hematoma	Subcapsular, >50% surface area or expanding; ruptured subcapsular or parecymal hematoma; intraparenchymal hematoma ≥ 5 cm or expanding
	Laceration	>3 cm parenchymal depth or involving trabecular vessels
IV	Laceration	Laceration involving segmental or hilar vessels producingmajor devascularization (>25% of spleen)
V	Laceration	Completely shattered spleen
	Vascular	Hilar vascular injury with devascularizes spleen

*Advance one grade for multiple injuries up to grade III

Our institution, PSGIMSR, Coimbatore, is a multi-speciality tertiary care centre with advanced trauma care facilities.

We look at the incidence of Splenic trauma cases that were admitted and managed in our institution over the past 15 yrs.

Objectives

To review the management of Splenic trauma (operative vs conservative management) and our outcomes

Type of Study

Retrospective observational study

Period of Study

2000-2015

Inclusion Criteria

1. Patients who were admitted in PSG Hospital with Splenic trauma
2. They should have a CECT Abdomen done here.
3. They could have been treated elsewhere initially but definitive treatment should have been in PSG Hospital.

Exclusion Criteria

1. If the patient was operated elsewhere.

2. If the patient has undergone a laparotomy primarily for other abdominal injuries and not for splenic injury.

Methodology

There have been 36 cases who were admitted with splenic trauma in our institution over the last 15yrs who fit into our inclusion and exclusion criteria.

ICD-10 Code S36.0 was used to identify these patients

A thorough review of their files was undertaken.

Definitions

1. Operative Management (OM): Patient taken up for emergency surgery within 24 hrs of admission.

2. Conservative Management (CM): non operative management till discharge.

3. Failure of Conservative Management (FOC): initial Conservative Management but eventually required Surgery after 24hrs

Results

- We collected 36 cases over the last 15 years (2000 -2015) which met our inclusion criteria.
- Patients ranged in age from 12 to 70 years with an average of 34.5 (median -35).
- A male preponderance was noted with 31 of the 36 patients falling in this category.
- Of the 36 cases, 26 were road traffic accidents.
- As expected in RTA's, the majority of patients were male (22 patients out of 26).
- Time taken for the patient to reach the emergency department, PSG Hospital after the RTA ranged

from 1hr 15 mins to 8 days. Some cases were initially evaluated and investigated elsewhere and then referred here to a tertiary trauma care centre for further management.

- Average length of stay was 8.7 days ranging from 1 to 21 days with a median of 8 days. The patient who was our failure of conservative management was the one who was admitted for 21 days.
- Type of injury was blunt injury in 34 cases while it was penetrating injury in 2 cases.

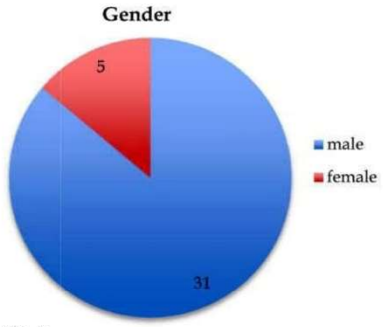

Fig. 1:

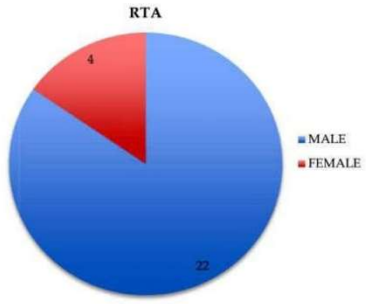

Fig. 2:

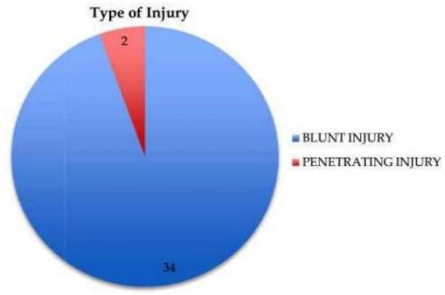

Fig. 3:

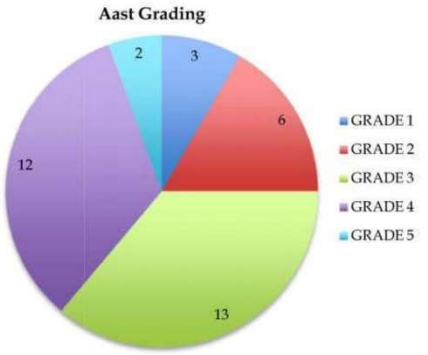
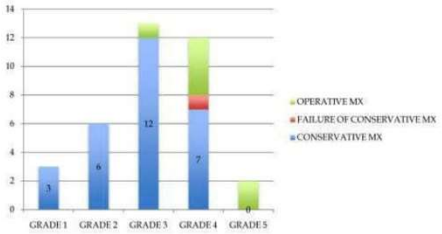
- AAST Grading for splenic injury was done for these cases and the results are as follows:



Gr 1 – 3 cases

Gr 2 – 6 cases



Gr 3 – 13 cases

Gr 4 – 12 cases

Gr 5 – 2 cases

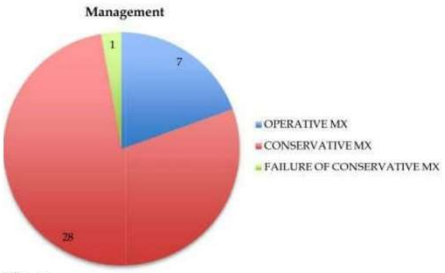
Of these, both cases of Grade 5 injury were operated immediately, while 4 out of 12 cases of grade 4 injury were operated immediately. Of the 8 cases of grade 4 injury which were managed conservatively, One case needed to be operated at a later date, which is our only case of failure of conservative management.

