In the present study among 150 subclinical hypothyroidism patients who were treated with thyroxine supplementation, 60 patients were adequately treated and 90 were inadequately treated. The adequately treated patients were diagnosed in the first trimester and the inadequately treated patients were in the late second and third trimester. Maternal complications like anemia, pregnancy induced hypertension, gestational diabetes, oligohydramnios, low birth weight were statistically significant (P value <0.05) in subclinical hypothyroidism group comparing to euthyroid. Leung et al, in his study found that there was a significant increased incidence of pre-eclampsia (15%) among inadequately treated subclinical hypothyroidism.[13] Ajmani et al, also observed 22.3% of pre-eclampsia and 12.11% of low birth weight in his study.[14] Fetal growth restriction and premarture rupture of membrane were not statistically significant (P value >0.05) in the subclinical hypothyroidism group compared to the euthyroid group.

[illegible]

The prevalence of subclinical hypothyroidism among the pregnant women in the present study is 7.06%, most of the adverse maternal and fetal complications are observed

in subclinical hypothyroidism. Since hypothyroid is easily treated, hence universal screening for hypothyroidism is recommended for all antenatal women especially in the first trimester to reduce the burden of adverse maternal and fetal outcome.

Abstract

Background Recent literature supports the removal of myomas during cesarean section, which traditionally was considered a relative contraindication, given a higher complication rate. This study is to share our experience of cesarean myomectomy in the last decade.

Methods This study is a retrospective review of our prospectively maintained database, from January 2008 to December 2017, at a tertiary care level teaching institution. All patients who underwent myomectomy during cesarean section were included. There were no exclusions.

Results A total of twenty patients underwent myoma removal along with the cesarean operation during this period with a mean age of 30 years. Majority of patients were nulliparous (70%). Common comorbidities were diabetes mellitus (40%) and hypothyroidism (20%). Mean size of myomas were 5.33 cm (± 2.08), and the number varied from one to three. The most common location was the posterior surface of the uterus with the commonest variety being subserous. Most patients were discharged on the fifth postoperative day.

Conclusion This study demonstrates that cesarean myomectomy to be a safe and feasible procedure in experienced hands. It offers the advantage of avoiding a second surgery in selected patients.

Keywords Cesarean myomectomy · Myoma uterus · Cesarean delivery · Myomectomy

Introduction

The myomas are the most common benign tumors of the uterus. The highest reported incidence of myomas during pregnancy is 10.7% [1]. The myomas are common during the reproductive period due to an influence of higher estrogen levels. Their increased incidence during pregnancy can be partly explained by the late age of conception [2]. Myomas in pregnancy are associated with a significantly higher risk for cesarean section (CS).

Conventionally, concomitant myomectomy during CS was considered a relative contraindication, given perceived higher complication rate. Last decade has witnessed emerging literature evidence supporting myoma excision along with CS, with acceptable results [3]. This study aims to share our experience of cesarean myomectomy during the last decade.

Materials and Methods

This study is a retrospective review of our prospectively maintained database of the last decade, from January 2008 to December 2017, at a tertiary care teaching hospital. All consecutive patients who underwent myomectomy during cesarean section, in this mentioned duration, were included.

This formed a small subset, among the patients, having uterine myomas and pregnancy, a majority of those underwent vaginal delivery or had LSCS, without myomas removal. Those not matching the inclusion were not considered. There were no exclusions. The institutional ethical committee approved the study, and waiver of consent was obtained, in view of retrospective nature.

Data were collected from outpatient and inpatient records, operative and discharge notes. Data included maternal demographics such as age, parity, medical diseases, prior surgery, gestational age at the time of CS, type of anesthesia, indication for CS, elective/emergency and number of previous operations including CS. Myoma characteristics such as size, number, location and variety were noted. Other parameters like an indication for myomectomy, the number of incisions made and the presence of adhesions were observed. The total duration of surgery was taken as the time from the initial skin incision to skin closure. Approximate intraoperative blood loss was measured, and record of transfusion if any was noted. Postoperative drop in hemoglobin was checked at 48 h after surgery, and blood transfusion was given if the fall was more than 3 gm/dl. Postoperative complications like pyrexia (> 38-degree C) and wound infection were analyzed. Duration of hospital stay was noted, and patients were followed up after 2 weeks in the outpatient department.

Patients were counseled during the early third trimester regarding the need for myomectomy depending on the mode of delivery and consent obtained for the same.

Experienced gynecologists performed surgery with minimum of 10 years of experience. Preoperatively, half an hour before skin incision Inj. Tranexamic acid 1 gm in 100 ml isotonic saline was infused over 20 min. Except in four cases, myomas were situated at the incision site, and in other instances, CS preceded myomectomy. When myomas were located at the lower uterine segment, myomectomy was performed before delivery of the fetus. During CS, myomas were inspected for their size, number, type and location after the closure of the uterine incision (Fig. 1).

Though myomectomy was tried with a single incision, in few cases where multiple fibroids were present, more than one incision over uterus was needed. An incision was made over myoma by using monopolar cautery, and the tumor was enucleated. To achieve hemostasis, bipolar cautery was used. The defect in the myometrium was closed with 1-0 vicryl suture (Fig. 2). High-dose oxytocin infusion was continued postoperatively for 24 h to prevent bleeding.

Results

A total of twenty patients underwent myoma removal along with the cesarean operation during this period with a mean age of 30 years. Majority of patients were nulliparous (70%).

Fig. 1 Multiple fibroids over the anterior surface of uterus postdelivery of the baby

Fig. 2 Postmyomectomy, closure by baseball sutures

Common comorbidities were diabetes mellitus (40%) and hypothyroidism (20%). One except all patients received regional anesthesia (spinal/epidural); the only case needed general anesthesia due to the presence of idiopathic intracranial hypertension. Sixty-five percent of surgeries were elective operations. The details of various preoperative characteristics are shown in Table 1.

Intraoperatively, two patients had small bowel and omental adhesions at the operative site. Two patients (10%) received a blood transfusion during the procedure. The mean hemoglobin drop reported 24 h postoperative was 1.23 (± 1.16) grams. No patient warranted blood transfusion in the postoperative period (Table 2).

Majority of patients got the discharge on the fifth day of surgery. There were no incidences of postpartum pyrexia or

surgical site infections. The patients were regularly followed in the outpatient department.

Discussion

Fibroid excision along with caesarian section was considered difficult until recently. Fibroids with pregnancy might cause miscarriage, preterm delivery, premature rupture of membranes, early separation of the placenta, labor dystocia, postpartum hemorrhage and increased rate of operative deliveries. Fibroids might also undergo red degeneration and associated complications. Myomectomy during CS has not been done routinely due to the risk of uncontrolled bleeding and the possibility of hysterectomy [4]. If myomectomy is not performed along with CS patient might need another surgery to remove it, which amounts to two operations, two anesthetic exposures and increasing cost, and there is also an enhanced risk of complications caused by fibroids in a subsequent pregnancy.

The average age of mothers in our study was 30 years. Most studies have shown myomas to be more common in nulliparous women [5]. We too observed a higher incidence of myomas among nulliparous women (70%) [6]. This could be explained due to hormonal changes and reduced sensitivity of leiomyoma to estrogen receptor [7].

Similar to many other studies, the average gestational age at the time of CS was 37 to 38 weeks in our study [4, 6, 8]. We had four patients delivering at 35 to 36 weeks of gestation. Among these four patients who had delivered prematurely, three deliveries can be attributed to the presence of fibroids. Two out of these patients have already undergone fibroid removal before becoming pregnant. The possible explanation for preterm labor could be decreased distensibility of uterine myometrium due to the presence of fibroids as the pregnancy advances [9].

Though CM is to be avoided in cases of the previous myomectomy due to more chances of complications [10], we had the opportunity to do repeat CS for one of our patient who underwent CS myomectomy 3 years ago. The indication for primary CS was a transverse lie. The malpresentation was suspected to be due to a single large (8 cm), intramural fibroid located in the lower uterine segment. Incidentally, this was the largest myoma we had come across in our study. As the fibroid was situated in the incision site, myomectomy was followed by CS. During repeat CS, which was done 3 years later, there was no fibroid detected intraoperatively. There were three more cases of lower uterine segment (LUS) fibroids; if they were less than 5 cm, then myomectomy were done following the delivery of the baby. All fibroids present in the LUS were removed through the same CS incision, without any additional incision on the uterus. The same technique was suggested in several other studies [11, 12].

Three of our patients had undergone myomectomy previously in the non-pregnant state. One of the women had undergone myomectomy twice before becoming pregnant. This confirms the well-established fact that fibroids are recurrent [13]. Among the study group, the patients who had undergone previous myomectomies had a high incidence of intraoperative adhesions as expected. However, in all three patients, the surgery was uneventful with minimal blood loss and no added morbidity.

Eight of our study subjects had multiple fibroids. Six patients had fibroids of size 8 cm (largest dimension). 55% of the myomas had size > 5 cm. The smallest dimension encountered was 2.5 cm. We had more anterior wall fibroids than posterior [4]. Traditionally myomectomy is avoided in cases of fundal and cornual sites because of excessive

bleeding and possible obstruction of fallopian tubes [14, 15], but in our study, myomectomy was done regardless of the location of the myomas.

Except for a single instance of the submucosal fibroid, there was an even distribution of intramural and subserosal fibroids. Removal of submucosal fibroids during cesarean section is usually avoided as it involves resection of the full thickness of myometrium and reduced contractility might lead on to increased hemorrhage [16]. Secondary changes due to red degeneration were found in a case with single sizeable fundal fibroid. Histopathological reports of all myomectomy specimens were closely followed up, and none showed malignant change.

The same incision removed fibroids in the anterior wall and close to CS incision. Whenever possible, a minimal number of incisions were made, and adjacent ones removed through the same incision. This was done to reduce blood loss and future adhesions and improve reproductive outcome. While the operating time was more or less uniform in most of our cases, two of the cases exceeded the average operating time significantly. In these two instances, the increased operating time could be explained by multiple fibroids needing more than a single incision for removal. Other studies have also observed more than average operating time in cases of multiple fibroids [17].

Intraoperative blood transfusion was done in two cases only as they met the criteria for blood loss of more than one liter. One case had a fibroid at the incision site. The second patient who had a loss of more than two liters which was the largest in our series had three fibroids at different locations and they were removed by as many incisions. Despite intraoperative transfusion and other pharmacological measures to attain hemostasis, she had a significant drop in hemoglobin at 48 h postoperatively and needed another transfusion. She had no other postoperative morbidity like pyrexia or ileus and was discharged on the fourth day after surgery.

CM is not done routinely, because of the associated hemorrhage and the need for the hysterectomy [15]. Specific hemostatic techniques have been advocated by various authors [18, 19], but we have followed tranexamic acid infusion, vasopressin instillation, uterine artery ligation, electrocautery and high-dose oxytocin. There was not a single case which needed a hysterectomy in our study of twenty cases, though patients were counseled regarding the possibility in the prenatal period due to intractable hemorrhage. We also found no increased postoperative morbidity or expanded hospital stay in any of our patients who underwent CM as was observed by Dam Hye Kwon et al. [8].

There are a few limitations to our study. Its retrospective design coupled with proportionally small sample size limits generalization of results. This study also lacks long-term follow-up of these patients and thus to highlight effect on future pregnancies. Additionally, as this study was conducted in a tertiary level medical college setup with available expertise, the results cannot be generalized, especially in comparison with smaller installations or in the absence of an expert.

We author would like to stress this to the readers that routine use of myomectomy during CS is neither advisable nor been followed in the current study. The CM should be carefully planned for selected patients in an appropriate setup and expertise. A similar conclusion is drawn by a recent review on this topic [20], recommending standardization of best practices for CM, with the availability of more robust data and in the presence of necessary facilities.

Conclusion

Overall, our series has shown CM to be a safe and feasible procedure in well-selected patients in a tertiary care center with experienced hands. It can offer an advantage of avoiding a second intervention in selected patients. Appropriate hemostatic techniques can curtail hemorrhage which is the most severe complication. Long-term morbidity concerning future reproductive outcome should be addressed in a study with large participants and reliable design.

Authors' Contributions All authors have a significant contribution for preparation of this manuscript, following ICMJE Guidelines. First and second authors share the first position.

Compliance with Ethical Standards

Conflict of interest No author has any potential conflict of interest.

Ethical approval The current study is approved by the responsible institutional ethics committee for human research and fully comply with the declaration of Helsinki for guideline on human research.

Abstract: ***AIMS & OBJECTIVE:*** *To assess the 1st trimester cervical length by Transvaginal USG as a predictor for spontaneous preterm birth.* ***MATERIALS & METHODS:*** *This cross sectional study was conducted from July 2012 to December 2012 in the antenatal clinic at PSGIMSR Hospitals. About 100 antenatal women who met the inclusion and exclusion criteria were enrolled in the study, the first trimester transvaginal ultrasonography was taken. These patients were followed up to determine gestational age at delivery.* ***RESULTS:*** *The data was entered into MS-Excel sheet and statistical analyses were performed using Statistical Package for Social Sciences (SPSS) version 19. All reported p-values are two-tailed, and confidence intervals were calculated at the 95% level. The data was presented using frequencies, percentages, descriptive statistics followed by charts, histogram and graphs.*

CONCLUSION: *Cervical length by first trimester transvaginal ultrasonography is not a predictor for spontaneous preterm birth.*

KEYWORDS: *first trimester ultrasound, cervical length, preterm birth*

Date of Submission: 16-10-2018 Date of acceptance: 31-10-2018

I. Introduction

Preterm delivery (PTD) defined by World Health Organization as birth before the completion of 37 weeks' of gestation, is the leading cause of perinatal mortality and long-term morbidity [1-3]. The incidence of PTD in ranges from 5% to 18% in developing countries and 5 to 10 % in developed countries [4-8].

Preterm birth (PTB) is the main cause of neonatal death and neurological handicap in children [9-11] . Consequently prediction and prevention of this complication is a major challenge in pregnancy care. Evaluation of the cervix has been used as a tool to predict Preterm birth based on the concept that the cervix acts as an anatomic marker of the underlying pathologic process leading to preterm delivery. The cervical length has been measured using a digital examination in the past. Investigations using transvaginal ultrasound measurement as the standard confirmed that digital examination underestimates cervical length and the majority of studies found that ultrasound assessment of cervical length is superior to clinical examination for the prediction of PTB.[6]

Transabdominal ultrasonography has limitations for the measurement of the cervix because the fetal presenting part may obscure the cervix and the full bladder may cause a lengthened measurement of the cervical canal. Transvaginal sonography (TVS) is the imaging modality of choice for measuring length of the uterine cervix. TVS is simple, reproducible acceptable to patients and is inexpensive. It also provides high-quality images of the cervix, enables the assessment of the cervical length and funneling as defined as dilatation of the internal cervical os, when present, and has little or no risk of carrying vaginal micro organisms into the cervical canal as the probe is placed in the vaginal fornix.

In the literature there is evidence that the detection of a short cervix in the late second trimester by means of TVS is a strong predictor of PTD [12,13]. Nevertheless, the role of this method as a screening tool to predict PTD before 16 weeks' gestation is still controversial [4].

The purpose of our study was to determine whether there is a relationship between the first trimester cervical length which was measured between 11-14 weeks in a low risk patients with singleton pregnancies and the risk of spontaneous preterm birth.

II. Aim

To assess the 1st trimester cervical length by Transvaginal USG as a predictor for spontaneous preterm birth.

III. Inclusion And Exclusion Criteria

The inclusion criteria is all antenatal patients who attended the antenatal clinic between 11 to 14 weeks gestational age and the exclusion criteria is with previous history of preterm delivery, multiple pregnancy, history of cervical conisation and patients who underwent cervical encerclage.

IV. Materials & Methods

This cross sectional study was executed between the period of July 2012 – Dec 2012 at PSG IMSR Hospitals after obtaining ethical approval, who met the inclusion and exclusion criteria in about 100 patients.
The transvaginal ultrasonographic examinations were performed between 11 to 14 weeks of gestation using Philips USG system with a 5MHz TVS probe. The antenatal women were asked to empty the bladder just before transvaginal USG examination and the transducer was placed in the anterior fornix without pressure to avoid any deformation or enlongation of the cervical canal. The entire length of the cervical canal is identified by the sonolucent endocervical mucosa and the callipers were used to measure the distance between internal and external os. These patients were followed up to determine the gestational age at delivery.

V. Results And Observations

The data was entered into MS-Excel sheet and statistical analyses were performed using Statistical Package for Social Sciences (SPSS) version 19. All reported p-values are two-tailed, and confidence intervals were calculated at the 95% level. The data was presented using frequencies, percentages, descriptive statistics followed by charts, histogram and graphs. Total number of antenatal women who underwent transvaginal ultrasonography between 11-14 weeks were 100.

TABLE 1 : MATERNAL DEMOGRAPHIC DATA AND PREGNANCY OUTCOME

CHARACTERISTICS	PRE TERM DELIVERY < 37 WEEKS (N=34)	DELIVERY ≥ 37 WEEKS (N=66)

Maternal height in centimeter	155 (138-169)	155.5 (143-172)
Gestational age	37 (28-37)	39 (38-40)

Table 1 describes the maternal demographic data and pregnancy outcome among the studied population into two groups < 37 weeks (34%) and term delivery ≥ 37 weeks (66%).
The mean ± SD GA at transvaginal ultrasound was 12 weeks ± 2 days (range, 11 +0 weeks to 14 + 1 week). The mean ± SD maternal age of the patients who underwent transvaginal ultrasound was 26.19 ± 4.3 years among which who delivered < 37 weeks is 26.29 ± 4.5 years (range 18 to 37 years), > 37 weeks is 26.14 ± 4.3 years, (range 18 to 40 years)

Figure 1 : Histogram

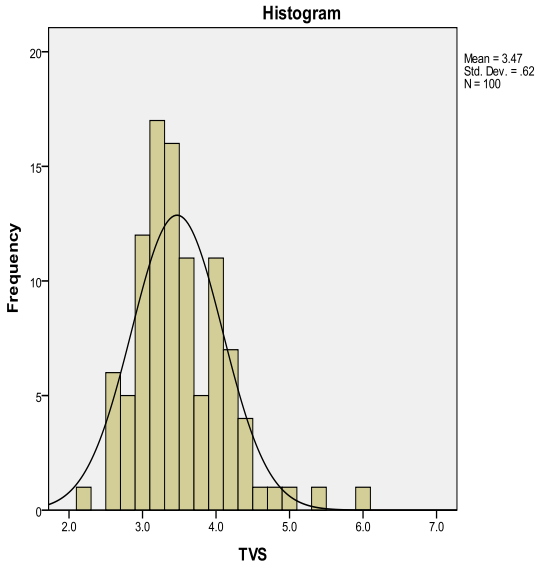

Figure 1 – Histogram shows normal distribution (solid line) and frequency distribution (bars) of cervical length at 11-14 weeks gestation [Mean ±SD,3.47±0.62; n=100]

TABLE 2 : TRANSVAGINAL CERVICAL LENGTH AND GESTATIONAL AGE AT DELIVERY

TVS CERVICAL LENGTH	GESTATIONAL AGE		Total
	≤ 37 WEEKS	≥ 37 WEEKS	
2.5 - 3.0 cm	12	12	24
	50.0%	50.0%	100.0%
>3 cm	22	54	76
	28.9%	71.1%	100.0%
Total	34	66	100
	34.0%	66.0%	100.0%

Table 2 shows the pregnancy outcome between the transvaginal cervical length and the gestational age at delivery which was statistically insignificant with P value of > 0.05
CHI-SQUARE TEST USING SPSS 19 ; P - >0.05, NOT SIGNIFICANT.