- usion criteria. One case of grade 3 injury was operated, while all cases of grade 1 and 2 were managed conservatively.
- Haemoglobin at admission, which is a criteria to asses the necessity for emergency surgery, ranged from 15.2 g/dl to 3.2 g/dl with the average being 10.4g/dl.
- Maximum drop in Haemoglobin was noted to be 4.9 g/dl.
- Maximum units of blood transfusion required preoperatively to stabilize the patient were 5

packed RBCs.

- The cases with low haemoglobin at admission and with significant or persistant drop in haemoglobin and the one requiring large volume blood transfusion were all taken up for emergency surgery.

We had 7 cases of Operative management (OM), 28 cases of Successful conservative management (CM) and 1 case of failure of conservative management (FOC).



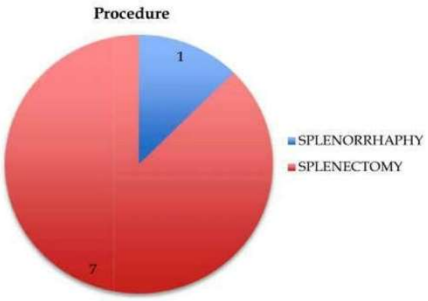


Fig. 6:

Splenoraphy was the procedure of choice for one patient, a 13 yr old girl, while the rest of the cases underwent splenectomy.

- As expected, those who were selected for emergency operative management were more severely injured and hence were more likely to have lower Blood pressure on admission, be hemodynamically unstable, have lower haemoglobin on admission and thus require more blood transfusions.

The only case of Failure of conservative management was a middle aged gentleman, who presented with H/O RTA. He was found to have a Grade 4 splenic laceration, but as he was hemodynamically stable and his baseline haemoglobin was within normal limits, the decision was made to manage him conservatively. His haemoglobin was checked twice daily and he was kept on strict bed rest and intensively monitored in Surgical ICU. On the seventh day post trauma, as he was showing some signs of deterioration, an urgent CECT abdomen was done which showed perisplenic contrast leak. His blood pressure dropped immediately after the CECT scan was done and the decision was taken to Operate immediately. Intra-operatively, he was found to have active oozing from the spleen and he underwent a splenectomy. He recovered well post operatively and was stable on discharge.

Conclusion

The goal of this study was to evaluate the success of the various strategies (conservative vs surgical) and their outcome. Our study shows that conservative management has a major role to play in hemodynamically stable patients even if their AAST grading of Splenic injury was 4. But these patients who are managed conservatively, need to be monitored closely and the surgeon should be ready to take the patient up for emergency surgery if any signs of worsening are evident.

The failure of non-operative management can be life-threatening and even fatal if the deterioration is not picked up immediately.

Follow Up of Surgical Treatment for Varicose Veins in the Last Three Years in our Institution

S. Karthikeyan*, S. Hemachandran*, Bichu Joseph Maliakal*, Adharshkumar M.*

Department of General and GI Surgery, PSG Institute of Medical Sciences and Research Peelamedu, Coim batore, Tamil Nadu.

Abstract

Objectives: To assess the influence of venous reflux pattern and superficial venous surgery on ulcer healing and long-term recurrence rates and also to prove that surgery for varicose veins will help in resolution of venous ulcer, thereby improving their quality of life and improve their efficiency at work. *Design:* Retrospective observational study *Methods:* Data was collected from the inpatient and outpatient records at a tertiary care setup hospital. All operated cases of varicose veins with venous ulcers(CEAP C class 6) were followed up. A proforma was made highlighting all the salient findings as type of varicose surgery and choice of post operative compression and datas were collected. Study duration was from june 2012 to june 2015. *Results:* A total of 91 cases of operated varicose veins (11 GSV stripping, 72 GSV stripping + perforator ligation and 8 cases of perforator ligation alone) with venous ulcers were studied, out of which 27 patients were non compliant to postoperative compression and 11 cases had recurrent venous ulcers with 6 cases having recurrent varicose veins. Pattern of superficial venous reflux and risk factors associated with recurrent ulcers were also studied. *Conclusion:* Superficial venous surgery done in an effective manner, with proper postoperative compression of these patients definitely produces good results with less recurrence of both venous ulcers and varicose veins.

Introduction

Varicose veins is a common disease condition we see in our daily practice and most of them present to us with non healing venous ulcers.

Chronic venous ulcers represent a major burden to health care services affecting at least 1-2 percent of our total population, often with a protracted course of delayed healing and multiple recurrences.Ulcer aetiology is often multifactorial and results from prolonged venous hypertension.

It has been suggested that surgery alone is sufficient to heal ulcers with isolated superficial reflux. Other consultants employ compression bandaging in addition to surgery. Patients are advised to wear elastic compression hosiery following ulcer healing, but compliance is often poor and difficult to assess.

The role of surgical correction of saphenous vein reflux as a therapeutic manoeuvre in the treatment of venous ulceration have demonstrated that saphenous vein ligation withstripping to the knee (combined with postoperative compression) results in ulcer healing ifthe deep veins are normal, with associated improvementin ambulatory venous pressure.

Because of the substantial morbidity, financial and psychosocial cost it is important to identify the most effective means of treatment for venous ulceration. The progressive development and modification of treatments are essential to contest the natural history of prolonged ulceration and recurrence that makes venous ulceration extremely difficult to cure.

Superficial or deep venous incompetence allows high- pressure venous blood to gravitate to the ankle, this venous hypertension is thought to be the principal cause of venous ulceration, secondary to superficial and deep venous in- sufficiency,obstruction to venous flow, and/or failure of the "venous calf pump". Other associated factors include elevated ambulatory

venous pressures, minor trauma, edema, obesity, arthritis and neuropathies.

Pathophysiological abnormalities contribute to changes at a cellular level that result in venous ulceration, for which a number of hypotheses have been put forward. Despite varying explanations for venous ulceration, it appears that correction of venous hypertension results in ulcer healing and lower recurrence.

Compression therapy and surgical correction of superficial venous incompetence are the main methods currently employed for the treatment for venous ulceration. Graduated external compression to the lower extremity has resulted in accelerated healing of venous ulcers and has become the mainstay of treatment. Compression bandaging therapy is thought to produce a decrease in ankle fluid, softening of the lipodermatosclerosis, decrease in venous volume, increase in deep venous velocity, blood shifts into central compartments, reduction in venous reflux, improvement of venous pumping, improvement in microcirculation and lymph drainage.

As Coimbatore district and surrounding areas is a highly industrialized region with thousands of manual laborers, We, the Department of General surgery, PSG IMS&R, tend to see a lot of patients with varicose veins. Most patients only come for treatment if they are symptomatic or if they have an ulcer. This study looks at the improvement in venous ulcers in patients undergoing varicose vein surgery in our institution.

Aim of Study

1. To assess the influence of venous reflux pattern and superficial venous surgery on ulcer healing and long-term recurrence rates.
2. To prove that surgery for varicose veins will help in resolution of venous ulcer, thereby improving their quality of life and improve their efficiency at work.

Materials and Methods

Study Type

Retrospective observational study

Study Population

91 patients with varicose veins and venous ulcers

Study Duration

3 years (June 2012 to June 2015)

Place of Study

Study was done at a tertiary care multispecialty hospitals (PSG hospitals , coimbatore).

Data Collection

Data was collected from both inpatient and outpatient files from PSG hospitals medical records department.

Inclusion Criteria

1. Patients with active venous ulceration (C-class 6 in the CEAP classification), that we have operated at our institution.

Exclusion Criteria

1. Patient numbers with healed venous ulceration (C-class 5 in the CEAP classification) that recurred after treatment and was operated.
2. All cases of varicose veins operated without a venous ulcer, (C-class 2-4 in the CEAP classification).

Data Analysis

The studies were analyzed and data abstracted with regard to the patient demographics; Number of cases operated; Type of surgery performed; Time of follow up; Size of ulcer; Time taken for ulcer healing; number of cases with recurrence to ulcer; time taken for ulcer recurrence; venous Doppler reports of those patients showing SFJ, SPJ and perforator incompetence; mean hospital stay and methods use postoperatively:comp. stockings/crepe bandage. We also collected data on risk factors associated with non-healing ulcers and ulcer recurrences.

Results

The study included a total of 91 cases of operated varicose veins at our hospital with active venous ulceration (C-class 6 in the CEAP classification).

Of these 11 cases had undergone only trendlenbergs procedure, 72 cases had trendlenberg with perforator ligation and 8 cases had only perforator ligation.

85 of these cases had ulcers lesser than 3 cms size and only 6 cases had ulcers > 3 cms and largest was a 6 cmssized ulcer. Size of ulcer was not associated with recurrence, as we also saw larger ulcers that healed well, post surgery.

All 91 cases had their first review within 10 – 15 days from the date of discharge and all 91 cases had good ulcer healing at their first review. 20 cases did not turn up for second review and all those cases were considered as not compliant to stockings/crepe bandage.

Some of the Risk factors associated with ulcer formation that we identified in our study was (i) Age of the patients usually fall greater than 40 years in more than 80% of cases; (ii) Sex of patient showed a female preponderance in more than 80% of cases; (iii) Occupation of patient is one of long standing professions in greater than 95% of cases.

Venous Doppler imaging studies were invariably done in all cases, which showed 90 % of cases to have SFJ incompetence, 50 % cases to have associated SPJ incompetence and 85% of cases to have associatedperforator incompetence. 100% of recurrent venous ulcer cases had multiple perforator incompetence and also had underwent surgeries for the same along with trendlenbergs procedure.

27 cases were not compliant to crepebandage / stockings application, of which 11 cases had recurrent venous ulcers and time period for recurrence ranged from 3 months to 6 months. 100% of these ulcers were healed well in 10 to 15 days post surgery, only to recur 3 months later.

Time taken for ulcer healing ranged from 10 days to 1 month in most of cases. Only 6 cases took a longer duration of 3 months to 6 months and all of them were positively associated with larger size of venous ulcer.

Post operatively, both compression stockings and crepe bandage were used. 27 cases were not compliant to these measures. Out of 11 recurrent cases, 100% of them were not compliant to stocking / crepe application. But it was not true otherwise, 27 cases were not compliant with these measures and not all of them were associated with recurrence.