TABLE 3 : PARITY AND TRANS VAGINAL CERVICAL LENGTH

TVS CERVICAL LENGTH	PARITY		
	PRIMI GARVIDA	MULTI GARVIDA	PARITY
2.5 - 3.0 cm	17	7	24
	70.8%	29.2%	100.0%
>3 cm	54	22	76
	71.1%	28.9%	100.0%
Total	71	29	100
	71.0%	29.0%	100.0%

Table 3 shows the comparison between the parity and pregnancy outcome which is again statistically insignificant of P value 0.98.
CHI-SQUARE TEST USING SPSS 19 ; P - 0.98, NOT SIGNIFICANT.

VI. Discussion

Pre term birth prediction and management is one of the most challenging problems in modern obstetrics. Cervical incompetence accounts for not more than 2% of miscarriages or pre-term delivery. Many studies have shown that cervical changes seen by TVS are associated with increased risk of preterm birth and that the length of the cervix is directly correlated to the duration of pregnancy, the shorter the cervix, greater the likelyhood of preterm delivery [14]. The mid trimester cervical length cutoff of 25mm is a good predictor of preterm delivery [4,14,15]. Moreover, patients with midtrimester cervical length of less than or equal to 15mm had 48% (19) and 52% (40) risk of early preterm birth (less than or equal to 32 weeks of gestation).

Naim et al in his study said TVS cervical length <3 cm before 16 weeks concluded that short cervix was associated with 23% risk of preterm delivery [16]. In our study although the risk for preterm delivery TVS cervical length <3cm was 35% (12), only 5.9% (2) of patients went into spontaneous preterm delivery, the remaining 23.5%(8) had premature rupture of membranes and 5.9%(2) had severe preeclampsia.

Hassan et al demonstrated that a mean cervical length of 37.5mm at 14 weeks of gestation was a weak predictor of preterm delivery than seen later in the midtrimester [17]. In our study the mean cervical length is 34.7mm between 11 to 14 weeks as shown in figure 1 histogram and found to be a weak predictor of preterm birth.

Hasegawa et al and Zorzoli et al found that there is no correlation between first trimester transvaginal cervical length and gestational age at delivery [18,19]. In our study out of 24 patient transvaginal cervical length between 2.5 to 3 cm and more than 3cm were 12 each who delivered at less than 37 weeks and more than 37 weeks GA, which is statistically insignificant, and we found that there is weak correlation between first trimester cervical length and gestational age at delivery.

Conoscenti et al in his prospective study performed TVS cervical assessment at 14 weeks of gestation as a screening test and concluded that it is not a predictor for pre-term delivery [20]. In our study also we found that first trimester cervical length by transvaginal ultrasound is not a predictor for preterm delivery.

VII. Conclusion

The first trimester cervical length by transvaginal ultrasonography is not a good predictor for spontaneous preterm birth.

ETHICAL CLEARANCE OBTAINED.

Abstract

Background: Surgical site infections (SSI) are one of the major health problems throughout the world with an incidence of 3%-16%. Hospital acquired surgical site infection is further complicated by the emergence of multi drug resistant strains. SSI surveillance is an established monitoring tool and has been shown to reduce infection rates. The importance of preventing surgical site infections is well recognized since they lead to increased morbidity, prolonged hospital stay, need for readmission, high end antibiotic treatment and re-surgery. This study was undertaken to determine the incidence, risk factors, and microbiological spectrum of surgical site infections and to identify the multidrug resistant strains. Analysis of the effectiveness of the existing surveillance methods was also done.

Methods: This retrospective study was done for a period of 1-year form Jan 2016 to Dec 2016. All patients with infection following caesarean section and abdominal and vaginal hysterectomy were included. Laparoscopic surgery and patients with preexisting infection were excluded.

Results: Incidence of SSI in present study is 5.27%. The major risk factors identified were obesity, diabetes and prolonged operating time. The commonest infective organism was Klebsiella Pneumoniae in 37% of which 19% were ESBL producing and 3.8% were carbapenemase producing. E. coli was identified in 20% of isolates. The incidence of ESBL in both isolates was higher.

Conclusions: Regular audit of SSIs is a very effective tool to analyse risk factors, identify causes and plan strategies to prevent infection.

Keywords: Drug resistance, Hospital acquired, Surgical site infection, Surveillance

Introduction

Surgical site infections (SSI) are significant source of morbidity, prolonged hospital stay and recovery and rarely mortality. They complicate 3 to 16%.[1-4] of all surgeries but even these estimates are likely to be low as some infections occur after the patient's discharge from the hospital or they report to other hospitals with infection. Hospital acquired SSIs are further complicated by the emergence of multidrug resistance strains. The importance of preventing surgical site infections is well recognized since they lead to increased morbidity, prolonged hospital stay, need for readmission, high end antibiotic treatment and resurgery.[1,3]

The Center for Disease Control (CDC) defines SSI as an infection related to an operative procedure that occurs at or near the surgical incision within 30 days. This time frame is extended to 12 months if a surgical implant is used. Infections are further divided into:

- Superficial involving skin and subcutaneous tissue
- Deep involving deeper soft tissue of the incision like fascia or muscle
- Organ or space involving any part other than the incised body layers.

Surgical wounds are further classified as clean, clean contaminated, contaminated and dirty.

Most obstetric and gynaecological procedures are classified as clean contaminated as the genital tract is entered into controlled fashion and there is no unusual contamination. Some surgeries like pelvis abscess, perforated bowel or positive culture pre-op are classified as dirty. SSI surveillance is an established monitoring tool and has been shown to reduce infection rates.

M□□□□□□

This retrospective study was conducted in the department of Obstetrics and Gynaecology at a teaching hospital in South India from the period of January 2016 to December 2016.

Inclusion criteria

- All emergency and elective obstetric and gynaec procedures like caesarean section, abdominal and vaginal hysterectomies and laparotomies were included.

Exclusion criteria

- Laparoscopic surgeries and patients who had pre-op infection.

The departmental protocol includes two visits after surgery: the first visit a week after discharge and second visit a month later. The charts were analysed at the end of a month after surgery to identify patients with infection. Their case records were analyzed for pre-op risk factors, intra-operative factors like timing of prophylactic antibiotics and duration of surgery and post-operative course. All patients with wound infection had a culture and sensitivity done. The culture report was analysed for the infecting organism and sensitivity pattern. A monthly audit of all SSIs in the department was done to determine the incidence and microbiological spectrum of the infecting organisms. Infection control practices currently in place were also reviewed and analysed to determine if there was a scope for improvement.

□□□□□□□

The numbers of surgeries in present study period who fulfilled in present inclusion criteria were 982 caesarean sections and 497 gynaec surgeries. The results are shown in Table 1.

C section	982	55	5.6%
Gynaec surgeries	497	23	4.62%
Total	1479	78	5.27%

The patients who had wound infection were analysed for pre-operative risk factors like obesity, diabetes, other medical disorders and intra operative factors like prolonged operating time, previous surgeries and presence of malignancy.

As shown in Table 2, obesity was the major risk factor as 48.7% of patients had BMI of >25. Other risk factors included diabetes and prior surgery with adhesions in 19.2%, anemia and hypertension was seen in 12% of patients. 9% of patients had prolonged operating time of >3 hours.

All patients who had discharge from the wound had a culture taken prior to starting antibiotics. The culture report was analysed for infecting organism and sensitivity pattern. The pathogens isolated is shown in Table 3.

Figure 1 shows the month wise analysis of the organisms which were MRSA (Methicillin Resistant Staph Aureus), ESBL (Extended Spectrum Beta Lactamase) and Carbapenemase producers.

□□□

giving an incidence of 5.6 %. 23 of patient who underwent gynaec surgeries had SSI giving an incidence of 4.62%. The total incidence was 5.27%.

This compares favorably with the reported rate of 11.8 % in the WHO review of SSIs in low and middle-income countries.[5] 93 % of these were superficial infections. Three patients had wound debridement and re-suturing under anaesthesia. One patient had a pelvic collection that got infected. However, it drained spontaneously through the vagina.

SSIs are hospital acquired infections and their occurrence is dependent on many factors. The profile of patients undergoing surgery is also changing. There is increase in the number of patients with multiple co-morbidities and in the older age group. Preoperative factors include patient characteristics like obesity, diabetes, other medical disorders, prior surgery and steroid use. Other pre-operative factors include skin cleaning and hair removal techniques.

Intra operative factors include timing and dose of prophylactic antibiotics, abdominal and vaginal preparation, duration of surgery and technique of wound closure. Post-operative factors include glycemic control in diabetic patients and presence of anemia and blood transfusion.

Table 2 shows the pre-op and intra-op risk factors identified in present study. A systematic review of 57 studies by the WHO from both high income and low and middle income countries identified high body mass index (BMI) , diabetes and prolongation of duration of surgery as risk factors associated with increased risk of SSIs .In patients with high BMI, various factors like increase in adipose tissue, need for larger incision, decreased circulation in fat tissue and increase in local tissue trauma related to retraction contribute to the increased SSIs in these patients. Obese patients also have an altered hemostatic balance and decreased immune function.

Hyperglycemia in patients with diabetes is a well-known risk factor for infections including SSIs. A study by Al-Niaimi et al compared 2 groups of post-operative patients after gynaecological oncology surgery. Patients whose blood sugar > 150mg/dl were managed either with intermittent subcutaneous insulin injection or insulin infusion. Patients who were on insulin infusion had significantly lower infection rates (19% versus 29% P=.001).[6] Hyperglycemia can have several deleterious effects on host immune functions, stimulation of inflammatory markers, increased thrombotic activity and endothelial cell dysfunction. This is of importance even in non-diabetics as stress hyperglycemia can have the same effects.

Prolonged duration of surgery was associated with increased incidence of SSIs in the majority of studies. There was also a linear correlation between operative time and the likelihood of SSIs. The reasons postulated for this are:

1. With increased operative time the patient's open incision is exposed to the environment for a longer time.
2. Tissue desiccation is more.
3. Tissue concentration of antibiotics will decrease as the procedure continues.

However, it is important to remember prolonged surgery may also mean more complex procedures and other intra operative factors like adhesions which by themselves can increase the likelihood of infection.

Other risk factors included anemia which diminishes the resistance to infection in 12.8% prolonged PROM >24 hours in 3.6% of caesarean sections and malignancy in 3.8%.

Other risk factors considered important in SSI in a study by Devjani et al included pre-operative hospital stay with exposure to procedures, therapies and hospital micro flora and administration of blood products. Allogenic blood products have immunomodulatory effects that may increase the risk of post-op infections.[7]

The prophylactic antibiotic policy at present in the hospital is administration of Injection Cephazolin 1 gm given within one hour of skin incision and the second dose 6 hours later. All the patients received the prophylaxis however the time was >1 hour in few patients. David Classen et al reported that administration of antibiotics within a 2-hour period before an operation was associated with the lowest infection rate.[8]

On analyzing the culture report, Table 3 shows the organisms isolated in present patients. *Klebsiella pneumonia* was seen in 29 patients (37.2%) of these 51% were ESBL producers and 10% were carbapenamase producers. The second commonest organism was E coli in 16 patients (20.5%) of these 43% were ESBL producing. Pseudomonas was isolated in 10%. Routine anaerobic cultures were not performed. More than one organism was isolated in 31 out of 78 patients (39.7%).

In a study conducted by Devjani De et al the most frequently isolated organism was Acinetobacter species in 32% followed by *Staphylococcus aureus* in 22.3%.[9] In mild infections, patients were started on Levofloxacin and Metrogyl pending the culture report. In more severe infections Cefotaxime and Metrogyl or Piperacillin/ Tazobactam was started.

The resistance pattern of the infecting organism was also analysed. Figure 1 and Table 4 shows the number and percentage of drug resistant organisms. MRSA infections are of concern and there is need to screen both the patients and the health care workers involved for asymptomatic nasal carriers. In 51 out of 78 patients

(65%) infection occurred after discharge from the hospital. This may be due to the policy of early discharge from the hospital. So, post discharge surveillance is important to arrive at a correct estimate of the magnitude of the problem. A WHO review on Global guidelines for SSI prevention reported that 13% to 71% of infections occurred after discharge from the hospital. Rosenthal et al determined that 63.8% of SSIs were detected in hospital and 36.2% after discharge.[10]

Surveillance of SSIs also includes a review and analysis of the preventive strategies in place in the hospital. Prevention of SSIs requires a multifaceted approach including proper air conditioning and ventilation engineering, appropriate cleaning and disinfection of the operating theatres and proper sterilization of instruments. Proper safeguards for checking sterilization of instruments, maintenance of OR discipline and sustained education of all OR personnel regarding safe practices are no less important.[11] Hence every hospital should have protocols for prevention of SSIs and follow continuous surveillance of infections.

As part of this, the hospital infection control committee met on monthly basis. The rates of various hospital acquired infections were discussed in the monthly hospital infection control committee meetings. SSI surveillance by surgical staff can also be cross checked by the infection control team.[10] In addition to the SSI rates in various surgical specialties, ventilator associated pneumonia and catheter associated urinary tract infection and blood stream infection rates were also discussed. Environmental surveillance included air sampling done by settle plate in all OTs and the results were analyzed. The incidence of multi drug resistant organisms in all areas in the hospital was analysed and compared to the previous months. To audit the usage of antibiotics, patients on high end antibiotics was analysed department wise and feedback was disseminated to the concerned department. Hand hygiene compliance by health care workers was also analysed in all acute care areas and feedback disseminated.

The information on Hospital Acquired Infection in developing countries is limited because of the lack of national surveillance systems.[12] Most of the reported studies are from single hospital and therefore are not representative of the entire country. Prevention of hospital acquired infection is one of the key agendas of various international bodies like the WHO, CDC and others.

Both the WHO and Center for Disease Control and Prevention guidelines for prevention of surgical site infection (2017) included the following strong recommendations[5,13]:

- Patients are advised to bathe with soap or antiseptic agents at least the night before surgery.
- Skin preparation: Hair removal if required is done only by clipping Shaving is strongly discouraged at all times Intra op skin preparation with alcohol-based chlorhexidine gluconate is recommended.
- Prophylactic antibiotics should be administered 1 hour before skin incision so that serum and tissue concentration are established before the incision is made. For clean and clean contaminated procedures additional prophylactic antimicrobial agents should not be administered after the surgical incision is closed in the operating room even in a presence of a drain. Topical antimicrobial agents should not be applied on the surgical incision.
- Protocols for perioperative glycemic control to be implemented using blood glucose target level of <200mg/dl in patients with or without diabetes.
- Perioperative normothermia should be maintained in all patients. Increased fraction of inspired oxygen should be administered during surgery and after extubation in the immediate postoperative period for patients with normal pulmonary function undergoing general anesthesia.

Transfusion of blood products should not be withheld from surgical patients as a means to prevent SSIs.

□□□□□□□□□□

Prevention of SSI is an important part of providing optimum care for patients. Throughout the world there is a growing concern about patient safety. This prompted the WHO to launch the World Alliance for patient safety. Prevention of health care acquired infection is the one of the first targets of the Alliance. “Clean care is safer care” was launched in October 2005. A key objective of the programme is to launch a feasible practical approach to improve hand hygiene in healthcare globally. Continuous audit and implementation of infection prevention strategies should part of the standard protocols of every hospital. It is challenging and requires dedication of both time and resources. This includes simple things like hand hygiene, pre-operative bathing and skin preparation that are no less important than tracking of multi drug resistant organisms and usage of high end antibiotics.

Abstract

Background: Ectopic pregnancy (EP) is a common, life threatening emergency during the first trimester and a significant cause for maternal morbidity and mortality. In any woman of reproductive age presenting with abdominal pain and vaginal bleeding, ectopic pregnancy should be considered. The objectives of the present study is to determine the incidence, risk factors, clinical presentation, type of ectopic pregnancy, treatment, morbidity and mortality.

Methods: Retrospective analysis of case sheets of patients admitted with ectopic pregnancy at PSGIMSR, Coimbatore during the period July 2011 to June 2016 was done. The details noted were age, parity, risk factors {previous abortion, previous EP, previous pelvic surgery, intrauterine contraceptive device, tubectomy, history of pelvic inflammatory disease}, treatment for infertility, clinical presentation, ultrasound findings, investigations including beta HCG value and hemoglobin level, treatment offered, need for blood transfusion, operative findings and morbidity.

Results: During the five year, there were 12,407 deliveries at our hospitals and 88 cases of ectopic pregnancies were managed. The incidence is 6.6/1000 deliveries. Among them 44% belonged to the age group of 25-30 years and multi gravida were 73.8%. Most common risk factors were previous abortion (23.8%) and previous surgeries including caesarean section, tubectomy, appendicectomy, tubal microsurgery (23.8%). Most common presentation was pain abdomen (85.2%). Out of the 88 cases, 73 patients were managed surgically (82.9%) and 11 cases were managed successfully with methotrexate (12.5%). Three of them underwent conservative management and one had Uterine Artery Embolization.

Conclusions: Early diagnosis based on risk factors and timely intervention plays a main role in reducing morbidity and mortality associated with ectopic pregnancy.

Keywords: Beta HCG, Ectopic pregnancy, Methotrexate, Risk factors, Salphingectomy Transvaginal USG

Introduction

An ectopic pregnancy is implantation of fertilized ovum outside the normal endometrial cavity i.e, fallopian tube, ovary, caesarean scar, cervix and peritoneal cavity.[1] In the first trimester, ectopic pregnancy is the most common cause for maternal morbidity and mortality.[2] It has also been shown that EP reduces future fertility and increases the chance of subsequent EP.[3] The incidence of EP is increasing since the last decade, but the incidence of complications like rupture and morbidity are declining due to early diagnosis with serial Beta-HCG(human chorionic gonadotrophin) monitoring, transvaginal USG(ultrasonogram) and minimally invasive surgery.[4] Early diagnosis not only reduces the risk of tubal rupture but also allows for conservative and medical management.[5] Prior damage to the fallopian tube due to PID(pelvic inflammatory disease), tubal surgeries, pelvic adhesions are the major risk factors for ectopic pregnancy.[6] The other identified risk factors are,

advanced maternal age, previous EP, previous pelvic surgeries, IUCD (intra uterine contraceptive device) insertion and infertility treatment.[7-12] Identifying these risk factors among high risk mothers helps in early diagnosis and reduces the morbidity related to this condition.[13] Unfortunately, most of the patients presenting with EP do not have risk factors.

M□□□□□□

This was a retrospective analysis of case records of patients admitted with ectopic pregnancy, done at PSG IMSR Hospital, Coimbatore from July 2011- June 2016.

Inclusion criteria

We included all the patients with suspected ectopic pregnancy who were confirmed by βHCG and transvaginal ultrasound.