It was also noted that 6 cases had recurrent varicose veins and 100% of them were associated with recurrent venous ulcers, non compliance to postoperative compression and also 100% of these had multiple perforator incompetence.

Fig. 1

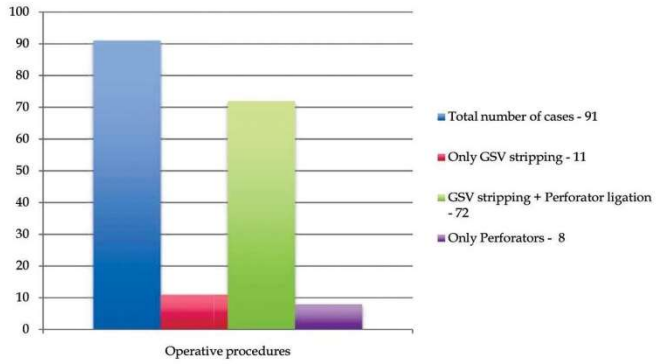

Fig. 2

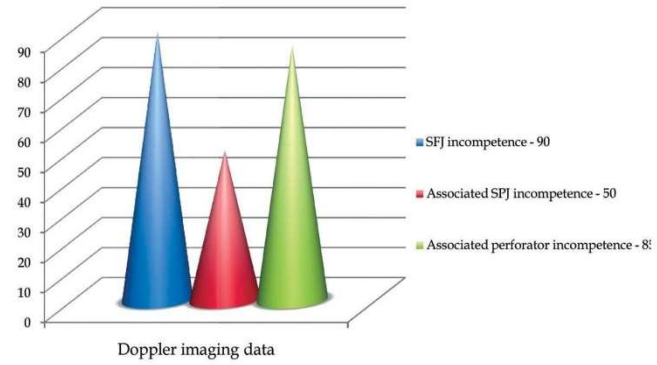

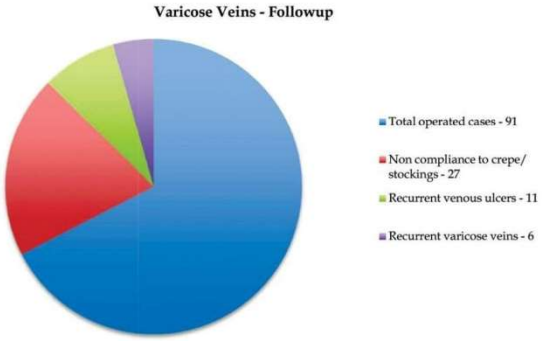

Fig. 3

Discussion

In this study a total of 91 operated cases of varicose veins were followed up and out of them 11 cases had recurrent venous ulcers and 6 had recurrence of varicosities .

Labropoulos *et al.* assessed the progression of 150 operated cases of varicose veins and venous ulcers in the New York region.The factors associated with nonhealing were advanced age, increased body mass index, history of DVT, non-compliance with compression therapy, and large ulcer area.

In our study, duration of active ulcer, pattern of venous incompetence, associated risk factors and poor compliance to postoperative compression, all correlated with a poor prognosis for healing. Butsize of ulcer was not associated with recurrence, as we also saw larger ulcers that healed well, post surgery.

Margolis *et al.*, in a U.S. study have shown that colonization and infection play a role in delaying the healing of chronic ulcers. In our sample, these factors (slough) were present in a substantial percentage of cases, demonstrating how often these conditions occur in patients with chronic leg ulcers. Infection was a major factor associated with worse prognosis during follow-up.

In our study, compliance with compression therapy had a major favorable effect on healing at 6 months. Other risk factors reported in the literature as having a negative influence on healing of chronic venous leg ulcers, such as, ulcer area at baseline, and post-thrombotic etiology, were not identified as such in our sample.

External compression is regarded as essential to the ulcer healing process. In our study 27 cases were not compliant to post operative compression and all 11 cases that had ulcer recurrence were positively associated with non compliance to postop compression. It shows Compliance with compression therapy has favorable effects on the healing process.

There is a consensus in the literature that the most effective intervention for treatment and prevention of recurrence in varicose is strong compression, as it minimizes the effects of venous hypertension on the affected leg. Compression acts on the macro circulation by increasing deep venous return, reducing pathological reflux during walking, and increasing the stroke volume during activation of the calf muscles. Limb compression increases tissue pressure, thus facilitating resorption of edema and improving lymphatic drainage. Furthermore, it acts on the microcirculation to decrease fluid and macromolecule outflow from the capillaries and venules to the interstitial space, and can also stimulate fibrinolytic activity.

It was also noted that 100% of recurrent venous ulcer cases had multiple perforator incompetence and also had underwent surgeries for the same along with trendlenbergs procedure, which may suggest left behind perforators may be a cause of recurrence in these patients.

Also the risk factors as increasing age, female preponderance and long standing occupation were all identified as additional factors that may have played a role in recurrence of varicosities and ulcers in those patients as suggested by various metastudies.

Conclusion

Evidence from the current literature, would suggest that superficial venous surgery done in an effective manner,with proper compression of these patients definitely produces good results with less recurrence of both venous ulcers and varicose veins.

Abstract

Preoperative prediction of morbidity in colorectal cancer (CRC) surgery helps to optimize the surgical outcome. In this study, we aim to develop a dedicated equation for predicting operative morbidity using colorectal possum scoring system and also to validate the predictive accuracy of CR-POSSUM scoring system in prognosticating actual complications. We did a retrospective analysis of 322 patients undergoing colorectal cancer surgery from a single centre in South India from 2004 to 2016. Mortality and morbidity risk factors as defined by CR POSSUM were collected from 322 patients who underwent CRC surgery and were used to derive equations to predict morbidity, and the results were compared with the observed morbidity. Logistic regression analysis was used to derive the equation. The model fit and model discrimination were analysed using the Hosmer-Lemeshow statistical test for goodness of fit, the Nagelkerke R^2 and area under the receiver operating characteristic (ROC) curve respectively. Out of 322 patients, 103 (32%) patients developed complications and 10 (3%) died due to complications. The regression equation we derived has an overall correct classification of about 70% ($P < 0.01$) with positive and negative predictive value of 60% and 73% respectively. The Hosmer-Lemeshow goodness of fit was 3.147 ($P = 0.829$), and the Nagelkerke R^2 was 17% and area under ROC as model discrimination was 71.6%. Hence, CR-POSSUM scoring which was originally used for predicting mortality risk can also be extrapolated to predict morbidity.

Introduction

Colorectal malignancy is the third most common malignancy among men and the second most common among women around the world [1]. Fortunately, in India, the incidence is not too high. However, the incidence has been found to be rising, with the AAR (adjusted annual incidence rate) for colon cancer in men and women being 4.4 and 3.9 per 100,000, respectively [2]. Being in a country, where people living with poor access to quality healthcare, extreme presentation like advanced stage and perforation are common in tertiary care centres [3, 4]. In such scenarios, the mortality and morbidity for the patients undergoing surgery are relatively high [5]. Complications following major surgeries will proportionately increase the hospital cost and duration of hospital stay [6]. Apart from such hardships, complications also had an adverse impact on long-term survival [7]. So in a country like India, where the spending on health by the government is low and health insurance is under-penetrated, morbidity following a major surgical procedure will further drain the already constrained resources [8]. The complication rates are not uniform and cannot be generalised, as there are certain factors, such as age, patients' co-morbidity and operative severity, influencing the outcome of surgery [9]. So, putting together these factors and assessing the postoperative outcome preoperatively will help in optimizing the available resources. In such cases, the predictive scoring has to be more accurate, and its predictive ability should

Key message: CR-Possum can be used to predict morbidity in patient undergoing colorectal cancer surgery.

[illegible]

[illegible]To analyse the risk-factors contributing to infection with multidrug-resistant organisms.

M[illegible] A 150 diabetic patients with foot ulcer were prospectively studied. Detailed clinical history and clinical examination of the ulcer were done for all patients. The microbiological profile was analyzed for each patient. Using internationally accepted criteria, the multidrug-resistant organisms were identified. Risk factors for acquiring MDRO infection were identified using appropriate statistical tools.

[illegible]MDRO were isolated from 99 patients of 150 (66%). A 54.8% (153 out of 279) of isolated organisms were multidrug-resistant organisms. By univariate analysis poor glycaemic control, previous hospitalisation, previous history of amputation, previous antibiotic usage, size of the ulcer, necrotic ulcer, recurrent ulcers, higher grade of ulcer, the presence of osteomyelitis, the presence of retinopathy, peripheral vascular disease, neuropathy and polymicrobial culture, were significantly associated with MDRO infected foot ulcers. Analysis by logistic regression indicated that only two factors significantly increased the risk of acquiring MDRO infection. They are recurrent ulcer (OR = 3.39, p <0.05, 95% CI = 1.081-10.664) and higher grade of ulcer (OR = 13.44, p <0.001, 95 % CI =3.595-50.278).

[illegible]The prevalence of MDRO is alarmingly high in infected diabetic foot ulcers. Recurrent ulcers and higher grade of ulcers are more prone to acquire MDROs.

[illegible]Diabetic foot, MDRO, Polymicrobial infection, Risk factors

[illegible]

India has the second largest number of patients living with diabetes world wide, with as many as 82 million adults suffering from this disease and its complications.[1] Development of foot ulcers is seen in 15% of all diabetic patients during their lifetime.[2] This is associated with a significant economic burden. The health expenditure is 5 times more in diabetics with foot ulcers than in those without foot ulcers.[1]

Infection of foot ulcers is often due to more than one organism and it is, therefore, imperative that appropriate antibiotic therapy is instituted.[3] Infection with multidrug resistance organisms will increase the morbidity and consequently, the finances involved, to a significant extent.[4] Emergence of multi-drug resistance organisms (MDRO) is the area of major concern in both developing and developed countries.[5] In India, a lack of adherence to protocol in prescribing antibiotics leads to the emergence of these super bugs.[6] Also patient related factors also play

an important role in the development of such organisms. Diabetes is one such factor and its complication such as foot ulcer harbors MDRO.

There are various other factors involved in the emergence of MDRO in diabetic foot ulers. Very few studies have been done in India, to elucidate the underlying risk factors for the development MDRO in diabetic foot ulcer. Present study aims to correlate the risk factors and their association with the development of MDRO in diabetic foot ulcers in South India.