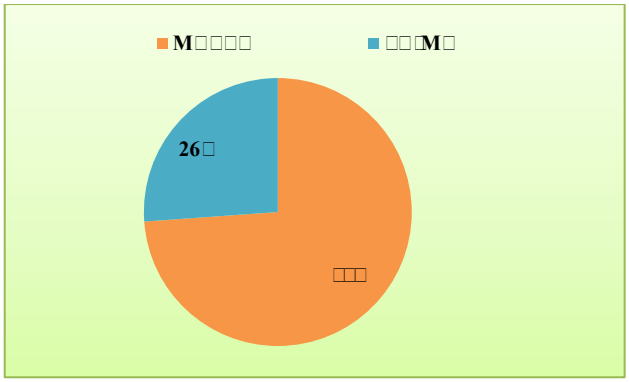
Exclusion criteria

None

Methodology

The case sheets were retrieved from medical record department and the details such as age, parity, risk factors like previous abortion, previous EP, previous pelvic surgery, contraception in the form of IUCD and tubectomy, history of PID, infertility treatment, clinical presentation, investigations including beta HCG value, hemoglobin level, treatment offered, need for blood transfusion, operative findings and morbidity were collected and analyzed.

Statistical analysis



No statistical tool used.

□□□□□□□

During the 5-year period, there were 12,407 deliveries at our institution and 88 cases of ectopic pregnancies were managed. The incidence was 6.6/1000 deliveries. Among the patients most of them belonged to the age group of 25-30 years (Table-1). 26% of patients were primigravida, 73.8% of patients were multigravida (Figure -1).

Twenty-one patients were fit into medical management, among them 12.5% of patients were managed medically with methotrexate successfully.

10 cases failed to medical management which were subsequently managed with either laparoscopic or laparotomy and salphingectomy.

3 cases were managed conservatively by observing the declining trend of Beta-HCG.

Other types of ectopic

Caesarean scar pregnancy was diagnosed in 3 patients, among them 2 patients underwent surgical excision. One patient was managed with UAE (uterine artery embolisation) followed by methotrexate. Heterotopic pregnancy following ovulation induction which resulted in twin intra uterine gestation and tubal ectopic was noted in one patient and she underwent emergency laparotomy and salpingectomy. Two patients were diagnosed as having ovarian ectopic and surgical excision was offered to both of them. Most common morbidity noted was anemia in 42%, out of which severe anemia (4-7gm) was seen in 5.6% (Table 8). Among them 28.4% of patients received blood and blood products. No surgical site infection or mortality was noted.

[illegible]

The incidence of ectopic pregnancy among women attending emergency department with first trimester abdominal pain, bleeding or both is between 6-16 %(14). A study conducted by Shraddha Shetty et al had incidence of 5.6/1000 deliveries.[15] In our study the incidence is 6.6%/1000 deliveries which is comparable. Majority of patients were between 25-30years which is similar to the above study and Khaleeqe et al.[15,16]

As in Karki et al (17), we had similar higher incidence of ectopic pregnancies (73.8%) in multigravida. In our study, the commonest predisposing factors were previous abortion either spontaneous or induced, previous pelvic surgeries including caesarean section, history of IUCD insertion, tubectomy, history of PID and infertility treatment, which are similar to various other studies.[17,18] As in the studies by Porwal Sanjay et al, Shraddha Shetty et al, the most common symptom in our series was pain abdomen which is comparable.[15,18]

Urinary beta HCG, serum beta HCG, transvaginal USG are the diagnostic tools for diagnosing EP. USG should be the investigation of choice for symptomatic women. In asymptomatic women, serial monitoring of serum beta HCG should be done. As in the study by Shraddha Shetty et al, we also had more number of right sided EP and involvement of the ampullary portion of the tube.[15]

Heterotopic pregnancy is rare in natural conception which is around 1 in 30,000 pregnancies. But the incidence is more in case of ovulation induction or with

assisted reproduction techniques. In our study, we had a case of triplet heterotopic pregnancy following ovulation induction with clomiphene citrate. It is recommended that even patients shown on ultrasound to have intrauterine pregnancy should be given comprehensive pelvic ultrasound so that possibility of synchronous heterotopic pregnancy can be excluded, particularly in pregnancies following fertility treatment.[19]

In our study, ruptured EP was noted in 53% of cases, 43.9% of cases had an unruptured ectopic gestation. In Latchaw G et al study, the same were 59% and 41% respectively.[20]

Laparoscopy and medical therapy have now emerged as the widely used therapeutic modalities with great success in terms of reduced morbidity, shorter hospital stay and conservation of fertility.[21] However choice depends upon early identification of ectopic pregnancy and hemodynamic status of the patients.[22] In our study, 11% of patients responded well to single dose of methotrexate.

Surgery should be the treatment of choice in unstable patient.[19] In our study 13.6% were unstable and all of them were managed surgically. Commonest surgery performed was partial/total salpingectomy. We did bilateral total salpingectomy for patients who had undergone tubectomy previously and were not desirous of future childbearing. It has been extensively studied and reported that conservative management does not increase the risk of future ectopic.[15] In our study, three patients were managed conservatively by observing the declining trend of Beta HCG. Morbidity included anemia, blood transfusion and wound infection. In our study, we had 42% of patients with hemoglobin level of less than 10grams. Among them 28.4% of patients received blood and blood products. No surgical site wound infection was noted.

No maternal mortality was noted in our study which is consistent with the study by A Abbas et al.[23] Early identification of the patients with EP by a multipronged approach including high index of suspicion, risk prediction, serum beta HCG and transvaginal ultrasound helps in improving the prognosis as far as morbidity, mortality and future fertility are concerned.[24]

□□□□□□□□□□

Identification of underlying risk factors, early diagnosis with essential investigating modalities like beta-HCG, transvaginal USG, timely intervention with medical or surgical method will definitely reduce morbidity and mortality and improve the future reproductive outcome.

Abstract

Background: Inspite of good monitoring in labour, there are still adverse labour outcomes. There is a need for supplementary test for early prediction of prolonged labour and fetal hypoxia. This study was undertaken to find to find the association between intrapartum amniotic fluid lactate level and labour outcome.

Methods: 103 antenatal patients low risk at term, who entered into active labour either spontaneously or induced between September 2012 to August 2013 were included. Amniotic fluid was collected after doing ARM and lactate level was measured. Chi square test was used to find correlation between lactate level and duration of labour, mode of delivery and Apgar score.

Results: In our study, patients with duration of labour between 8-<20hours 88 % had lactate level <10mmol/l, thus intra partum amniotic fluid lactate levels had a good negative predictive value when it was compared with the duration of labour. When the mode of delivery was analysed using Chi square test there was no statistically significant correlation ($p<0.825$) with amniotic fluid lactate. Spearman Rank correlation was done to observe correlation between lactate levels and Apgar which showed a correlation of 0.20 with $p<0.05$.

Conclusions: Amniotic fluid lactate levels had better correlation with duration of labour and Apgar score. The lower the amniotic fluid lactate level, the better is the Apgar at birth. Better correlation could have been observed if amniotic fluid lactate levels were repeated every 3-4 hours during active labor. However, this was not possible due to practical difficulty in collection of sample.

Keywords: Apgar score, Duration of labour, Lactate, Mode of delivery

Introduction

Inspite of close monitoring in labour according to established guidelines, there are still adverse labour outcomes.[1,2] One of the most important causes is dysfunctional labour.

The major cause for perinatal mortality and morbidity is birth asphyxia secondary to abnormalities occurring during labor. Many trials have been done in the past for detection of the abnormalities in labor, so that timely intervention can be done to improve perinatal outcome without increasing the caesarean section rate. Maintaining a partogram is very useful for assessing the dysfunctional labor.

However this alone was not sufficient in some patients. Many labors which were shown as abnormal had normal parturition without any adverse maternal or perinatal outcome, so there is a need for supplementary tests for early prediction of adverse labor outcomes.[3,4] So research are being carried out in this direction.

Studies have shown that if there is increased muscle activity there is accumulation of lactate in response to it. In cases of prolonged labour due to exhaustion of uterine musculature and hypoxia, there is to accumulation of lactate. Hypoxia is known to reduce the force and co-ordination of smooth muscle contraction[5]. Inefficient uterine action is one of the most common causes of poor progress in labor.[6] So based on this principle assessment of lactate in the amniotic fluid will help in the diagnosis of dysfunctional labor, This method has the advantage of being more precise and objective in diagnosis of prolonged labor which can cause adverse maternal and perinatal outcome.

So, the resulting increase in the acidity in the myometrium is the cause for the decreased force of further contractions which will lead to dysfunctional labour. The increased level of lactate in the uterus is measured in the amniotic fluid sample. Therefore it is believed that the raised amniotic fluid lactate levels are mostly associated with dysfunctional labour. Partogram along with the amniotic fluid lactate levels is better than using partogram alone in predicting the need for operative intervention in dysfunctional labor.[7] Level of amniotic fluid lactate may provide useful information while assessing progress of labour. Trials have shown that the lactate levels are many times lesser in the maternal and fetal blood when compared to amniotic fluid.

According to earlier studies when the level of lactate in the amniotic fluid is normal, it indicates that the likelihood of adverse neonatal outcome is very low [8], so that patient can be allowed for normal delivery if all other parameters are normal. A higher level of amniotic fluid lactate showed that the probability for normal delivery is less, if at all present it is almost always associated with instrumental delivery, and may have abnormal CTG findings. This study was conducted to find the association between intrapartum amniotic fluid lactate levels and labour outcome. The parameters studied were Duration of labour, Mode of delivery and APGAR score at birth.

M□□□□□□

A prospective study was conducted in the Department of Obstetrics and Gynaecology, PSG Hospitals, Coimbatore from September 2012 to August 2013.

Study population

Study group consisted of low risk pregnant women at term admitted in PSG Hospitals, who entered into active labour either spontaneously or by induction

Inclusion criteria

- Women in active labour without any obstetrical complications
- Vertex, presentation
- Term, Post-dated pregnancy

Exclusion criteria

- <37 Weeks not in active labour
- Obstetrical complication
- Biohazard
- Multiple gestation
- Absent/Ruptured Membranes

Methodology

All patients who entered into labour during the study period and who were eligible for the study were included. They were given information about the study and collection of amniotic fluid. After obtaining informed written consent regarding the study, these patients were followed up accordingly.

When the patients entered into labour either spontaneously or by induction, initial per vaginal examination was done and Bishop Score was assessed. The fetal wellbeing and the pelvis were assessed. Based on the findings patient were allowed to progress spontaneously or further augmentation was done. In induced labour per vaginal examination was repeated after 6 or 12 hrs if PgE2 gel 0.5 mg kept intracervically, 24 hours later if the labour was induced by Foleys induction with or without extra amniotic saline infusion, 6 hours later if induced with oral misoprostol 25mcg, 4 hours if augumented with vaginal misoprostol 25 mcg. Once the patient entered active labour, vaginal examination was done every 4 hours.

ARM was done when cervix is at least 3 cm dilated. With the bladder empty the patient is put in supine position with legs dorsiflexed and under aseptic precautions speculum examination is done. ARM is done under vision with good light and the amniotic fluid is collected.

Once the patient enters active labour, labour progress is monitored with partogram. If a repeat PV examination finding crosses the alert line, labour was augmented with oxytocin or in patients who were in induced labour with oxytocin; the dose used was 2.5 Units in 500 ml of Ringer Lactate infused with infusion pump. Depending upon the uterine contractions infusion was increased by 4 drops per minute every half an hour. Choice of labour analgesia was selected according to the patient's wish, either with pethidine 50 mg and inj phenergan 12.5 mg or by epidural analgesia. Entonox gas inhalation also used if needed.

The amniotic fluid of at least 2 ml was collected in a syringe after doing ARM. Amniotic fluid was transferred into a biochemistry laboratory container and it was labelled with the patient's details (name and medical record number). The amniotic fluid used in the study only if it was clear and not blood or meconium stained, as this

might alter the value of lactate. The sample reached the laboratory within 5 minutes through the pneumatic system in the hospital. The amniotic fluid sample is centrifuged in the laboratory and analysed immediately by automated lactate analyser, and the reporting was done immediately. So the delay in reporting was prevented. The result was viewed from the labour ward using hospital information system.

Once the patient entered the second stage of labour, she was encouraged to bear down. When the fetal head was seen, the obstetric and neonatology team were ready for delivery and neonatal resuscitation. Normal delivery was done either with or without episiotomy. Instrumental delivery was done either with vacuum or forceps depending upon the obstetric indication. The duration of the first and second stages of labour were noted. The baby's weight, initial, 5 minute and 10 minute APGAR scores were noted. If the patient was taken up for emergency LSCS, the same details of the baby were noted. The indication for LSCS and instrumental delivery were also noted down. All the details were entered in the study proforma and the results were analysed finally through statistical analysis.

The objectives are to correlate:

- Amniotic fluid lactate levels with duration of labour
- Amniotic fluid lactate levels with mode of delivery
- Amniotic fluid lactate levels with APGAR score

□□□□□□□□

Around 70 % of the study group whose lactate levels was 5-<8mmol/l had duration of labour between 8-<20 hours. Of the patients whose duration of labour was in 8-<20 hours, 88 % had lactate levels less than 10. The intra partum amniotic fluid lactate levels had a good negative predictive value when it was compared with the duration of labour.

In the group of 14 patients whose duration of labour >20 hours, 11 patients had normal lactate levels.

		Count	17	72	14	103
		% within lactate	16.5%	69.9%	13.6%	100.0%
Total	% within duration of labour		100.0%	100.0%	100.0%	100.0%
	Pearson Chi-square		2.222		P=0.695	

When the duration of labour was analysed there was no statistically significant correlation between amniotic fluid lactate and duration of labour. But it had good negative predictive value. When lactate level was >10 mmol/l, 10 patients had normal vaginal delivery.

When the mode of delivery were analysed there was no statistically significant correlation between amniotic fluid lactate and mode of delivery.

When we analysed amniotic fluid lactate and Apgar score:

- In lactate levels 5-<8 mmol/l-9.1% had Apgar <7
- In lactate levels 8-<10 mmol/l-15.6% had Apgar score <7.
- But in lactate levels mmol/l >10-35.7% had low Apgar score.

However spearman rank correlation showed a correlation of 0.20 with P < 0.05. When the Apgar score was analysed there was statistically significant correlation between amniotic fluid lactate and Apgar score.

Pearson chi –square test was used to find association between categorical variables. All statistical analysis was done using SPSS Software (statistical package for social sciences).

Chi square were used to find correlation between lactate

level and duration of labour, mode of delivery and apgar score. In addition Spearman Rank correlations were also done to observe correlation between lactate levels and apgar score.

Amniotic fluid lactate levels were measured during active phase of labour, and the mode of delivery, duration of labour and the Apgar score were noted down and correlation was analysed with these three. Results

correlating amniotic fluid lactate levels and duration of labour: Around 70 % of the study group who had lactate level between 5-<8 mmol/l had duration of labour between 8-<20 hours. Of the patients whose duration of labour were between 8-<20 hours, 88 % had lactate levels <10 mmol/l.

The intra partum amniotic fluid lactate levels had a good negative predictive value when it was compared with the duration of labour. Results correlating amniotic fluid lactate level and mode of delivery:

When lactate levels were more than 10, only 14% had normal vaginal delivery. When the mode of delivery were analysed there was no statistically significant correlation between amniotic fluid lactate and mode of delivery (p value of 0.825). Result correlating amniotic fluid lactate level and Apgar score:

- In lactate levels 5-<8 mmol/l – 9.1% had Apgar <7
- In lactate levels 8-<10 mmol/l - 15.6 % had Apgar score <7.
- But in lactate levels > 10 mmol/l - 35.7 % had low Apgar score.

Chi square test for Apgar score was analysed P value=0.079, there was no statistically significant correlation between amniotic fluid lactate and Apgar score.

Spearman Rank correlation was also done to observe correlation between lactate levels and Apgar score and showed correlation of 0.20 ($P < 0.05$) and was found to be statically significant. Thus high lactate concentration in amniotic fluid before delivery indicated an increased risk of adverse neonatal outcome at delivery.[8]

In normal labour during contraction there is decrease in the uteroplacental blood flow which gets restored immediately after the contraction is over when the uterus gets relaxed. But when the uterine contractions become irregular, the uteroplacental blood flow gets reduced for longer period as there is lesser duration for uterine muscles to relax.

As a result feto-maternal unit gas exchange is reduced and this leads to fetal hypoxic-ischaemia and lactic acidosis. There is a hypothesis that when there is hypoxia of myometrium there is increased production of lactate which is reflected as increased concentration of lactate in the amniotic fluid. This explains the adverse neonatal outcome in patients having increased lactate level in amniotic fluid. So the labour duration by itself does not affect the neonatal outcome[1].

The neonatal outcome may not be affected if the myometrial tissue is oxygenated well. We were not able to repeat the lactate levels just before the delivery due to difficulty in collection. But if the lactate levels were repeated just before delivery then further correlation could have been found out.

□□□□□□□□□

The myometrial capillary blood lactate increases in women following prolonged labour. The amniotic fluid lactate is 4-6 times higher when compared with fetal and maternal blood, which occurs mainly during dysfunctional labour. The traditional partogram is a good tool used for diagnosing dysfunctional labour. The combination of intrapartum amniotic fluid lactate levels along with WHO partogram could be used as a better tool in diagnosing dysfunctional labour.

According to our study, the intra partum amniotic fluid lactate levels had a good negative predictive value for normal labour outcome. Amniotic fluid lactate levels had better correlation with duration of labour and fetal scalp lactate has been demonstrated to have good correlation with APGAR score. The lower the amniotic fluid lactate levels, the better is the APGAR score.

Better correlation could have been observed if amniotic fluid lactate levels were analysed 4-6 hours after the initial assessment. However, this was not possible due to practical difficulty in collection of sample. Lactate analysis is a simple easy method of analyzing the labour outcome and the results of this test can be obtained very fast since its analyzed with auto analyzer. The laboratory results are also standardised since its done with the auto analyzer. The intrapartum amniotic fluid lactate levels can be correlated with umbilical cord blood lactate and fetal scalp blood lactate for further analysis.

ABSTRACT

Objectives: To analyse patients with moderate to severe thrombocytopenia in labour, to identify the etiology, assess severity, correlate with the maternal disease and management.
Methods: A retrospective study of all pregnant women admitted in labour or in obstetric critical area and found to have a low platelet count were included in a study period of 18 months from July 2013 to Dec 2014.
Results: 25 women out of 2738 deliveries were identified and commonest cause was severe pre-eclampsia with or without HELLP. Coincidental dengue with super added pre-eclampsia was found in 3 women. Severe thrombocytopenia was found in haematological conditions like ITP and aplastic anemia.
Conclusion: Low platelets or fall in platelets showed a worsening of disease condition. Platelet transfusion needs to be done if the cut off is below the desired target level. Timely administration of platelets and discrete use of SDP especially when massive platelet transfusion is required required as mandatory. Delivery should be as atraumatic as possible, avoidance of episiotomy to be practiced. Sometimes treatment can be challenging and involve multi-disciplinary approach.