M□□□□ □ □□□

One hundred fifty diabetic patients with foot lesions were included in the study, conducted between January 2011 and July 2012, at PSG Institute of Medical Sciences and Research, Coimbatore, India, after obtaining approval from the institutional review board. Clinical history was collected using structured case report forms. Mode of presentation of foot ulcers were classified as grade I to V as per Meggit Wagner Classification System (Wagner, 1981). Ulcers were categorised into necrotic/non-necrotic ulcers based on signs of infection (swelling, exudates, surrounding cellulitis, odour, tissue necrosis and crepitation). Size was determined by multiplying the longest and widest diameters expressed in centimeters squared (cm^2), and the diagnosis of extension to the bone was made by plain radiographs. Presence of neuropathy was detected by assessing vibration sensation using a 128 HTZ tuning fork and a 10gm Semmes - Weinstein monofilament. Peripheral diabetic neuropathy was defined as an abnormal monofilament test, as described by the international consensus on the diabetic foot.[7] Presence of nephropathy was detected by screening the patient's urine for micro / macro-albuminuria after ruling out urinary tract infection. The fundus was examined by the ophthalmologist for evidence of retinopathy. Absence of both dorsalis-pedis pulsations and/or an Ankle Brachial Index (ABI) less than 0.9 was termed as peripheral vascular disease.

Wound swabs were obtained from the floor of the ulcer, before starting empirical antibiotic therapy. Direct microscopic examination and aerobic cultures were done by standard methods. The bacteriological spectrum and the sensitive antibiotics were noted for each patient. All patients were started on empirical antibiotics depending on the status of the wound. In mild infection amoxyclav (amoxicillin/clavulanic acid) was given by oral route. But in patients with necrotic wounds, an additional antibiotic, clindamycin or metronidazole, was added for anaerobic and gram-negative coverage and the intravenous route was preferred. In the presence of an unhealthy ulcer, surgical debridement / amputation was done immediately after admission. Later wounds were managed with regular dressings and antibiotics modified according to the culture report. All patients were re-inspected or enquired over phone after a period of 10 weeks to assess the status of wound. For each patient, the following details were entered: age, sex, duration of ulcer, duration of diabetes, glycaemic control, presence of retinopathy, presence of micro/macro-albuminuria, hypertension, history of smoking, history of previous amputation, duration of hospital stay, interventions (medical and surgical), organisms cultured from ulcer, antibiotic profile and status of ulcer after 10 weeks. Previous hospitalization was defined as any hospital stay, which was not necessarily for the management of ulcer, during the year preceding the current hospitalization. Previous antibiotic usage was defined in present study, as those who had received antibiotics in six months preceding current hospitalization.

The data was collected and entered in the SPSS data sheet. The data was analysed using SPSS 20 for descriptive statistics. To assess the risk factors for acquiring MDRO, the patients were grouped into MDRO and non-MDRO groups. All patients, who had at least one multidrug resistant organism, were grouped under MDRO group. The test variables were compared using Chi-square test for qualitative variables and Student's test for quantitative variables. The variables for which the association was statistically significant ($p<0.1$) were introduced in a logistic model. Univariate analysis was performed to compare infected ulcers according to the presence or absence of MDRO. Logistic regression was used to identify explanatory variables for the presence of MDRO.

□□□□ □□□□

Seventy-eight percentage of the patients were 51 years or older. A 74.6% of the patients were males, showing a distinct male preponderance. Most of the patients (44%) belonged to class II socio-economic status followed by class III (26 %), as per Modified Prasad's classification (Table 1).[8]

Sixty-eight percentage of patients had ulcers of less than one-month duration. Concerning the size of the ulcer, most were between 4 to 8cm^2 and 8 to 16cm^2. Most of the patients had Wagner's grade II, III, or IV ulcers. There were very few ulcers with Wagner's grade V. There was an almost equal distribution of necrotic and non-necrotic ulcers and also recurrent and non-recurrent ulcers.

Thirty-four percentage of ulcers had associated osteomyelitis. 28% of ulcers were seen in the heel, followed by 21.33% in digits/inter-digital areas (Table 3).

A total of 279 organisms were isolated from 150 patients. On an average 1.86 species were isolated from each patient. 58.66% of patients (88 of the 150 patients) had polymicrobial culture. Among the isolates, most were gram-negative rods (69.89%), and almost all the rest were gram-positive cocci. There was a solitary gram-negative coccus. Gram-positive to gram-negative ratio, among the isolates, was 1:2.3. Among the isolates, *Escherichia coli* was the most common one constituting 17.9%. MDROs were seen in 99 of the 150 patients (Tables 4).

Peripheral arterial disease was seen in 52.66%, retinopathy detected in 24.66% and albuminuria suggesting nephropathy was found in 48.66%. Majority of the patients had neuropathy. 61.33% were hypertensive.

Fifty percentage of the patients were smokers and 41.33% alcoholics. History of previous hospital admission in the last one year was seen in 53.33%. 21.33 % of patients had history of some form of amputation. 42.66% of the patients had a history of antibiotic use in the preceding six months before admission (Table 5).

Results of the univariate analysis showed poor glycemic control, previous hospitalization, previous history of amputation, previous antibiotic usage, size of ulcer, necrotic ulcer, recurrent ulcers, higher grade of ulcer, presence of osteomyelitis, presence of retinopathy, peripheral vascular disease, neuropathy and polymicrobial culture, were significantly associated with MDRO infected foot ulcers (Table: 6). However logistic regression results indicated that only two factors significantly increased the chances of acquiring MDRO infection; recurrent ulcer (OR=3.39, p <0.05, 95% CI=1.081-10.664), higher grade of ulcer (OR=13.44, p <0.001, 95% CI=3.595-50.278) (Table 7).