INTRODUCTION

Thrombocytopenia is the most common hemostatic abnormality in pregnancy occurring in approximately 10% of all pregnant women. Abnormalities of platelet count may either be mild when the platelet count is between 150,000 and 100,000/mm^3, moderate when the count is between 100,000 and 50,000/mm^{3}or severe when the count is < 50,000/mm^3 (1). Gestational thrombocytopenia is the commonest cause of low platelets in pregnancy, however the count rarely falls below 70,000/mm^3 and is not of much clinical significance. Moderate to severe thrombocytopenia may occur due to either pre-existing disease like immuno thrombocytopenia (ITP), Systemic lupus erythematosus (SLE), anti-phospholipid syndrome (APLA) or pregnancy related conditions like pregnancy induced hypertension (PIH), HELLP, acute fatty liver of pregnancy (AFLP), ect (Kam, 2004). In labour low platelet count is a risk not only to the mother but also to the fetus. Most patients with mild thrombocytopenia do not have any hemostatic risk and do not require treatment unless the degree of thrombocytopenia worsens.

However moderate to severe thrombocytopenia is associated with adverse effects. The threshold for significant spontaneous bleeding is a count of 10,000/mm^3 and in the case of surgical interventions or delivery the threshold is higher >50,000/mm^3. The underlying disorder may manifest as thrombocytopenia and warrant immediate termination. The obstetrician concern is how to obtain hemostasis in the event of delivery and may involve multidisciplinary approach. Many articles describe thrombocytopenia in pregnancy however in labour only few references could be found. The aim of this article is to analyse the etiology of thrombocytopenia in labour, clinical features, management, platelet transfusions and fetal outcome.

MATERIALS AND METHODS

A retrospective study of all pregnant women admitted in labour or in obstetric critical area and found to have a low platelet count were included in a study period of 18 months. Only women with counts less than 1,00,000/mm^3 were included. The cases were analysed for the following:

- Etiology
- Clinical features
- Platelet count on admission
- Correlation with platelet count and maternal disorder.
- Need for platelet transfusion
- Gestational age at presentation.
- Outcome of pregnancy.

The condition of the baby in terms of gestational age, live birth or stillbirth were also assessed. Problems during transfusion were also assessed. The criteria for severe pre-eclampsia were blood pressure > 160/110mmhg, proteinuria +++ or more, oliguria, visual disturbance, epigastric pain, thrombocytopenia or impaired liver function.

Criteria for HELLP were

- Hemolysis as shown by peripheral smear or elevated billirubin > 1.2mg/dl
- Elevated liver enzymes : AST > 72IU/L, LDH > 600 IU/L
- Low platelets : count < 100,000/mm^3.

Management of these women, when and how they were terminated, type of transfusions and problems encountered were also analysed.

RESULTS

Table 1. Analysis of etiology

Cause	Number of cases
Severe pre-eclampsia with and without HELLP	18
PIH with Dengue	3
Megaloblastic anemia	1
ITP	1
Aplastic anemia	1
DIC	1
Total cases	25

Table 2 : Clinical features – combination of clinical features were seen

Clinical feature	Number of cases
Elevated BP	21
HELLP	7
Severe anemia	2
Eclampsia	4
Abruption	2
Renal failure	4
Bleeding episodes	6
Fever	3
Abdominal distention	1

Table 3. Correlation between platelet count on admission and diagnosis

Platelet Count	PIH	PIH with Dengue	Megaloblastic anemia	ITP	Aplastic anemia	DIC
100,000-50,000	10		1			1
50,000-20,000	6					
20,000-10,000	2	1		1		
<10,000		2			1	

The total number of deliveries were 2738 in the study period. The number patients with severe to moderate thrombocytopenia were 25.

The etiology was predominantly PIH seen in 18 women. PIH with super added dengue was seen in 3 women. Hematological disorders like ITP, aplastic anemia and megaloblastic anemia were seen in one each. One patient was found to have hemoperitoneum after caesarean and was found to have DIC. The clinical features at presentation were predominantly those of severe pre-eclampsia as shown in table 2. Combination of features like elevated blood pressure, HELLP, eclampsia, abruption and renal failure were seen. Bleeding episodes like haematuria, malena, bleeding from IV sites, bleeding gum, purpuric spots were seen in 6 women. Fever with elevated BP, abdominal distention following caesarean were also seen.

Table 3 shows the correlation between the platelet count on admission and diagnosis. The platelet count was moderate thrombocytopenia in 12 women, severe thrombocytopenia in 13 women. In the severe thrombocytopenic group 3 women had counts <10,000 cells/mm^3 and 4 women had counts between 10,000 to 20,000 cells/mm^3. In the PIH group platelet count was moderate thrombocytopenia in 10 out of 18 women. 6 women had counts between 50,000 to 20,000 cells/mm^3 and only 2 women had counts between 20,000 to 10,000 cells/mm^3. In patients with dengue and superadded PIH (3 women) the platelet count was <20,000 cells/mm^3 in all. The woman with megaloblastic anemia and dilutional coagulopathy had counts of 60,000/mm^3. Woman with ITP and aplastic anemia had very low counts <20,000cells/mm^3 and <10,000cells/mm^3 respectively. On analysis of platelet transfused in PIH women only 8 received transfusion and 10 did not. All women with dengue received multiple transfusions of 20 to 24 units. The woman with ITP received 44 units of platelet transfusion and the women with aplastic anemia received 40 units of platelets and 10 units of single donor platelets (SDP) as shown in table 4. There was one spontaneous expulsion at 26 weeks of pregnancy, live births were seen in 19 women and 5 women had IUD or stillbirth. 8 women delivered before 34 weeks and 16 women delivered 34 to 38 weeks of pregnancy. Table 5 shows the gestational age at presentation and fetal outcome.

DISCUSSION

Pregnancy is a hypercoagulable state with increased level of clotting factors. However platelet count declines as pregnancy advances. A platelet count < 150,000/mm^3 occurs in 1% of population but occurs in 6 to 12% of pregnancy women at term (McCrae, 2003; Boehlen, 2000). Approximately 1% of all pregnancy women have a count <100,000/mm^3 and about 1 in 1000 to 2000 have a count <50,000/mm^3. In our series also the incidence was similar around 1% of all patients had counts <100,000/mm^3 and severe thrombocytopenia was seen in 4-5/1000 women. In general, patients with a platelet count < 20,000//mm^3 are at risk of spontaneous bleeding. Platelet counts between 20,000 to 50,000/mm^3 have a risk of bleeding during procedures or delivery (Andra, 2013). Patients with counts >50,000/mm^3 generally have minimal risk of bleeding. PPH is the leading cause of maternal mortality (Lale, 2014) and when a patient enters the labour room with a low platelet there is great fear as to whether she would bleed during delivery, how much and how to prevent PPH. Therefore there is great concern to ascertain the diagnosis and immediate treatment. In our study pre-eclampsia was the commonest cause of severe and moderate thrombocytopenia.

Table 4: Transfusion chart

Platelet Count	PIH		Dengue		Megaloblastic anemia		ITP		Aplastic anemia		DIC	
	R	NR	R	NR	R	NR	R	NR	R	NR	R	NR
100,000-50,000	2	8			1						1	
50,000-20,000	4	2										
20,000-10,000	2		1				1					
<10,000			2						1			

R – Received, NR – Not Received

Table 5. Gestational age at presentation & fetal outcome

Gestational age	PIH	Others	IUD/Still birth
< 28 weeks	1	0	1
28 to 34 weeks	7	1	3
34 to 38 weeks	13	3	2
>38 weeks	0	0	0

Pre-eclampsia is said to be present in 21% of maternal thrombocytopenia[6]. Thrombocytopenia occurs in 50% of pre-eclampsia and occasionally precedes other manifestation of the disease. A decrease in platelet count is considered as an early sign of worsening of pre-eclampsia and may occur even before other clinical manifestation of disease are apparent (McCrae, 2003). The severity of thrombocytopenia directly correlates with the severity of the lesion. HELLP syndrome is often considered to be a variant of pre-eclampsia and in 1982 Weinstein coined the term HELLP and also stated that its presence is an indication for delivery as there is increased risk of maternal and fetal mortality (Weinstein, 1982). The hallmark of HELLP is microangiopathic hemolytic anemia, elevated liver enzymes and low platelet count. The reported cutoff value have ranged from 75,000/mm^3 to 229,000/mm^3 with a level of <100,000/mm^3 most often cited. HELLP may be complete with all the elements or partial with one or two components. HELLP occurs in 0.5 to 0.9 of all pregnancies and in 20% of all cases with severe pre-eclampsia.

The Mississippi Triple class system classifies this syndrome based on platelet counts (Joshi, 2010).

- Class I< 50,000/mm^3
- Class II50,000 to 1,00,000/mm^3
- Class III1,00,000 to 1,50,000/mm^3

In our study of 21 women with PIH, 7 women had HELLP, 5 belonging Mississippi Class I and 2 to Class II. Abruption was found in 2 and eclampsia was found in 4. HELLP, abruption and eclampsia require immediate termination irrespective of the gestational age. All our patients were terminated before 38 weeks of pregnancy, most of them were early or late preterm. Only one patient expelled at 26 weeks. M Sibai et al also states the same in his analysis of 442 pregnancies with HELLP syndrome [9]. In a study of 437 women who had 442 pregnancy with HELLP syndrome, serious maternal morbidity including DIC (21%), abruption 16%, ARF 8%, Pulmonary edema 6%, liver haematoma 1%, retinal detachment 1%. 55% of patients required blood component therapy and 2% required laparotomy for bleeding. Maternal mortality was 1%. Of 21 patients with low platelets with PIH, transfusion was done only in 11 patients, 9 of them had counts <50,000/mm^3 and only 2 had counts >50,000/mm^3 - one had 55,000/mm^3 and other had 62,000/mm^3, since LSCS had to be performed platelet transfusion was done as per British guidelines. Platelet count of > 80,000/mm^3 is recommended for epidural anesthesia by the British committee for the standards in hematology [10]. The count that was aimed in our patients was 50,000/mm^3 for vaginal delivery and 80,000/mm^3 for LSCS.

Dengue with super added PIH was seen in 3 patients. 2 of these patients in addition had HELLP-one complete and another partial. These patients had extremely low platelet counts (7,000/mm^3). The counts were much lower than those seen in severe pre-eclamsia. All of them had bleeding tendencies and all required transfusions. 24 units were given for the patient with 9000/mm^3, 22 units for a patient with twins and a count of 7,000 cells and 7 units for a patient with partial HELLP and previous caesarean. The rise in platelet count was very slow in this group, it took 10 days for platelet count to stablise. Dengue is a common tropical disease in our country. All our 3 patient had secondary dengue with super added pre-eclampsia and presented with bleeding tendencies. No reports of dengue with pre-eclampsia have been reported so far. The compounded effect of pre-eclampsia and dengue lead to very low platelet count and massive platelet transfusion was required in these women. The interval between the diagnosis and delivery was within 2 to 3 days. Termination was done immediately for all case of abruption, eclampsia, renal failure and HELLP after platelet correction to the desire level. In preterm mothers steroid administration was done for lung maturity and subsequently induction or LSCS was resorted to based on other parameters.

Haematological disorders must always be borne in mind especially when the clinical situation rules out pregnancy related conditions like PIH. In cases of severe anemia, megaloblastic anemia must always be thought of as was done in our case. In case of megaloblastic anemia the patient was referred as severe anemia with hemoglobin of 4.3gm/dl, platelet count showed 60,000cells/mm^3 . Anemia was more profound in this case and peripheral smear and bone marrow confirmed the diagnosis. A patient with known ITP presented at 28 weeks with PROM. She was on steroids. After delivery she developed hemothorax. She was treated as per ASH guidelines (The American Society of Hematology, 2011) Since she did not respond to steroids, Anti Rh immunoglobulin was given. She received a total of 44 units of platelets. Splenectomy was done as a last resort. A normotensive woman was referred as severe anemia with low platelet count. Dengue and drug history were ruled out. ITP was initially thought of, but inspite of transfusion the platelet count never raised. The expected rise was 5000cell/mm^3 after the single unit of transfusion but in this patient even after 4-5 units the counts did not raise. Further evaluation was done and ultimately a bone marrow confirmed aplastic anemia. We had to delivery her for fear of abruption or bleeding elsewhere and planned to refer her for bone marrow transplant. The patient was delivered under cover of single donor platelet.

However following delivery the counts fell to <2000/mm^3, she developed huge vulval haematoma, multiple bleeds, cerebral bleed and could not be resuscitated. Sometimes massive bleeding as in PPH may result in dilution coagulopathy as seen in our patient. This patient was referred from outside with abdominal distention after caesarean section, was found to have hemoperitoneum with platelet count of 60,000cells/mm^3, hemoglobin of 5gm/dl, fibrinogen of 150mg/dl, INR 1.6, she was diagnosed as DIC. NIH consensus conference report noted that pathological haemorrhage in a patient receiving massive transfusion is caused more frequently by thrombocytopenia than by depletion of coagulation factors. This may be due to hemodilution using crystalloids or using only packed cells. In such a situation it is always worthwhile to serially check for platelet count, PT & INR to see if dilution coagulopathy has occurred, since unless it is corrected bleeding would not stop (Platelet Transfusion Therapy, 1986). Still birth and IUD were seen in 6 women all in the PIH group. The high perinatal mortality was due to prematurity and IUGR. Similar reports are quoted by Kubilay Ertan (A Kubilay Ertan, 2002). However thrombocytopenia was not related to the preterm birth.

Factors to be considered in thrombocytopenic patients in the last trimester are

- When to terminate?
- What is the mode of termination?
- What is the ideal count to be obtained?
- What is the type of transfusion to be given?

Termination needs to be thought of only for maternal conditions like PIH, HELLP or abruption. The severity of thrombocytopenia directly correlates with the severity of the lesion[(14)]. Patient with severe PIH need to be serially monitored and a drop in platelet count may heralds the onset of HELLP. Careful surveillance is necessary. Vaginal birth is the preferred mode delivery. The chance of bleeding is less when trauma is minimal. Even episiotomy need to be given only where necessary because 1 patient with aplastic anemia had huge vulval haematoma after delivery. Both British and American guidelines suggest a platelet count >50,000/mm^3 is safe for vaginal delivery. British guidelines suggest aiming at a platelet count >80,000/mm^3 for a caesarean section. The count that was aimed in our patients was 50,000/mm^3 for vaginal delivery and 80,000/mm^3 for LSCS.

A single unit of platelet transfusion rises the platelet count by 5,000/mm^3. A unit obtained by apheresis of a single donor (SDP) contains an equivalent of 5 to 6 units raising the platelet count by around 30,000 to 60,000/mm^3. Platelet should be ABO and Rh compatible. Since stored platelets have a very short shelf- life, procuring many units may be a problem as the blood bank may not have that many bags. When requirement of platelet is large SDP is preferred as the risk of blood born pathogenesis is low, as also alloimmunisation. Where aphaeresis unit is not available, obtaining one required a lot of effort and co-ordination. Since the presentation varied interdepartmental assistance was often required. Good co-ordination with blood bank was required for procuring blood and blood products. In addition consultation with intensivist, haematologist, nephrologist, anesthetists and pediatrician was required. Team approach was the secret of success of survival of these patients.

Conclusion

Unlike in the antenatal period, moderate to severe thrombocytopenic patients near term are in a grave situation – one because the diagnoses has still to be made and secondly due to limited time constraints as delivery is imminent. A detailed history & physical examination is necessary in evaluating a patient with thrombocytopenia. Timely administration of platelets and discrete use of SDP especially when massive platelet transfusion is required helps prevent risk of infection and alloimmunisation. A platelet count of above 10,000cells/mm^3 must be maintained even after delivery to prevent spontaneous bleeding. Delivery should be as atraumatic as possible, avoidance of episiotomy to be practiced. Any pregnancy with a low platelet count less than 50,000cells/ml requires to be shifted to a tertiary centre, since etiology is varied and treatment is multidisciplinary.

RESEARCH ARTICLE

Labor Pattern in South Indian Population

Chitra Bhat[1], Seetha Panicker[2]

Abstract

Aim: Labor dystocia is one of the commonest indications of lower segment cesarean section (LSCS). Recent studies have shown a dramatic change in the rate of cervical dilatation and labor progress. There are no large studies to assess labor in this ethnic group and hence this study has been done to find out labor behavior in women with spontaneous labor in South India.

Materials and methods: A retrospective study was done in our teaching hospital. Labor was managed as per protocol and a partogram was maintained. Data were extracted from case-records and analyzed.

Results: Labor progress was much slower than what was thought of. There was wide variability in the duration of labor.

Conclusion: Many women took time up to the 95th percentile and some even crossed three times the median time to deliver.

Clinical significance: Though many women will deliver in the expected time, it is important to know the maximum time or the 95th percentile for each dilatation so that sufficient time can be allowed before labeling a case as prolonged labor.

Keywords: Labor curve, Labor duration, Rate of cervical dilatation, Slowest rate of dilatation.

Journal of South Asian Federation of Obstetrics and Gynaecology (2020): 10.5005/jp-journals-10006-1839

Introduction

Cervical dilatation is one of the key determinants of the progress of labor and may be dependent on many factors. There have been many attempts to define the norms for the progress of labor that have yielded variable results.

This is not an easy task as there are many challenges to accurately measure the duration of labor. The labor norms are also dependent on a woman's ethnicity, age, parity, BMI, use of epidural analgesia, and may vary among population groups. Despite all these difficulties, it is important to arrive at a proper understanding of labor norms and identify the slowest acceptable rates of cervical dilatation.

The rates of cervical dilatation in the active phase of labor largely stem from the data published by Friedman in 1950.[1] The Friedman's labor curve and the active management of labor pioneered by O'Driscoll et al.[2] where the lowest acceptable rate of dilatation is 1 cm/hr has influenced obstetric practice worldwide. WHO partogram[3] is practiced all over the world and the expected rate of dilatation is 1 cm/hr in the active phase. Any shift to the right and if the curve crosses the action line, labor is labeled as prolonged labor or non-progression of labor, and lower segment cesarean section (LSCS) is performed.

Dystocia characterized by a delay in progression of cervical dilatation is one of the most common indications for primary cesarean sections, ACOG Bulletin states it is the leading cause contributing to around 50% of all primary LSCS being performed.[4]

Zhang et al. reassessed Friedman's curves.[5] They studied the electronic records of 62,416 parturients and found the rates of cervical dilatation to be much slower. Data from this study formed the basis of the new guidelines for the active phase of labor. Labor may take even 6 hours to progress from 4–5 cm and more than 3 hours to progress from 5–6 cm. Only after 6 cm was the progress faster.

Due to ethnic differences, it is important to have insight regarding labor in our population that is critical in diagnosing labor dystocia and making a decision regarding the mode of delivery

Aims and Objectives

- To determine the duration of labor and the rates of cervical dilatation in low-risk primigravida and multigravida women with spontaneous onset of labor.
- To determine the slowest acceptable rates of cervical dilatation.
- To create a labor curve for this population.

Materials and Methods

This was a prospective observational study done in a teaching hospital in South India between 2017 and 2018.

The study population included both primigravida and multigravida who were admitted with spontaneous labor.

The inclusion criteria were term gestation, singleton pregnancy, and vertex presentation with spontaneous onset of labor who delivered either normally or by assisted vaginal delivery. The exclusion criteria were induced labor, pre-term labor, mal-presentations, and patients who were delivered by cesarean section.

The institutional protocols for monitoring of labor were followed. Maternal and fetal monitoring was done in the usual way. The progress of labor was assessed by monitoring uterine contractions per 10 minutes for every half an hour, cervical

dilatation, and descent of the head was assessed by vaginal examination every 3–4 hours in the first stage of labor.

The rate of cervical dilatation was plotted on a partogram with time in hours on the x-axis and cervical dilatation on the y-axis.

Ethical clearance was obtained from our institutional human ethical committee.

Statistical Analysis

The data was entered on an Excel spreadsheet and analysis was done using SPSS STATA13.1 software.

The data were analyzed concerning maternal demographic characteristics. The cumulative labor duration from cervical dilatation on admission (i.e., at 1, 2, 3, 4, 6, 7) to reach 10 cm was assessed. Data were extracted according to two parity groups nulliparous and parous women.

With each starting dilatation, the mean rate of dilatation was calculated for primigravida and multigravida. Taking the value of 2SD, the slowest rate of dilatation was also calculated.

A non-regression model was used to plot the labor curve with cervical dilatation against time in hours.

Results

The total number of deliveries during the study period was 4150.

A total of 2558 women were delivered by cesarean section. The number of women with spontaneous onset of labor who delivered vaginally was 1196. A total of 152 patients who had incomplete data and 21 patients who were admitted at more than 8 cm were excluded. So, only 1023 deliveries were analyzed.

Primigravida were 556 in number and multigravida were 467 in number. The age, cervical findings on admission, and mode of delivery are shown in Table 1.

The cumulative time taken for each dilatation starting from 1 to reach 10 cm was analyzed in both primigravida and multigravida.

In our study, the median duration of labor was chosen, as the mean duration may be skewed by a few laborers of very short or long duration. If the labor duration is positively skewed, the mean duration will be longer than the median duration as shown in this study thus at 2 cm the mean duration was 7.7 hours and the median duration was 7 hours.

Table 2 shows the cumulative mean time taken for each dilatation to reach 10 cm in primigravida and multigravida, respectively. It shows that multigravidae took a shorter time to progress to 10 cm when compared to primigravida. Primigravida took a median time of 9 hours to reach 10 cm from 1 cm, whereas it was 8 hours in multiparous women. At 2 cm it was 7 and 6 hours. At 3, 4, 5, 6–10 cm it was 5, 3, 3, and 2 hours in primigravida and 4, 3, 2, and 2 hours in multigravida.

Table 2 also shows the 5th and the 95th percentile, the number of women who crossed the 95th percentile, and the maximum time allowed for labor to continue that resulted in normal vaginal delivery.

At 2 cm though the meantime was 7.7 hour in primigravida, 16 women crossed the 95th percentile and 10 patients had a vaginal delivery after almost three times this mean-ranging from 18–26 hours. In six multiparous women at the same dilatation, labor was prolonged to 16–27 hours and 15 women crossed the 95th percentile.

At 3 cm dilatation, although the mean duration of labor was 5.5 hours, four primigravida women had a vaginal delivery after 19, 17, 16, and 13 hours, respectively. Correspondingly three multigravidas had taken 21, 15, and 13 hours to deliver from 3 cm dilatation for a mean of 4.7 hours.

At 4 cm against a mean of 3.8 hours, five primigravidas had taken between 8 and 11 hours to deliver, and in multigravida for a mean of 2.9 hours four had taken between 6 and 9 hours. At 7 cm a multiparous woman took 6 hours to reach full dilatation.

With each starting dilatation, the mean rate of dilatation was calculated for primis and multis. Taking the value of 2SD, the slowest rate of dilatation was also calculated as shown in Table 3.

The labor curve obtained was hyperbolic and not a sigmoid curve. There was no definite point of acceleration seen (Figs 1 and 2).

Table 1: Demographics

Details	*Primigravida*	*Multigravida*
Number of cases	556	467

Discussion

A total of 1023 patients were analyzed, out of which 556 were primigravida and 467 were multigravida. We found the following in our study:

- In the active phase, the average time taken was more than that described by Friedmann.[6,7] In his study, he has stated that from 2.5 cm to reach 10 cm the average time is 4.6–4.9 hours, and once they reach 4 cm half of them deliver in 2.6 hours. Our corresponding figures were 7.7 hours to reach 10 cm from 2.5 cm and the mean duration at 4 cm was 3.8 hours against 2.6 hours. Peisner and Rosen[8] found that 75% of women at 3 cm, 50% at 4 cm, and 25% at 5 cm do not dilate at the indicated rates associated with active labor.

However, recent studies have shown a longer first stage of labor with slower acceptable rates of dilatation. Zhang et al. derived the average labor curves from 27,170 nulliparous women in the US population with spontaneous onset of labor. The curve had a slower progression of 1.1 cm/hr with no definite inflection point. The slowest acceptable rate was 0.6 cm/hr.

Albers et al.,[9] Albers,[10] and Jones and Larson[11] found that labor progression takes a longer time than the thought of earlier. These investigators have reported that in the active phase of labor from 4 cm to reach 10 cm the time ranges from 6.2–7.7 hours on average. In Albers's study, the time taken was 7.7 hours since there was no use of oxytocin and labor was spontaneous.

- The second derivative was that there was a wide difference in time taken between individuals. When women were admitted at 2 cm, the median time taken to reach 10 cm was 7 hours in primigravida and 6 hours in multigravida. However, 2SD at this dilatation was 4.5 hours extending labor to 11.5 hours. Many women crossed the 95th percentile and also, ten primigravidas delivered normally after a duration that was almost three times the median ranging from 18–26 hours indicating wide variability in the duration of labor are still associated with normal outcomes. The same was seen at all dilatations. Our findings were similar to that quoted by Oladapo et al.[12] as part of WHO BOLD PROJECT (better outcome in labor difficulty) where he says median cumulative duration of labor indicates that nulliparous women admitted at 4, 5, and 6 cm reached 10 cm within an expected time, but their corresponding 95th percentile shows that labor could last up to 14, 11, and 10 hours.
- It was found that the rates of cervical dilatation accelerate as labor progresses and for each dilatation, an acceptable slow rate of progress exists. This is comparable to the study by Zhang et al. who found that the slopes of cervical dilatation progressively steepen with each passing centimeter. In his study, he also found that the median rates of dilatation between 3–4, 4–5, 5–6, 6–7, 7–8, 8–9, and 9–10 cm were 0.4, 0.6, 1.2, 1.7, 2.2, 2.4, and 2.4 cm, respectively. At the 5th percentile that is used to define the slowest normal dilatation rates the rates were 0.1, 0.2, 0.3, 0.5, 0.7, 0.8, and 0.7 cm/hour, respectively.
- Finally, the labor curve that was obtained showed a smooth hyperbolic curve, there was no point of acceleration. A similar labor curve pattern is seen in other studies. Suzuki et al.[13] studied the labor patterns in 2369 low-risk nulliparous Japanese women with spontaneous onset of labor and derived the labor curve for that population. It showed that the curve had a smooth shape with an active phase duration of 5.1 hours with slower progression than that of Friedman's curve. The deceleration phase was not observed and the rate of dilatation started to double from 5–6 cm onwards. A study done in South India by Pitchaimuthu and Bhaskaran[14] showed the same pattern

of slower dilatation, a smooth labor curve, and no point of inflection.

The limitations of this study include interpersonal variations in the assessment of cervical dilatation. The effect of ARM and oxytocin were not analyzed since many patients were subjected to either both or one of them.

Conclusion

In low-risk women, both primigravida and multigravida with spontaneous onset of labor, there is wide variability in the duration of labor with normal maternal and fetal outcomes. Our study showed that in low-risk women admitted in early spontaneous labor, half of them took more than the meantime and a significant number of women took even three times the mean. The rate gradually increased with dilatation and in nulliparous women at 6 cm of dilatation the rate was much higher. It is worthwhile to note that many women despite crossing the 95th percentile delivered normally, hence, revision of the expectations of the rate of cervical dilatation would reduce both unnecessary interventions in labor and cesarean sections for slow or abnormal progress of labor. Labor should be more patient-centered and the same pattern will not fit all.

Acknowledgments

I sincerely thank both of the statisticians Dr. Varun and Dr. Karthikeyan who took great efforts in analyzing the data and deriving the labor curve. I thank all the staff involved to retrieve the case sheets and the junior residents who helped me with data entry.

A Comparative Study of Right and Left IJV Cannulation Using Surface Anatomy or USG Guidance: A Prospective Randomized Study

C. Ganesan*, Prashant A. Biradar, Saranya Vishnumathy Sampathkumar***, Anitha Sunny******

Abstract

Context: Internal jugular vein (IJV) is cannulated in a variety of patients. Left IJV cannulation sometimes becomes necessary. *Aim:* This study was done to evaluate the usefulness of ultrasonography (USG) in performing left and right IJV cannulation compared with use of surface anatomy landmarks. *Setting and Design:* Prospective randomized study in a tertiary care teaching hospital. *Methods:* Ninety one American Society of Anesthesiologists (ASA) class I, II or III adult patients scheduled for elective cardiothoracic, vascular, neurosurgical or major abdominal surgeries requiring IJV cannulation were randomized to undergo either right IJV cannulation using surface landmarks (Group 1) or USG (Group 2) or left IJV cannulation using surface landmarks (Group 3) or USG (Group 4). The number of attempts, time taken, the success rate, any change in technique or side of cannulation and any complications were recorded. *Results:* There was a significant difference in the success rate and number of complication between group 3 and group 4 ($p<0.05$). There was a statistically significant difference in the time taken for cannulation between Group 3 and Group 4 (273.9±127.6 Vs 135.2±105.1 sec, $p<0.001$). There was a significant difference in the number of attempts between Group 1 and Group 2 (2.05±1.2 Vs 1.46±0.64, $p<0.05$) and between Groups 3 and Group 4 (2.78±1.41 Vs 1.69±0.18, $p<0.01$). Complications (carotid puncture) were significantly more common on left side using surface landmarks ($p<0.05$). *Conclusion:* Ultrasound significantly improves the success rate of left and right IJV cannulation when compared to use of surface landmarks. It also reduces the number of attempts, the time required for cannulation and incidence of complications.

Keywords: Cannulation; Central Venous; Jugular; Ultrasonography; Vein.

Introduction

Internal jugular vein (IJV) is cannulated for a variety of indications in perioperative period and in the critically ill. This includes both diagnostic and therapeutic indications. The right IJV is usually chosen because it has a relatively straight course to the heart, has a lesser chance of pneumothorax and avoids the risk of injury to thoracic duct altogether [1,2]. The clinician's experience with right IJV is also commonly greater than with left IJV. However, left IJV cannulation frequently becomes necessary when the right IJV cannulation is unsuccessful or the right IJV is thrombosed or has a catheter in-situ or the right carotid artery is significantly stenosed.

Ultrasonography (USG) greatly improves the success rate and reduces the risks of IJV cannulation, particularly for inexperienced clinicians [3]. And the NICE guidance suggests the two-dimensional (2D) imaging USG as the preferred method for cannulation of the IJV in adults and children in elective situations [4]. However, in majority of studies on use of 2D-USG for IJV cannulation the right IJV was used. Since the left IJV is longer, more tortuous and smaller in calibre than the right IJV, it is more likely to be difficult to cannulate [5]. To our knowledge, there is only one randomized study that compares right and left IJV

cannulations using surface landmarks or USG [6]. Unlike these authors, in patients scheduled for major elective surgeries we perform IJV cannulations before induction of anesthesia which could affect the results of the study. We performed a randomized study to evaluate the usefulness of real-time USG in cannulation of left or right IJV compared to use of surface landmarks.

The primary objective of our study was to compare the success rate and complications of left and right IJV cannulation using real-time USG versus use of surface landmarks. The secondary objectives was to compare the number of attempts and access times for left and right IJV cannulation performed with or without USG.

Materials and Methods

After Institutional ethics committee approval and written informed consent from each patient a total of 106 ASA class I, II &III patients scheduled for elective cardiothoracic, vascular, neurosurgical and major abdominal surgeries requiring IJV cannulation were enrolled into the study. With the exclusion of 15 patients who did not meet the inclusion criteria, the final study population was 91 patients and was randomly allocated into 4 groups using a computer-generated table of random numbers (Figure 1).

Patients were excluded from randomization if they have had a previous IJV cannulation, neck dissection, burns or radiotherapy to the neck, have a mass or infection at the cannulation site or refuse to participate. Patients underwent either right IJV (RIJV) cannulation using surface landmarks (group 1) or using USG (group 2) or underwent left IJV (LIJV) cannulation using surface landmarks (group 3) or using USG (group 4).

All cannulation were done as per the recommendations and practice guidelines suggested by the ASA Task force on central venous access, under strict aseptic precautions and sterile draping with a slight Trendelenburg positioning and head turned by about 30° to contralateral side, using Seldinger technique. All cannulations were performed by staff anesthesiologists experienced in IJV cannulations and expertise in USG-guided technique.

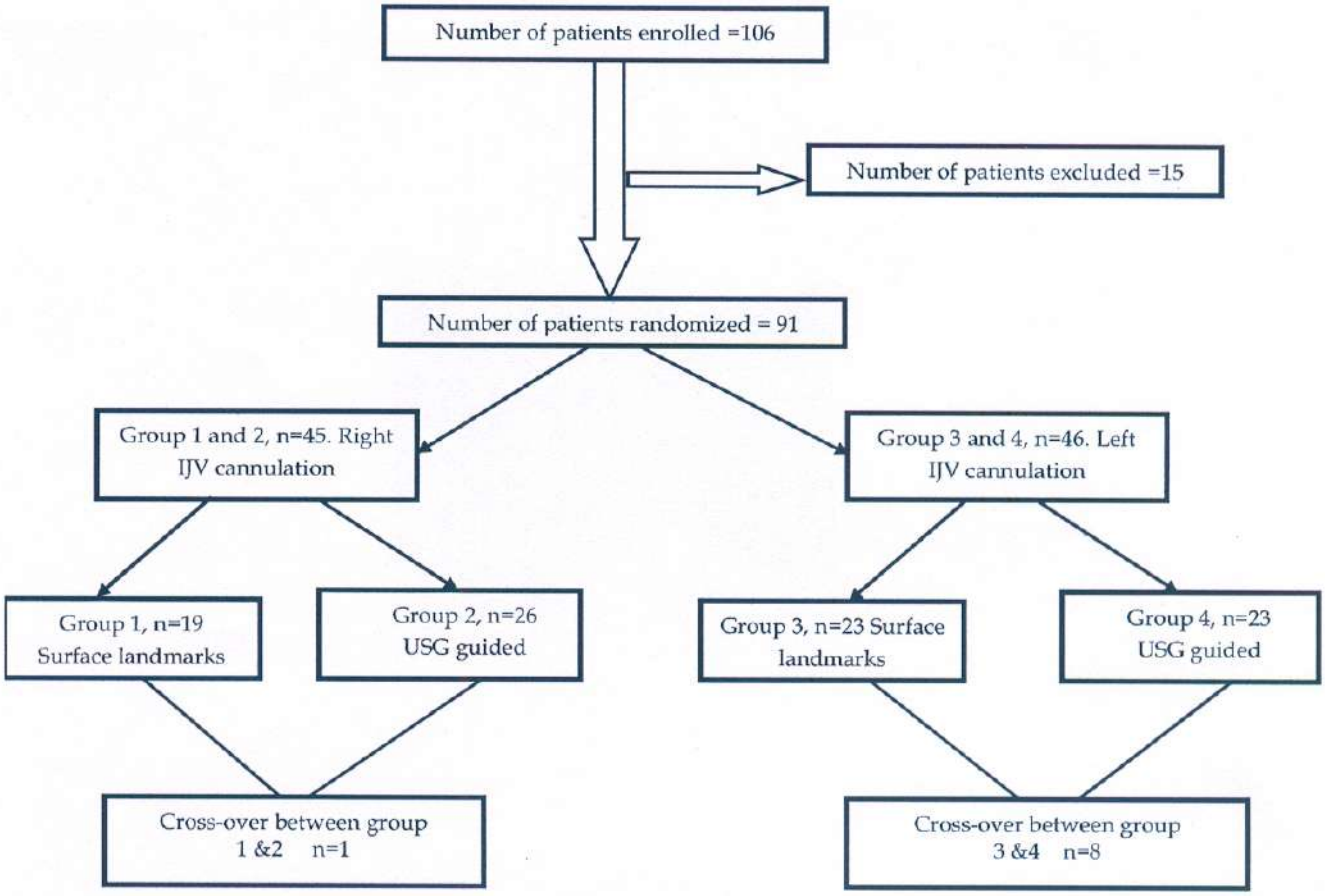

Fig. 1: Study design

Surface Landmark Approach

The site of puncture was the apex of the triangle formed by the clavicle and the two heads of sternomastoid muscle. A 23G locator needle was inserted at an angle of approximately 45° and directed towards the ipsilateral nipple. Aspiration of dark, non-pulsatile blood guided a subsequent 16G cannulating needle in the same direction. A further aspiration of dark, non-pulsatile blood was followed by guidewire insertion through the cannulation needle. And a 7 Fr triple- or double-lumen catheter was inserted over the guidewire (Cetrofix, B. Braun, Melsungen AG, Germany).

An attempt at cannulation was defined as the number of skin punctures and the technique was considered successful if the guidewire was successfully inserted on the ipsilateral side using the technique the patient was randomly assigned to. Whenever the IJV was not located by more than six attempts or there was difficulty in passage of guidewire or there was arterial puncture with the 16G cannulation needle, USG was used to guide ipsilateral IJV cannulation. In the event of guidewire placement using USG being unsuccessful, the contralateral IJV was cannulated under ultrasound guidance.

Ultrasound-Guided Approach

A 7.5MHZ linear array ultrasound transducer probe (Vivid-i) covered in ultrasonic gel was wrapped with a sterile plastic bag and connected to a USG machine (vivid-i, GE Medical Systems, Milwaukee, USA). The probe was placed on the neck at the level of cricoid cartilage and the IJV was then identified by its shape, absent pulsations, probe compressibility and by colour flow Doppler. A 16G cannulating needle was then used to puncture the IJV visualized in short axis in real-time USG. After aspiration of blood, guidewire was inserted and its position confirmed by USG of IJV in long axis.

Data Collection and Analysis

The data collected included the number of successful cannulations in each group, number of attempts, time taken from initial skin puncture to successful guide wire placement, incidence of complications such as arterial puncture, hematoma and pneumothorax, and the number of patients in whom cross-over of technique was used. Post-procedure chest X-ray films were taken routinely. Data analysis was done using STATA statistical software version 19.0., independent sample T-test for continuous variables and chi- square test for categorical variables.

Results

There was no statistically significant difference among the groups with respect to age, gender distribution, weight or height (Table 1). There was a significant difference in the success rate and number of complication between group 3 and group 4 ($p<0.05$). However, there was no significant difference in the success rate or complications between group 1 and group 2 (Table 2). The only complication observed in our study was carotid artery puncture. One patient in group 1 and 8 patients in group 3 had carotid puncture. Cannulation in these patients was accomplished using USG on the same side. None of the patients developed hematoma. Also the success rate was significantly higher in group 1 compared to group 3.

There was a significant difference in the number of attempts between group 1 and group 2 and between group 3 and group 4 (Table 3). There was no significant difference in the number of attempts between group 2 and group 4. Using surface landmarks, cannulation of the LIJV took significantly more time compared to RIJV. Ultrasonography greatly reduced the time taken for cannulation on left side compared to surface landmark (Table 3, Figure 2).