Infection with MDRO in diabetic foot ulcers associated with inadequate glycemic control and increased requirement of surgical management.[9] In this study presents a comprehensive clinical and microbiological profile of infected diabetic foot ulcers, especially about multidrug-resistant organisms. With a large number of patients being admitted with diabetic foot ulcers and with the growing global problem of multidrug-resistant organisms, this was a study to ascertain the role of multidrug-resistant organisms in relation to diabetic foot ulcers.

In the present study, the foot ulcers were more prevalent in the fifth and sixth decade of life. The average age of the patients with foot ulcer was 58.21±9.3 years, which is similar to the age prevalence described in another Indian study.[10] The foot ulcers were more common in male. Similar gender preponderance was observed in another study conducted in India.[11]

Most of the patients (68%) had ulcers of less than 1-month duration which is similar to the observations from a north Indian study.[11] An early presentation is often due to the fact that ulcers with acute onset often have systemic symptoms. Comparable with the literature, most of the patients in the present study had poor glycaemic control.[11] Poor glycaemic control is associated with higher degree of microvascular complications.

Majority of the patients in present study had a higher grade of ulcers (Wagner's grade III or worse) similar to the other north Indian studies.[11,12] The reason for presentation with higher grade could be because of lack of structured health care delivery in the country, attempted self-medication and trust in traditional healers.[12]

In the present study, the neuropathy was seen in 77.33% of the diabetic foot ulcer patients. The other studies reported from India showed a similar high prevalence (86.2%, 66.6%, and 56.8% respectively).[9,11] A prevalence ranging from 32 to 33.5% have been reported in studies done in Europe.[13,14] Studies elsewhere have a shown a varied prevalence ranging from 12.7% to 77.8%. This marked variation in the prevalence may be due to different methods used for diagnosing neuropathy. A higher prevalence in Indian population, could be because of patient's ignorance and poor glycaemic control.

In the present study, the prevalence of retinopathy was 24.66%. Studies conducted in northern India showed a higher prevalence.[9,12]

Peripheral arterial disease was observed in 47.33% of present study group. A very high prevalence of 85% was seen in a north Indian study.[9] The prevalence of nephropathy was 48.66% in present study. The north Indian study showed a high prevalence (75%).[11]

The bacteriological evaluation of diabetic foot ulcer from present study showed that the gram-negative organisms were found to have a higher occurrence than gram-positive organisms in the ratio 2.3: 1. Some of the other Indian studies also showed a higher occurrence of gram-negative organisms.[9,12] However, most of the western literature showed a predominance of gram-positive organisms as supposed to gram-negative organisms.[15-17] This could be partly due to differences in the causative organisms occurring over time, geographical variations, or the types and severity of infection included in the studies.[18]

Diabetic foot infection is usually polymicrobial in nature which is well documented in the literature. In present study, 58.66% of ulcers had polymicrobial culture. Similar observations were found in other Indian studies and western studies.[9,12,18] There are, however, a few studies which showed more patients with monomicrobial culture.[19,20] Polymicrobial infection, to a certain extent, may be due to prior treatment history of the patients studied, as reported earlier.[21,22]

In the present study, the rate of isolation of organism per ulcer was 1.86 while two other Indian studies showed a rate of 1.25 and 2.3 organisms per ulcer.[9,11] A study from Malaysian reported 1.47 organisms per lesion.[20] A study from US showed a very high rate of 5.8 organisms recovered from the ulcer.[23]

The commonest organism isolated in present study was *Escherichia coli* followed by *Staphylococcus aureus*, *Pseudomonas* and *Klebsiella pneumoniae*. Most of the other studies from India and other countries showed Staphylococcus aureus as the commonest isolate from diabetic foot ulcers.[9,11,16,18,20]

In the present study, 66% of the ulcers grew multi-drug resistant organisms (MDRO) and 54.8% of all isolated organisms were multidrug resistant. Many different definitions for multi-drug resistant organisms were used in medical literature. Due to a lack of uniform definition for MDROs, the overall prevalence of MDRO, as seen in the literature, could not be studied. European centre for disease prevention and control has arrived at a definition for MDROs and has defined specific criteria for categorising an organism as MDRO.[24]

Apart from the multi-drug resistant organisms like MRSA, ESBL and VRE which were extensively studied in the literature, other groups of organisms like MDR *Pseudomonas*, *Acinetobacter*, *Enterococcus* and *Enterobactereciae* were also identified in present study. The higher prevalence of multidrug-resistant organisms was also observed in another north Indian study.[9] The higher antibiotic resistance in tertiary care hospitals is because, widespread use of broad-spectrum antibiotics results in selective survival of drug-resistant organisms. In contrast, a western study showed a lower prevalence of MDRO when compared to Indian literature, which is perhaps a reflection of higher antibiotic use and abuse.[16] The increasing occurrence of MDROs is disconcerting because infection with these organisms limits the choice of antibiotic treatment and may lead to a worse outcome.

In the present study, univariate analysis showed that, poor glycaemic control, previous hospitalisation, previous history of amputation, previous antibiotic usage, size of the ulcer, necrotic ulcer, recurrent ulcers, higher grade of ulcer, presence of osteomyelitis, presence of retinopathy, peripheral vascular disease, neuropathy and polymicrobial culture, were significantly associated with MDRO infected foot ulcers.