Table 1: Patient demographics

	IJV		LIJV	
	Group 1 (SL, n=19)	Group 2 (USG, n=26)	Group 3 (SL, n=23)	Group 4 (USG, n=23)
Age (yrs)	51.4±12.0	56.9±13.0	49.8±10.2	56.56±10.0
Gender

*p<0.05 compared to group 1, #p<0.05 compared to group 3 at respective number of attempts

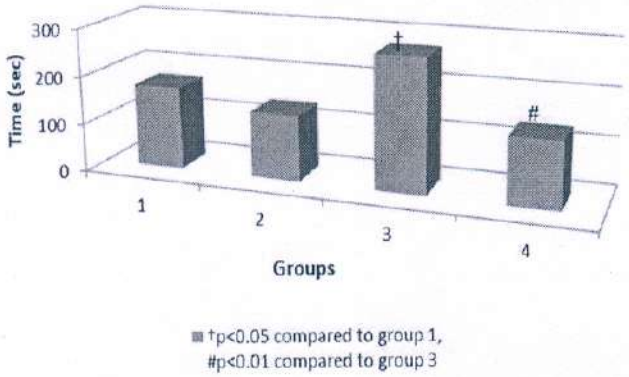

Fig. 2: Access time

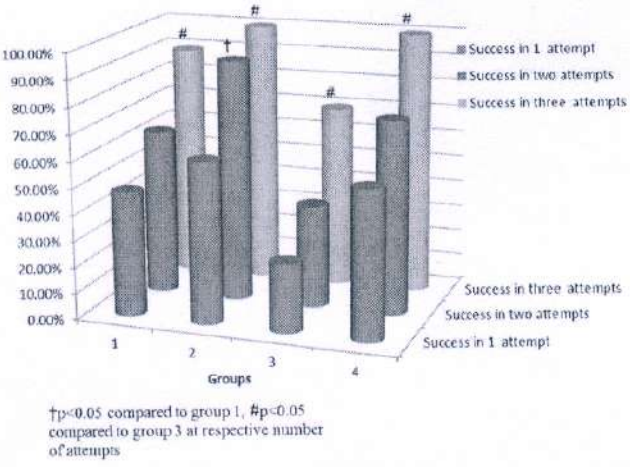

Fig. 3: Cumulative success in multiple attempts

We also evaluated the usefulness of ultrasonography in improving the success rate with every attempt at cannulation after a failed first attempt. Cumulative success in one, two and three attempts is shown in Table 4, and Figure 3. There was a significant improvement in the success rate in upto 3 attempts in group 4 compared to group 3. On the right side, USG improved the success rate in two attempts at cannulation (Table 4, Figure 3).

Discussion

Our study showed that ultrasonography significantly improves the success rate and reduces the complications of left IJV cannulation. On the right side however, the success rate and complications were not different statistically with or without USG, probably because all the cannulations were done by faculty with vast experience in IJV cannulations. Our success rate of right IJV cannulations is comparable with previous studies [7,-9]. Denys and Uretsky have shown that IJV is located anterolateral to the carotid artery (CA) in 92%, >1 cm lateral to the carotid in 1%, medial to the carotid in 2%, and outside of the path predicted by surface landmarks in 5.5% of patients [10]. A failure rate of 7.0% to 19.4% is due partly to the inability of external landmarks to precisely correlate with the location of the vessel [11,12]. The

failure rate of 5.3% on right side using surface landmarks in our study is well within this range.

Using surface landmarks, the left IJV was more difficult to cannulate compared to the right IJV. It took more time and attempts to cannulate the left IJV than the right IJV using surface landmarks. This may be due to its longer and more tortuous course compared to right IJV. In addition, the vertical and horizontal diameter of left IJV is smaller than the right IJV as measured by preoperative CT scans [13]. Left IJV also lies deeper compared to right IJV. On the right side USG did reduce the number of attempts compared to surface landmarks.

Our study also showed that when multiple attempts are made at cannulation of left IJV, a USG-guided technique is more likely to succeed than a surface landmark guided technique. Since there is a strong direct correlation between the number of attempts and the incidence of complications, increasing patient anxiety and discomfort, it may be prudent to use USG for all left IJV cannulations. Patient head position also has important implications for the relation between CA and IJV. Sulek CA *et al* have shown that the percentage of overlap between the IJV and the CA increased as the head was rotated contralaterally from neutral (0°) to 40° to 80° [14]. When overlap occurred, it was always more on the left than the right side, and it was significant at 80 degrees head rotation ($P < 0.05$). In our study patient head was rotated by about 30°. The concern with overlap of IJV and CA is that it increases the likelihood of unintentional CA puncture by a through-and-through puncture of the IJV. The accidental puncture of the posterior wall of IJV can occur even with the use of USG when short axis view is used for the cannulation [15]. As the advancing needle indents the anterior wall of the low-pressure IJV, it collapses and in the absence of blood aspired from the needle the advancing needle could puncture the posterior wall of IJV and then the CA. Vessel overlap increasing with head rotation is most apparent among patients with increased body surface areas (>1.87 m^2) and increased body mass indexes (>25 kg/m^2) [16]. The 5.2% right CA puncture incidence in our study is much less compared to those reported in previous studies [7-9]. This may be because of several factors including experienced operators, low mean body mass index (BMI) among our study groups of 21.7kg/m^2 and head turned to contralateral side by about 30°. The incidence of CA puncture on the left side using surface landmarks was 34.8 % which is high compared to a previous study [6], probably because of a smaller sample size and our lack of familiarity with the left IJV cannulations using surface landmarks. Ultrasound can be used to alter the approach angle to avoid CA puncture by directing the advancing needle away from the CA [17]. In our study, there was no incidence of CA puncture using USG on right or left side.

Our study showed that USG-guided cannulation provides advantage of increased success rate with decreased number of attempts and complications compared to the use of surface landmark as shown in previous studies [18-19]. Ultrasound has a definite role in achieving vascular access for difficult-to-cannulate patients with increased success rate and decreased complications. However, USG is a specialized technique and requires advanced training and knowledge [20]. Continued training of physicians in USG techniques ensures that it can be used in various clinical applications to improve the patient outcome.

Conclusion

Ultrasound significantly improves the success rate of left and right IJV cannulation when compared to use of surface landmarks. It also reduces the number of attempts, the time required for cannulation and incidence of complications. Since the left IJV is more difficult to cannulate and has a higher potential for complications than the right IJV, it may be prudent to use USG for all left IJV cannulations.

Key Message

The left IJV is particularly difficult to cannulate using surface landmarks and has higher potential for complications. Hence, USG should be used in all left IJV cannulations

Abstract

Background: Cancellation of surgery on the scheduled date poses physical, psychological and emotional disturbances not only to the operating surgeon, but it also includes the perioperative physician as well as the patients. The most common cause of cancellation of elective surgery on a scheduled day in a teaching institution includes lack of operating time in theatre. The reasons to quantify the cancellation list is usually vivid and difficult. **Aim:** The objective of this audit was to find out the prevalence and the reasons for cancellation of elective surgery on the scheduled day and to find out the clinical quality indicator with regard to effective theatre utilization time on a scheduled day. **Materials and Methods:** This retrospective analysis was included for one year duration in a tertiary teaching hospital. We coined the cancellation of the elective surgery as any proposed surgery which was listed and planned the previous day; and subsequently not done on the scheduled day of surgery. The source of audit was the documentation maintained in cancellation records in the anaesthesia department and these data were analyzed. The most common cause for cancellation of surgery was categorized as Patient related, Pre operative (or Surgical) preparation related and Facility related factors. Observations and **Results:** All the data were entered in the Microsoft excel spreadsheet and a Pareto chart was constructed to prioritize the reasons and analyzed using Epi info software version. Out of 10,306 patients during the scheduled period in our audit, 532 (5.16%) patients had cancellation on the elective list. **Conclusion:** Appropriate pre operative assessment, better inter departmental coordination, adequate optimization prior to surgery, improving man power availability and increasing the operation theatre utilization time help to avoid cancellation of surgery on the scheduled day.

Key Words: Cancellation, elective surgeries, scheduled day, teaching institution

INTRODUCTION

Surgery is the primary modality of treatment in specified diseases and it requires a multi disciplinary team work approach in the operating room. Pre anaesthetic assessment, adequate preparation and optimization of the surgical patient prior to the elective surgery, avoids the major catastrophic events perioperatively and also decreases the morbidity and mortality of the surgical patients. Cancellation of surgery on the scheduled date poses physical, psychological and emotional disturbances not only to the operating surgeon, but it also includes the perioperative physician as well as the patients.[19] The prevalence and the cause for cancellation of elective surgery on a scheduled day is diverse and vary from one institution to another. The incidence of cancellation is between 10% and 40% among the booked elective list in various institutions[1,6,15,16,17]. The most common cause of cancellation of elective surgery on a scheduled day in a

teaching institution includes lack of operating time in theatre[1,2,16,17,18] (running beyond the scheduled hours), poorly optimized surgical patients due to varied medical conditions or the administrative reasons[1,7,16,17,18]. Delayed start of elective list, unanticipated anaesthetic or surgical problems or shortages of the operating staff also contribute an pivotal role in cancellation[10]. The reasons to quantify the cancellation list is usually vivid and difficult. Hence the simplest approach is to evaluate the cause for cancellation of surgery and the specified issues needs to be focused preventing the postponement of the elective surgery.

AIM

The objective of this audit was

1. To find out the prevalence and the reasons for cancellation of elective surgery on the scheduled day and to focus on improving the quality of health care
2. To find out the clinical quality indicator with regard to effective theatre utilization time on a scheduled day and thereby offering better utilization of theatre services and resources

MATERIALS AND METHODS

This audit was a retrospective analysis and an observational study conducted in a NABH accredited, ISO certified 1300 bedded tertiary teaching hospital PSG Institute of Medical Sciences and Research, Coimbatore. The audit study period was included for one year duration from 1st October 2017 to 30th September 2018. The elective operating list scheduled for the next working day was planned by the concerned operating surgeon by 3 pm the day prior to operation and the list is printed and displayed in the department. The operating list included the complete elective surgery list on the scheduled day and the cancellation list were maintained in a separate registers along with a detailed note mentioning the details of cancellation. Our hospital comprises of 10 operating room in the main Operation Theatre block involving surgeries with various specialities like General surgery, laparoscopic surgery, obstetrics and gynecology, orthopedic surgery and neuro surgery on all days; with a separate theatre in labor ward and 2 cardiothoracic theatre functioning exclusively separately. Speciality surgeries like pediatric surgery, ENT, plastic surgery, hepato-biliary surgery, surgical gastroenterology, urology and transplant surgery with allocation for three days in a week for elective surgery. The scheduled elective surgery operating duration list was included between 8 am and 5 pm in our institution, with exceptions working on Sundays and public holidays. We coined the cancellation of the elective surgery as any proposed surgery which was listed and planned the previous day; and subsequently not done on the scheduled day of surgery. The source of audit was the documentation maintained in cancellation records in the anaesthesia department and these data were analyzed. The most common cause for cancellation of surgery was categorized as Patient related, Pre operative (or Surgical) preparation related and Facility related factors. All the data were entered in the Microsoft excel spreadsheet and a Pareto chart was constructed to prioritize the reasons and analyzed using Epi info software version. Although the audit was done for improving departmental work under quality assurance, this study received ethical committee approval (Ref No: PSG/IHEC/2018/Appr/Exp/207/ Proposal No.18/202 dated 13.08.2018).

OBSERVATIONS AND RESULTS

Table 1: Cancellation of cases Month wise from October 2017 to September 2018

Month	Number Of Cases (n)	Cancelled Cases (n)	Case Cancelled (%)
October 2017	775	52	6.70
November 2017	900	70	7.77
December 2017	851	50	5.87
January 2018	754	38	5.03
February 2018	740	35	4.72

*OT Utilization Rate = OT Utilization Time in hours X 24 / Resource Hours X 100

DISCUSSION

The National Health Service (NHS), UK through its Modernization Agency Theater Program has defined case cancellation as those that occur after the patient has been notified of operation date[8]. Few define it as the procedures that were cancelled either on the day on which the surgery was scheduled, or cases which appeared in the definitive scheduled list but ultimately was not performed. Out of 10,306 patients during the scheduled period in our audit, 532 (5.16%) patients had cancellation on the elective list. Rakesh Garg *et al*[5,17] in a north Indian government hospital reported 30.3 % cancellation list followed by, Ezike *et al*[7] stated 25.3 % cancellations, Rajendra Kumar *et al*[16] in an government hospital showed 17.6 % cancellation, Abderrazak Sahraoui and Mohammed Elarref *et al*[2] observed 13.4 % and JimEnez *et al*[9] noted with 3.9 % as cancellation comparable to a study in a Jordanian hospital[11] with 3.6% cancellation on the elective list respectively. The cancellations at a teaching hospital in south india was found to be 4.4 % which was in accordance with our study (5.16%). In our audit, the frequency of cancellations was pronounced more in pre operative or surgical preparation related factors accounting for 265 patients (49.81%), followed by facility related factors in 142 patients (26.69%) and 125 patients (23.49%) in patient related factors respectively. On categorizing Surgical (or pre operative) preparation related factors which includes patients presenting with active respiratory infections, acute exacerbation of any medical conditions, electrolyte disturbances, uncontrolled blood sugar or blood pressure; the overall cancellation was maximum with abnormal laboratory values (21%) on the day of surgery. URI-related cancellations was reported by Palomero Rodriguez *et al*[13], however this decreased from 12.9% in 2001 to 7.2% in 2003 through enhanced communication of simple and appropriate information to parents resembling with 7.54% in our audit. Knox *et al* reported a significant reduction in medical-related surgical cancellations after the establishment of a preoperative assessment clinic (P = 0.013).[12] Patients unwillingness for surgery accounted for 53% with regard to patient related factors for cancellation of surgery. Patients not willing for surgery at the last moment prior to surgery were due to fear, unfavorable conditions existing in the family or unawareness about the importance of surgeries. Female patients who were menstruating on the day of surgery were also considered in our study. Study by Fayed *et al* showed that 9% of patients decided not to undergo elective surgery on the day of surgery[4]. Being a teaching medical institution, few reasons for lack of operating time such as teaching and training the junior residents and interns could not be avoided. There was no issues with administrative or logistic causes such as power failure in operating room, failure of air conditioners, availability of oxygen source, usage of anaesthetic drugs, availability of blood and blood products, suture materials, linen, supply of water, bed availability and hospital workers strike in our audit. Cancellation by Insurance sanctioning availed by government scheme and private insurance peaked maximum cause due to delayed clearance or failure of obtaining the insurance. In general, surgeons took longer than estimated time to finish the procedure and was especially true for less-experienced surgeons and trainees. Surgeons are sometimes too optimistic and aware of the long waiting lists, but they want to operate as many patients as possible. This reason can be avoided by a better internal organization of work as well as planned use of staff breaks and the adequate preoperative preparation of the patients. Patient non compliance regarding medication regimens. Schofield *et al*[18] reported bed availability and theatre time management as a main reason for cancellation; which was not an issue in our audit. Pandit JJ, Carry A[14] estimated that over-booking of operation list is the common cause for postponement due to waiting list pressures. Windokun *et al*[20] reported surgeon's un-availability as main reason. Dufek *et al*[3] recommended the improvement in protocol for pre-op patients' evaluation to address these problems. Most of the reasons for cancellation were debatable as an issue of health care quality and was avoidable by judicious scheduling of lists and careful planning by the team involved in surgeries. We justified with improving following recommendations in our institution :

- Calm, smooth, pleasant and noiseless pre operating assessment room can avoid missing major clinical findings
- Closed loop communication and good rapport with the patient helps to instill confidence preventing the patient's bias regarding the anesthesia and surgery
- Follow appropriate pre operative instructions to improve the health care system avoiding major issues on the day of surgery
- Alleviation of the psychological distress of cancelling the surgery
- Early start of the first case in the operating room
- Surgical patients were adequately counseled, optimized their medical condition, appropriate continuation of medications and obtained informed consent regarding all relevant procedures
- Inter departmental coordination in managing complicated and high risk cases
- Increased utility of operating time in the theatre complex during the working hours

- Following the medical ethics and to practice in accordance with the law

LIMITATIONS

Our study was related to inherent bias in categorizing the cancellation of cases due to varied reasons on behalf of multi factorial components leading to cancellation. The study was confined only to our institution and may not be standardized since the hospital policies varies in other teaching institutions.

CONCLUSION

Although cancellations were only 532 (5.16%) out of 10,306 patients of total elective surgeries, this can even be reduced by implementing and following the recommendations as per guidelines proposed, so that the potential causes can be avoided. To improve the better quality of life we recommend that the cancellations of surgeries can be reduced by improving pre operative assessment, requesting patient information on inter current illnesses between preadmission and surgery, better inter departmental coordination and adequate optimization prior to surgery, improving man power availability, availability of adequate resource sources and increasing the operation theatre utilization time to avoid cancellation of surgery on the scheduled day. Frequent conduct of audits, rectifying the pitfalls in the institution will definitely improve the better healthcare facility in the teaching hospital.

SUMMARY

A 60-year-old man presented with severe abdominal pain, two episodes of massive haematemesis and chest discomfort. CT angiography showed a saccular aneurysm of the juxtaphrenic aorta with possible oesophageal erosion. Upper GI endoscopy revealed external compression of the lower oesophagus—near total luminal obstruction with impending rupture of the aortic aneurysm. Emergency aneurysmal repair by interposition grafting using 20 mm Dacron graft with oesophageal–gastric reconstruction done. Postoperative period was uneventful

BACKGROUND

This report describes the management of a life-threatening rare vascular emergency of aneurysm of the juxtaphrenic aorta with oesophageal erosion leading to formation of aorto-oesophageal fistula complicated with acute dissection. The presentation was inevitable for cardiovascular collapse in the absence of timely surgical intervention. The aneurysm being located in the descending thoracic aorta, the repair requires a left atrium-to-femoral bypass to maintain perfusion to the abdominal viscera and lower extremities. During the repair, the brain and the spinal cord is protected by cerebrospinal fluid drainage.

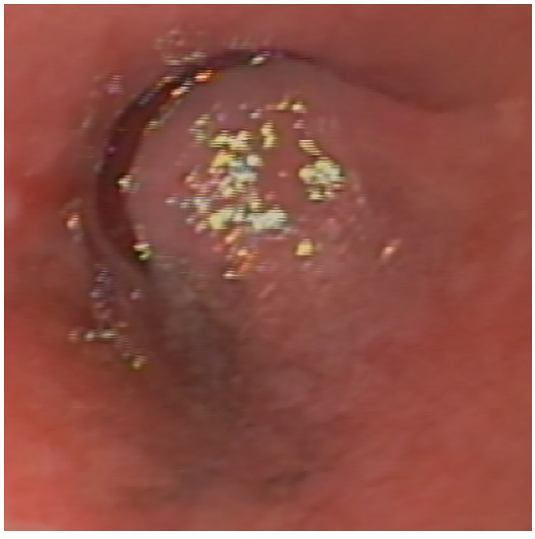

Figure 1 Upper gastrointestinal endoscopy—lower oesophageal external compression—near total luminal obstruction with impending rupture/ leaking nature of aortic aneurysm with mucosal ulceration of oesophagus covered with blood clot, eroding the distal oesophagus just above the oesophageal hiatus of the diaphragm.

Figure 2 CT angiogram.

CASE PRESENTATION

A moderately built 60-year-old man, habitual smoker for 40 years with recently diagnosed hypertension not on medications was admitted with severe abdominal pain, two episodes of massive haematemesis and chest discomfort for the last 2 days. The abdominal pain was sudden in onset, gradual in progression, localised to the epigastric region.

On examination, he was conscious, oriented, afebrile, pallor present with pulse rate of 86/min, blood pressure 100/80 mm Hg and respiratory rate of 30/min. On cardiovascular system examination, S1, S2 heard in the mitral, tricuspid, aortic and pulmonary area with no murmur. Respiratory system examination, normal vesicular breath sounds heard with equal bilateral air entry, no added sounds. On abdomen examination, soft, non-tender with no organomegaly. On central nervous system examination, clinically normal with no focal neurological deficits.

INVESTIGATIONS

Routine investigations revealed haemoglobin of 90 g/L, blood group O negative, bleeding parameters

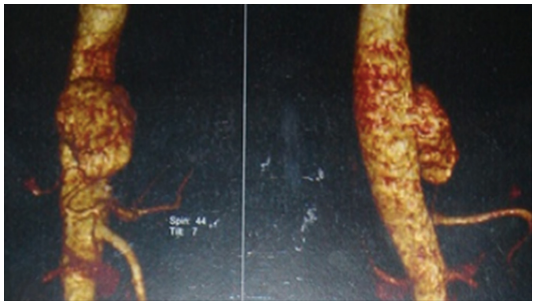

Figure 3 CT angiogram: large saccular aneurysm of juxtaphrenic aorta with large intramural thrombus and sign of impending rupture.

were normal, renal and liver function test was normal, serology for HIV and hepatitis B was negative

Lower oesophageal external compression—near total luminal obstruction with impending rupture/leaking nature of aortic aneurysm with mucosal ulceration of oesophagus covered with blood clot (figure 1).

Large saccular aneurysm of juxtaphrenic aorta with oesophageal erosion (Figures 2 and 3).[1]

TREATMENT

Management strategies

The patient was taken up for emergency aneurysm repair with interposition grafting and oesophago–gastric anastomosis. By thoracolaparotomy—left atrium femoral bypass was done, following which oesophageal repair by excision of the perforated segment with gastric anastomosis was done. After intubation, while positioning, the patient developed massive amount of bleeding evidenced through mouth with cardiovascular collapse as a result of aneurysm rupture into the oesophagus.

Emergency aneurysmal crash care

Step 1

- Emergency thoracotomy performed.
- In view of massive ongoing bleeding, manual compression was given to the descending thoracic aorta proximal to the aneurysm.
- Fluids and blood transfusion given for resuscitation.
- Extension of thoracotomy to thoracolaparotomy.

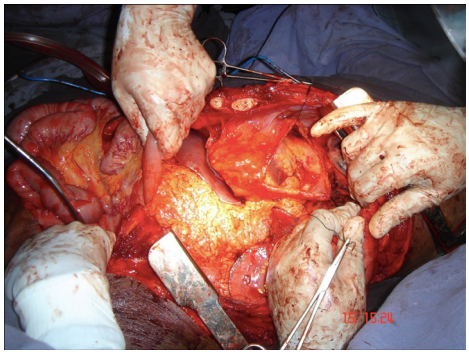

Figure 5 Oesophagectomy and stomach pull through with oesophago gastric anastomosis.

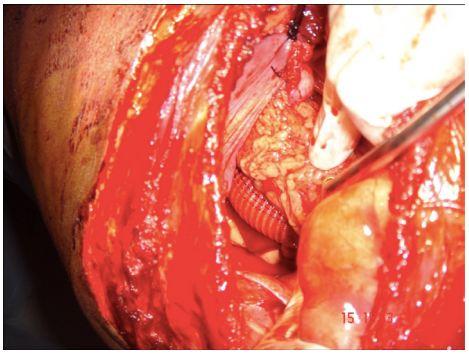

Figure 6 Lie of the Dacron graft and the oesophago gastric anastomosis covered by pedicled omentum.

- Loop control of supradiaphragmatic thoracic aorta and cross clamping above the aneurysm.
- Loop control of suprarenal abdominal aorta below the aneurysm and cross clamping.

Step 2

Left atrium femoral bypass done.

Step 3

Aneurysm repair—the aneurysmal segment reconstructed with 20 mm interposition Dacron graft (figure 4).

Step 4

Off left atrium femoral bypass.

Step 5

Oesophagus continuity established by gastro-oesophageal anastomosis after excising the distal perforated segment of the oesophagus, oesophageal gastric anastomosis wrapped with pedicled omentum (figures 5 and 6).

Step 6

Thoracolaparotomy closed with apical and basal pleural drain.

OUTCOME AND FOLLOW-UP

- The postoperative period was uneventful.

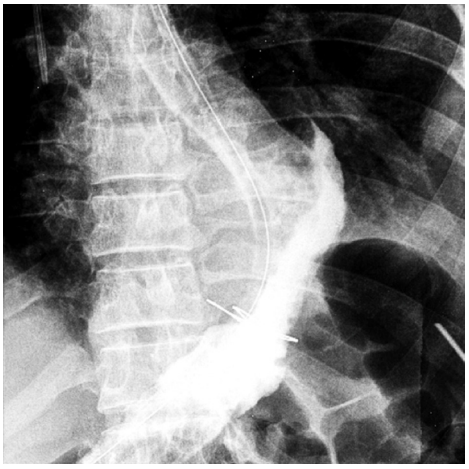

Figure 7 Immediate postoperative period—barium swallow using gastrografin dye performed—oesophagogastric anastomosis integrity is good, no leaks.

BMJ Case Rep: first published as 10.1136/bcr-2021-245396 on 29 November 2021. Downloaded from http://casereports.bmj.com/ on November 29, 2021 by R Anand. Protected by copyright.

- Postoperatively routine complete blood count, liver function test and renal function test was done and was normal.
- Chest X-ray was taken—lung expansion is good, no pleural effusion.
- Barium swallow using gastrografin dye performed—oesophagogastric anastomosis integrity is good, no leaks (figure 7).
- The patient was followed continuously for 15 days with daily haemoglobin monitoring, the haemoglobin value before discharge was 114 g/L.
- The patient was subsequently followed for 6 years, Echocardiogram (ECHO), gastrografin study, routine lab investigations like complete blood count was done.

DISCUSSION

Aorto-oesophageal fistula is a potentially a fatal condition, characterised classically by Chiari triad,[2] that is, midthoracic pain, sentinel arterial haemorrhage and exsanguination after a symptom free period. The causes of this fistula could be a primary aortic aneurysm or secondary causes like foreign body ingestion, oesophageal malignancy or an endoaortic stent causing erosion of oesophagus leading to fistula formation.[1]

The fistula formed between the descending thoracic aorta and oesophagus causes high pressure blood jetting into the oesophagus,[3] causing massive haematemesis and the patient can exsanguinate before they reach the hospital for further care.

The diagnosis is based on specific investigations like CT angiogram and upper GI endoscopy.

The volume of blood that flows through thoracic aorta is at higher pressure, greater than any other vascular structure, any condition that disrupts the integrity of the thoracic aorta such as aneurysm can lead to catastrophic consequences, therefore, emergency surgical repair is required and protecting the brain and spinal cord during such repairs is critical.[4 5] Slash thoracotomy, aortic loop control, volume resuscitation and appropriate circulatory support saved this patient.

The patient was taken up for emergency aneurysm repair with interposition grafting. By thoracolaparotomy—left atrium femoral bypass was done, following which oesophageal repair by excision of the perforated segment with gastric anastomosis was done. The oesophago–gastric anastomosis was covered with pedicled omentum to safe guard the anastomotic line from the synthetic graft.

Patient's perspective

I take this opportunity to thank all the doctors to identify my disease and treat it promptly on time.

Learning points

- Emergency surgical repair with simultaneous resuscitation is mandatory.
- Adequate amount of blood products needs to be kept ready.
- Postoperative follow-up with gastrografin study is done to check for anastomotic leaks.

Abstract

Background: The gold standard and ideal position for laryngoscopy is sniffing position. Trauma life support guidelines recommend the use of Manual In Line Stabilization or a rigid collar to stabilize the spine in suspected cervical spine injury patients. The gold standard for intubation in patients with cervical spine injury is fibre-optic bronchoscopy. But its use is restricted by lack of expertise, availability and time requirement. C-MAC blade and McCoy blade have been independently compared with Macintosh laryngoscope in simulated difficult airway. Aim: In our study, we compare C-MAC D blade and McCoy blade laryngoscope in simulated cervical spine injury using Manual In Line Stabilisation (MILS). **Materials and methodology:** 100 patients of age group between 18 – 65 years belonging to ASA 1 & 2 posted for elective surgeries under general anesthesia with endotracheal intubation participated in this study. Patients were randomly allocated to one of the two groups by computer generated random table number. Group C - Endotracheal intubation done using C-MAC D blade video laryngoscope and Group M - Endotracheal intubation done using McCoy blade laryngoscope. Observation and results: Baseline characteristics were presented as mean ± S.D. Two-sided unpaired t-test and chi-square test was applied to analyze the data and p value less than 0.05 were considered as significant. **Conclusion:** C-MAC video laryngoscope requires less time for laryngoscopy, provides better visualisation of glottis, lower IDS score with similar duration of intubation and haemodynamic responses when compared to McCoy laryngoscope in patients with simulated cervical spine injury.

Key Word: C-MAC blade, McCoy blade, laryngoscopy, simulated cervical spine injury, manual in line stabilization

INTRODUCTION

The gold standard and ideal position for laryngoscopy is sniffing position. The sniffing position aligns the oral, pharyngeal and laryngeal axes and provides better glottic visualization.[2] The sniffing position produces flexion of the lower cervical spine, extension of the upper cervical spine and extension of the atlanto–occipital joint.[3] Trauma life support guidelines recommend the use of Manual In Line Stabilization (MILS) or a rigid collar to stabilize the spine in suspected cervical spine injury patients.[4] MILS prevents head extension and neck flexion which is necessary for optimal alignment of three airway axes.[5]

How to site this article: S Rohini, R Arun Kumar, G Dhanabagyam. Comparison of C-MAC blade and McCoy blade for laryngoscopy in adult patients undergoing tracheal intubation for elective surgeries with simulated cervical spine injury using manual in line stabilization. *MedPulse International Journal of Anesthesiology.* August 2019; 11(2): 129-135. http://medpulse.in/Anesthsiology/index.php

The presence of collar can worsen the laryngoscopic view and makes the intubation difficult with conventional laryngoscope.[4] To overcome this various devices and options like direct laryngoscope with the aid of gum elastic bougie, fibre-optic bronchoscopy, airway scope, McCoy laryngoscope, Intubating laryngeal mask airway, C-Trach and Bullard laryngoscope has been recommended by many authors.[6] The gold standard for intubation in patients with cervical spine injury is fibre-optic bronchoscopy. But its use is restricted by lack of expertise, availability and time requirement.[4] The McCoy levering laryngoscope is a modification of the standard Macintosh blade.[6] It has a hinged tip and the angle of the hinged portion can be altered by a lever attached to the handle.[7,8] Depression of the lever towards the handle elevates the tip.[8] The hinged tip aids in improving the Cormack and Lehane laryngoscopic view by 1 grade in comparison to Macintosh blade in patient with cervical spine injury. The blade is available in size 3 and 4.[4] The latest generation C-MAC video laryngoscope has several distinct improvements.[8] It has external light source and small digital camera at the distal third of the blade, which extends to a video display monitor.[9] It provides optimum view of the glottis by direct and indirect view.[9] C-MAC laryngoscope can accommodate Macintosh blade 2, 3 & 4. A special D blade with greater curvature is designed to facilitate intubation of the difficult airways.[8] Both the devices have been independently compared with Macintosh laryngoscope in simulated difficult airway. Only a few studies are available comparing C-MAC and McCoy laryngoscope.[4] This study was carried out to compare the efficacy of C-MAC D blade and McCoy blade laryngoscope in simulated cervical spine injury.

AIM

To compare C-MAC D blade and McCoy blade laryngoscope in simulated cervical spine injury using Manual In Line Stabilisation (MILS) with the following parameters.

Primary Aim:

- Duration of laryngoscopy
- Duration of intubation
- Total duration of intubation
- Ease of intubation - Intubation Difficulty Scale (IDS score)

Secondary Aim:

- Haemodynamic responses

MATERIALS AND METHODOLOGY

A study titled "Comparison of C-MAC D blade and McCoy blade for laryngoscopy in patients with simulated cervical spine injury" was done in PSG Institute of Medical Sciences & Research, Coimbatore. This study was done after obtaining ethical committee clearance and informed written consent from all the patients participated in this study. It was a prospective and randomised study. 100 patients of age group between 18 – 65 years belonging to ASA 1 & 2 posted for elective surgeries under general anesthesia with endotracheal intubation participated in this study.

Inclusion criteria

- Patient's acceptance
- Patients aged between 18 – 65 years
- ASA 1 and ASA 2 patients
- Patients undergoing elective surgery under GA with endotracheal intubation

Exclusion criteria

- Anticipated difficult airway
- Risk of aspiration
- Hypertensive patients
- Patients on β-blockers, Clonidine.
- Duration of intubation exceeding 120 sec
- Change in laryngoscopy during intubation
- Emergency surgeries

Routine pre-operative assessment was done and the patients were kept nil per oral from 10 pm the day prior to surgery. Informed written consent was obtained. All the patients were pre-medicated with tablet Ranitidine 150mg orally at night the day prior to surgery and at 6 am on the morning of surgery. Patients were randomly allocated to one of the two groups by computer generated random table number.

Group C: Endotracheal intubation done using C-MAC D blade video laryngoscope

Group M: Endotracheal intubation done using McCoy blade laryngoscope

Parameters recorded

Duration of laryngoscopy - defined as the time taken from insertion of the blade between the teeth until the anaesthetist obtained the best possible view of the vocal cords

Duration of intubation - defined as the time taken from when the anaesthetist indicate the best view at laryngoscopy until the tracheal tube was placed through the vocal cords, as evidenced by visual confirmation by the anaesthetist.

Total duration of intubation - It is the sum of the duration of laryngoscopy and the duration of intubation

Ease of intubation - Intubation Difficulty Scale (IDS score). It includes the following:

1. Number of intubation attempts
2. Number of operators
3. Number of alternative technique used
4. Glottis exposure – CL gradin
5. Lifting force required

6. Necessity for laryngeal pressure
7. Vocal cord mobility

Haemodynamic responses - Heart rate, systolic BP, diastolic BP, mean arterial BP after 1st min, 3rd min and 5th min of intubation. The intubation difficulty scale (IDS)[37] : In 1997 Frederic Adnet *et al* evaluated and proposed an Intubation Difficulty Scale (IDS) score characterising the complexity of endotracheal intubation in both the prehospital and operating room settings to assess the degree of difficulty. The Intubation Difficulty Scale (IDS) score is a function of seven parameters, resulting in a progressive, quantitative determination of intubation complexity and they are as follows:

Parameters	Definition		
N^1-The number of intubation attempts	An attempt is defined as one advancement of the tube in the direction of the glottis during direct laryngoscopy	N^1 = 0 if only one attempt	Every additional attempt adds one point
N^2-The number of supplementary operators	It represents the number of additional persons directly attempting intubation	N^2 = 0 if only one operator	Every additional operator adds one point
N^3-The number of alternative techniques used	Change in approach - oral intubation to blind nasotracheal intubation, change in material – blade, endotracheal tube, addition of stylette	Change in approach	Each alternative technique adds one point
N^4-Glottic exposure	defined by the Cormack grade minus one	GradeI (N^4 = 0) GradeII(N^4 = 1) GradeIII(N^4= 2) GradeIV(N^4=3)	Glottic exposure is evaluated during the first attempt by the first operator
N^5- Lifting force applied during laryngoscopy	If little effort is necessary If subjectively increased lifting force is necessary	N^5 = 0 N^5= 1	
N^6- Necessity for external laryngeal pressure for optimizedglottic exposure	If no external pressure is applied If external laryngeal pressure is necessary	N^6= 0 N^6= 1	
N^7- Position of vocal cords during intubation	if vocal cords are in abduction if the vocal cords are in adduction	N^7= 0 N^7= 1	

The degree of difficulty is described according to IDS score as follows

IDS Score	Degree of difficulty
0	Easy
1 – 5	Slightly difficult
>5	Moderate to major difficulty
Infinity	Impossible intubation

Patients were connected to ASA standard monitors – ECG, Non invasive blood pressure(NIBP) and pulse oximeter (SpO_2) and baseline readings recorded. Intravenous line started and patency of the vessel checked. Patients were pre oxygenated with 100% Oxygen for 3 minutes and Induced with Fentanyl 2mcg/kg, Lignocaine (preservative free) 20mg and Propofol 2mg/kg intravenously. After ensuring adequate mask ventilation, patients were paralysed with Inj. Succinylcholine 1.5mg/kg. Pre intubation heart rate, systolic BP, diastolic BP, mean arterial BP were recorded. After 1 minute MILS was achieved by an anaesthetist, standing to the side of the patient, using fingers and palms of both hands to stabilize the patient's occiput and mastoid process and gently counteract the forces created by the intubator. Laryngoscopy was done by another anaesthetist who is experienced with both the techniques. Laryngoscopy was done with C-MAC D blade laryngoscope in group C and McCoy blade laryngoscope in group M. After visualization of the cords, patients were intubated with appropriately sized endotracheal tube with stylet bent to hockey stick shape. During intubation the duration of laryngoscopy, the duration of intubation and the ease of intubation (IDS scoring) were recorded. After securing the endotracheal tube, the tube position was confirmed with stethoscope and $ETCO_2$ monitoring, anaesthesia was maintained with Oxygen & Nitrous oxide 40:60 with 6 litres fresh gas flow, Sevoflurane 2% and Inj.Vecuronium (loading dose 0.1mg/kg). Heart rate, systolic BP, diastolic BP, mean arterial BP were recorded after 1st min, 3rd min and 5th min of intubation.

Statistical analysis: Data were statistically analysed with the SPSS version 17.0 software. Baseline characteristics were presented as mean ± S.D. Two-sided unpaired t-test and chi-square test was applied to analyze the data and p value less than 0.05 were considered as significant. A repeated measure of ANOVA was applied for the two groups to know the with-in subject variability in Ease of intubation and $p < 0.05$ was considered to be significant.