However, analysis by logistic regression revealed that only recurrent ulcers and higher grade of ulcers were significantly associated with multi-drug resistant organism infections. It is possible that patients with recurrent ulcers have had several courses of antibiotics, both during previous hospital admissions and from practitioners in the community, which led to resistance to multiple antibiotics. Higher grade of ulcers has an associated systemic sepsis and excessive local necrotic tissues.

Another study from India showed that presence of neuropathy and ulcer size >4cm^2 were significantly associated with multi-drug resistant organism infections.[9] The two significant factors associated with MDRO, in a study from France, were previous hospitalization and proliferative retinopathy.[16]

Factors like previous hospitalization, previous antibiotic usage, poor glycaemic control, ischemic ulcers have emerged as possible risk factors for MDRO in several other studies.[4,9,16] However, we have not found any significant association in present study.

Although author have identified a few factors associated with MDRO, the effect of diabetes-related immunopathology has not been studied. This and its possible impact on infection need a closer look.

□□□□□□□□□□

The prevalence of multi-drug resistant organisms is alarmingly high in infected diabetic foot ulcers. Recurrent ulcers are more prone to acquire multi-drug resistant organisms. Higher grade of ulcers is more prone to acquire multi-drug resistant organisms.

Abstract

Background: Intertrochanteric fractures occur mostly in elderly patients, and the outcome may be extremely poor if there is prolonged bed-rest. The best treatment for trochanteric fracture remains controversial. Proximal femoral nail antirotation (PFNA) II has excellent fit as the design is adapted to the anatomical situation of small statured patients also. It has a medial lateral angle of 5 degrees. It has several distal locking options viz static/dynamic. Objective of this study was to observe the operating time, blood loss and fracture union in intertrochanteric fractures treated with PFNA II from the data collected from patient's case sheets and post-operative X-rays.

Methods: 25 patients who were operated with PFNA II for unstable intertrochanteric fracture were selected using random selection and following parameters were noted from the records.

Results: The mean age of the participants is 70.72±8.55 years with range from 52 years to 89 years. The mean duration was 1.98 hours ±0.66. The median duration was 2 with interquartile range from 1.5 to 2.5 hours. Mean blood loss was estimated to be 390 ml±62.78. The median blood loss was 370 ml with interquartile range from 360 to 420 ml.

Conclusions: The PFNA II is an ideal implant for unstable intertrochanteric fracture since stable intramedullary fixation can be achieved with almost 100% union in the studied population.

Keywords: Intertrochanteric fractures, PFNA2, Proximal femoral nailing

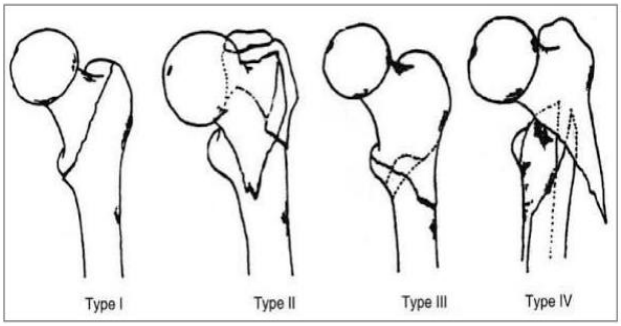
Introduction

Intertrochanteric fractures occur mostly in elderly patients, and the outcome may be extremely poor if there is prolonged bed-rest. The best treatment for trochanteric fracture remains controversial.[1-3] Many methods have been recommended.[4-6] Stable fixation that allows early mobilization is the treatment of choice. Cephalomedullary devices are favored as the treatment for unstable A2 and A3 fractures, especially in the absence of medial buttressing.[2,3,6,7] While there are numerous operative devices for treatment of trochanteric fractures, none of them are totally free of complications. There is no advantage to an intramedullary nail versus a sliding compression hip screw for low-energy pertrochanteric fractures classified by arbeitsgemeinschaftfür osteosynthesefragen/orthopaedic Trauma Association (AO/OTA) 31-A1 and A2, specifically given its increased cost and the lack of evidence to show decreased complications or improved patient outcome.[4]

Proximal femoral nail antirotation (PFNA II) has excellent fit as the design is adapted to the anatomical situation of small statured patients also. It has a medial lateral angle of 5 degrees. It has several distal locking options viz static/dynamic.

Insertion of the blade compacts the cancellous bone. The inserted PFNA blade achieves an excellent fit through

bone compaction and requires less bone removal compared to a screw.[6,7]



Boyd and Griffin (1949) classified fractures in the trochanteric area of femur into 4 types. Their classification is useful in planning treatment and estimating prognosis.[8,13]

Type 1 fractures that extend along the intertrochanteric line from the greater to the lesser trochanter. Reduction usually is simple and is maintained with little difficulty. Results generally are satisfactory.

Type 2 comminuted fractures, the main fracture being along the line, but with multiple fractures in the cortex. Reduction of these fractures is more difficult because the comminution can vary from slight to extreme.

Type 3 fractures that are basically subtrochanteric with at least one fracture passing across the proximal end of the shaft just distal to or at the lesser trochanter.

Type 4 fractures of the trochanteric region and the proximal shaft, with fracture in at least two planes, one of which usually is the sagittal plane and may be difficult to see on routine anteroposterior radiographs. If open reduction and internal fixation are used, two plane fixations are required because of the spiral, oblique, or butterfly fracture of the shaft.