DISCUSSION

Approximately 2-5% of trauma patients will have cervical spine injury. Patient with cervical spine injury may require airway management for airway protection, to prevent hypoxia and hypoventilation.[1] In our study, we have compared the efficacy of C-MAC D blade and McCoy blade laryngoscope in simulated cervical spine injury by comparing duration of laryngoscopy, duration of intubation, total duration of intubation, ease of intubation (IDS score) and haemodynamic response. In our study the demographic variables like age, gender and BMI were comparable between both the groups. The mean duration of laryngoscopy when compared between two groups, it was shorter in C-MAC group (12.5 seconds) than McCoy group (14.47 seconds) and it was statistically significant. The mean duration of intubation when compared between two groups, it was longer in C-MAC group (13.85 seconds) than McCoy group (12.07 seconds) and it was statistically significant. The mean total duration of intubation was comparable between C-MAC group (26 sec) and McCoy group (26.55 sec) and statistically not significant. Even though the time taken for laryngoscopy was shorter in C-MAC group, the time taken for successful intubation was prolonged. So the

mean total duration of intubation was comparable and statistically insignificant between the groups. Our results of duration of laryngoscopy, duration of intubation and total duration of intubation were similar with the study done by Jain *et al*.[4] comparing McCoy and C-MAC video laryngoscope in simulated cervical spine injury. The ease of intubation was observed in our study using IDS scoring. In our study 48 patients in C-MAC group and 44 patients in McCoy group were intubated in the first attempt and were comparable. This results were similar to study by Jain *et al*.[10,11] who compared the conventional C-MAC and the C-MAC D blade with direct laryngoscopes in simulated cervical spine injury (manikin study) and observed that out of 33 patients, 30 patients were intubated in first attempt using C-MAC D blade and 24 patients using McCoy and was not statistically significant. 50 patients in group C and 47 patients in group M required single operator and all the patients were intubated using single technique in our study. In C-MAC group 47 patients had CL grade 1 and 3 patients had CL grade 2. In McCoy group 34 patients had CL grade 1 and 16 patients had CL grade 2. Hence the glottis exposure was better with C-MAC group than McCoy group and it was statistically significant which was similar in studies by Jain *et al*.[4] and Sabry *et al*.[8] Jain *et al*.[4] compared McCoy laryngoscope and C-MAC video laryngoscope in simulated cervical spine injury and observed that out of 30 patients, 29 patients in C-MAC group and 16 patients in McCoy group had CL grade 1 and was statistically significant. Sabry*et al*.[8,12] compared C-MAC D blade and McCoy laryngoscopes during cervical immobilization and observed that out of 30 patients, 16 patients in C-MAC group and 4 patients in McCoy group had CL grade 1 and was statistically significant. The McCoy group (18 patients) needed more lifting force for visualisation of glottis than C-MAC group (5 patients) and it was statistically significant. 14 patients in C-MAC group needed external laryngeal pressure during intubation compared to 8 patients in McCoy group, but it was not statistically significant. The IDS score between both the groups was found to be statistically significant. The use of C-MAC resulted in more number of easy intubation when compared to McCoy[13]. This was similar to a study by Jain *et al*.[4] comparing C-MAC and McCoy laryngoscopes where C-MAC resulted in lower IDS than McCoy group. In our study the heart rate, systolic BP, diastolic BP and mean BP recorded at all times were comparable between C-MAC, McCoy group and was statistically insignificant. This was similar to study by Jain *et al*.

CONCLUSION

In our study though there was a statistical significance in duration of laryngoscopy and duration of intubation, the total duration of intubation was comparable and insignificant. Because with C-MAC the time taken for successful intubation was prolonged though the duration of laryngoscopy was shorter. The C-MAC group had better glottic visualisation, needed optimal lifting force and clinically insignificant external laryngeal pressure with lower IDS score when compared to McCoy group. To conclude C-MAC video laryngoscope requires less time for laryngoscopy, provides better visualisation of glottis, lower IDS score with similar duration of intubation and haemodynamic responses when compared to McCoy laryngoscope in patients with simulated cervical spine injury.

Abstract

Background:: Pain is defined according to the International Association for the study of pain, as"An unpleasant, sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage"**Aim:** The aim of the study is to compare the hyperbaric bupivacaine 0.5% and hyperbaric 0.5%+Fentanyl 20 micrograms in spinal anesthesia for elective lower abdominal and lower limb surgery. **Methods**: This prospective comparative study was conducted in patients of grade I and II physical status, undergoing elective surgeries of lower abdomen and lower extremities aged 18 to65 years. In Group A 30 patients received 2.5ml of hyperbaric bupivacaine 0.5% with 0.4ml of Normal saline and in Group B 30 patients received 2.5ml of hyperbaric bupivacaine 0.5% with 0.4ml of (20ug) of fentanyl citrate and normal saline was added to 5ml syringe containing 2.5ml of bupivacaine using a 1ml syringe for accuracy. **Results**: Out of 60 patients, 30 patients included in group A and 30 patients included in group B.In group A meantime for two-segment regression was 83.0 minutes and in group B was 114.5 minutes, time for full motor recovery in group A was 192.7minutes and in group B was 206.6 minutes, the meantime for complete sensory recovery in group A was 214 minutes and in group B it was 242 minutes, the time for the first request of analgesics postoperatively in group A 246.7 minutes and in group B it was 333minutes. The visual analogue score in group A at 3 hours, 6hours postoperatively and 24 hours was 0.6,4 and 4.0 and, in the group, B was 0.1, 1.7, 2.6. **Conclusion:** From this study, we concluded that the addition of 20ug of fentanyl to 0.5%hyperbaric bupivacaine in spinal anaesthesia, prolongs the duration of sensory and motor blockade, increase the duration and quality of postoperative analgesia 12 – 24 hours without causing any gross haemodynamic disturbances or adverse effects.

INTRODUCTION

Pain is defined according to the International Association for the study of pain, as "An unpleasant, sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage".[1] Spinal anaesthesia consists of the temporary interruption of nerve transmission within the subarachnoid space produced by injection of a local anaesthetic solution into cerebrospinal fluid**.** SA is a routinely used anaesthetic technique for operations involving the lower limbs, lower abdomen, pelvis and perineal surgeries.[2,3,4] An increasing proportion of the patients undergoing these surgical procedures are the elderly.[5] Age-related changes in physiology and pharmacology can affect every aspect of pre-operative care.[6] The use of spinal anaesthesia is increasing in popularity compared to general anaesthesia.[2,3,7] Used widely, safely and successfully for

How to site this article: MS Prasanthkumar, S Shaik Mushahida. Comparison of Intrathecal bupivacaine with fentanyl to intra thecal bupivacaine for elective lower abdominal and lower Limb surgeries. *MedPulse International Journal of Anesthesiology.* April 2020; 14(1): 09-13.http://medpulse.in/Anesthsiology/index.php

almost 100 years spinal anaesthesia has many potential advantages over general anaesthesia, especially for operations involving the lower abdomen, the perineum and the lower extremities.[2,3,4] The role of an anaesthesiologist is to render pain free during surgical procedures. However, the patient's problem with pain does not end with surgical procedures. Pain during the postoperative period is a cause of concern not only for the patient but also for the surgeon and the anaesthesiologist. Postoperative pain control is generally best managed by an anesthesiologist because they offer regional techniques of anaesthesia as well as pharmacological expertise in analgesics. Spinal anesthesia is advantageous in that it uses a small dose of anaesthetic, is simple to perform and offers a rapid onset of action, gives reliable surgical and good muscle relaxation. These advantages are sometimes offset by a relatively short duration of action and complaining of postoperative pain when it wears off. Spinal anesthesia with hyperbaric bupivacaine 0.5% is a popular method, but there is a need for increasing the duration of analgesia without increasing the duration of motor blockade and thus prolong the duration of postoperative analgesia. The addition of fentanyl has been suggested as a method to accomplish these goals. This study is designed to quantitatively examine the effects of adding fentanyl to hyperbaric bupivacaine on the duration and recovery of sensory and motor block.

AIM

The aim of the study is to compare the hyperbaric bupivacaine 0.5% and hyperbaric 0.5%+ Fentanyl 20 micrograms in spinal anesthesia for elective lower abdominal and lower limb surgery.

MATERIALS AND METHODS

A prospective comparative study was conducted in the PSG hospitals, Coimbatore over a periodof 18monthstocompare the Hyperbaric bupivacaine 0.5% and hyperbaric 0.5%+ Fentanyl 20micrograms in spinal anesthesia for elective lower abdominal and lower limb surgery under different study parameters like onset and duration of analgesia, duration of sensory and motor blockade, quality of analgesia and side effects or complications. Inclusion criteria include ASA grade I and II physical status, undergoing elective surgeries of lower abdomen and lower extremities aged 18 to 65 years and exclusion criteria include the history of allergy or sensitivity to local anaesthetic or opioids, any contraindication to regional anaesthesia and ASA grading IIIand IV.A detailed pre-anesthetic examination including history, clinical examinations, the systemic examination of the cardiovascular, respiratory, central nervous system and examination of spine for deformity was performed. Routine investigations like haemogram, bleeding time, clotting time, blood sugar, blood urea, serum creatinine, ECG, Chest X-Ray were done wherever necessary. Patients' weight and height were also recorded prior to surgery. Premedication was standardized with Tab diazepam 0.2mg/kg preoperative on the night before surgery. All patients were instructed about the visual analogue scale(VAS).Patients were allocated into two groups viz., groups A, group B. In Group A 30 patients received2.5ml of hyperbaric bupivacaine 0.5% with 0.4ml of Normal saline and in Group B 30 patientsreceived 2.5ml of hyperbaric bupivacaine 0.5% with 0.4ml of (20ug) of fentanyl citrate andnormal saline was added to 5ml syringe containing 2.5ml of bupivacaine using a 1ml syringe foraccuracy.Before the start of the procedure, patients' pulse rate, blood pressure, respiratory rate, oxygensaturation was recorded. An intravenous line was secured using an 18G intravenous cannula.All patients were preloaded with 500mlof Ringer's lactate prior to spinal anaesthesia. Thepatients were kept nil per orally for 8 – 10 hours beforesurgery. The side effects of intrathecalfentanyl-like nausea, vomiting, pruritis, shivering respiratory depression (respiratory rate<10min), drowsiness, hypotension euphoria, chest tightness and urinary retention were noted.Hypotension was defined as a decrease in systolic blood pressure more than 20% of the baselinevalues and was treated with injection mephentermine 5mg intravenous increments andbradycardia (pulse rate <60/min) was treated by atropine 0.6mg intravenous stat.Under aseptic precautions lumbar puncture was performed in the left lateral position or sittingposition by midline approach by using disposable quincke spinal needle (23-26G) at L3-L4,intervertebral space. Patients were monitored continuously using sphygmomanometer, pulseoximeter and electrocardiogram, patients pulse rate, blood pressure, oxygen saturation wererecorded at 0,5,10,20,30,60,120 and 180 minutes. The sensory level was tested by pinprick using a hypodermic needle and the motor level was assessed by the Bromage scale. A pretested proforma will be used for collecting relevant data. Quantitative data will be analysed by students'"t" test and qualitative data will be analyzed by the chi-square test.

RESULTS

The mean age group A was 39.3 years and group B 42.6 years. The two groups did not differ significantly (P=0.28) with respect to their age. In Group A There were 10 male and 20 female patients. In Group B there were 12 male and 18 female patients. The height of patients in group A ranged from 4 feet (ft) 1 inch to 5 feet 9 inch with a mean height of 5.33 ft. In group B also theheight ranged from 4 feet 1 inch to 5 feet 9 inches but the mean height was 5.24ft. The height of patients in group A

ranged from 4 feet (ft) 1 inch to 5 feet 9 inch with a mean height of 5.33 ft. In group B also the height ranged from 4 feet 1 inch to 5 feet 9 inches but the meanheight was 5.24ft.

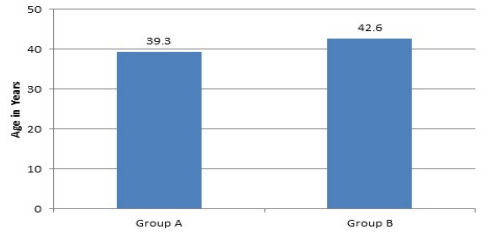

Figure 1: Age wise distribution

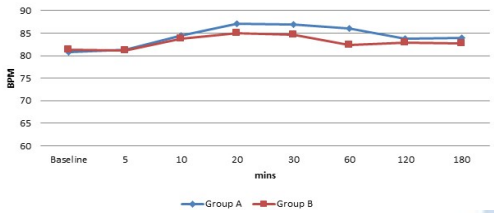

Figure 2: Distribution of Heart rate

In Group A the mean baseline heart rate was 80.8bts/min. In Group B the mean baseline heart rate was 81.33 beats/min.

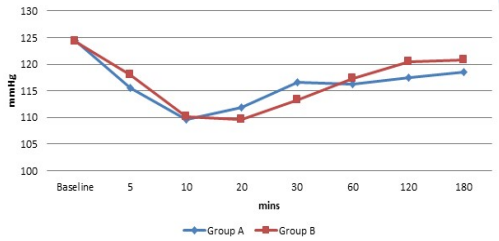

Figure 3: Distribution of Systolic BP

In Group A the mean systolic BP was 116.3mmHg. In Group B the mean systolic BP 116.75mmHg.

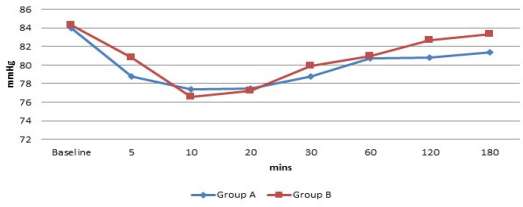

Figure 4: Distribution of Diastolic BP

The preoperative mean diastolic blood pressure in group A was 84.0mmhg, In Group B the preoperative mean diastolic blood pressure was 84.3mmhg. The mean time of onset of sensory blockade in Group A was 134.4 ±14.9 seconds and group B was 137.5 ± 13.5 seconds.

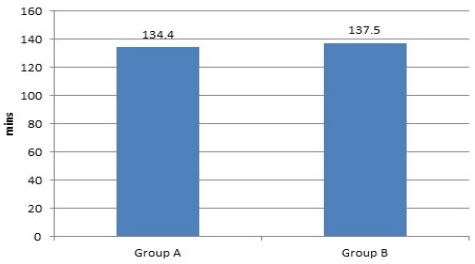

Figure 5: Onset of sensory blockade

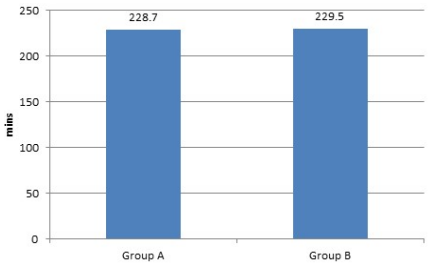

Figure 6: Onset of motor blockade

The mean time of onset of motor blockade group A was 228.7 ± 20.5 seconds and the meantime of the onset of the motor blockade in Group B was 229.5 seconds.In this study out of 60 patients the meantime for two-segment regression in groupA was 83.0 Minutes and in group B was 114.5 minutes.

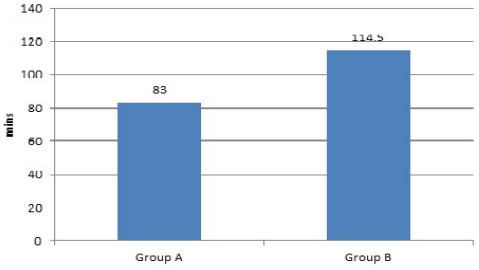

Figure 7: Time for two segment regression of sensory level

In this study out of 60 patients, the time for full motor recovery in group A was 192.7 minutesand in group B was 206.6 minutes.

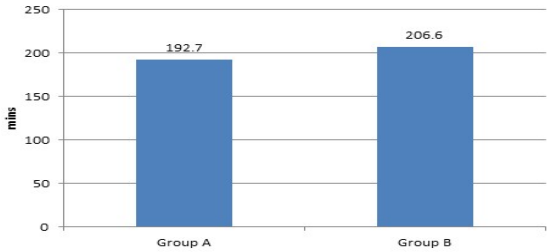

Figure 8: Time to full motor recovery

In this study out of 60 patients the meantime for complete sensory recovery in group A was 214minutes and in group B it was 242 minutes.

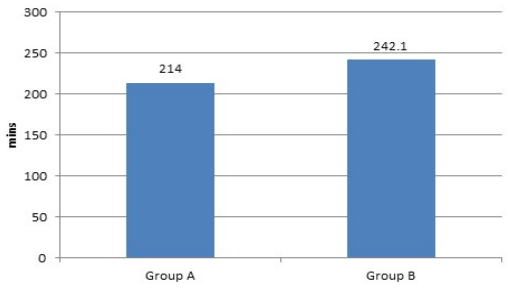

Figure 9: Time for complete sensory recovery

In this study out of 60 patients the time for the first request of analgesics postoperatively in group 246.7 minutes and in group B it was 333 minutes.

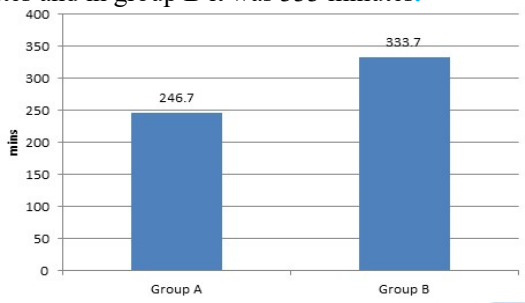

Figure 10: Time for the first request of analgesics

In this study out of 60 patients the visual analogue score at 3 hours was 0.6 in group A and 0.1 in Group B. At 6 hours postoperatively VAS was 4 in group A and 1.7 in group B. At24 hours VAS `was 4.0 in group A and 2.6 in Group B.

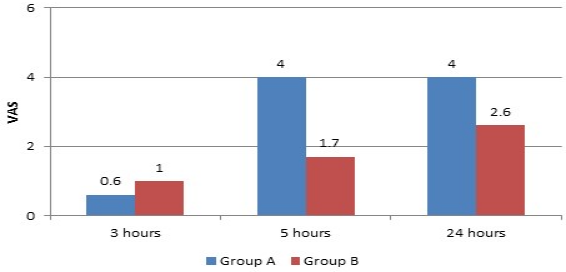

Figure 11: Visual analogue scores (vas) at different time

DISCUSSION

The subarachnoid block is one of the commonest local anaesthetic technique and would probablymaintain its place in the developing countries, because of simplicity minimal skill requirement,rapidity of onset, economy and minimum postoperative complications. It has the advantage thatit is easy to perform, requires a small dose of the drug, making systemic absorption unimportant. The disadvantage is the limited duration of action and lacks postoperative pain relief.The drugs used for the spinal subarachnoid block are lignocaine and bupivacaine. The disadvantage of spinal anaesthesia with local anaesthetic is that analgesia ends with regression of the block, which means there is an early postoperative need for analgesia.The use of neuraxial opioids has increased dramatically in recent years, augmenting the analgesiaproduced by local anaesthetic by binding directly to opiate receptors. The synergistic action of local anaesthetic and morphine is well known, but Fentanyl may have an advantage over morphine because of its rapid onset of action and superior intraoperative conditions.In the present study the patients studied in both the groups did not vary much with respect to age,sex, weight or height. Majority of the patients were middle-aged in both groups between 26-55years, with mean age of 39.3 years in group A and 42.4 years in group B. In both the groups'females were more, 66.66% of females were studied in group A and 60% of females in group B. The mean height and weight in either group were also identical. The type of surgeries performed was also identical in both groups. These parameters were kept identical in both groups to avoidthe intraoperative and postoperative outcomes of patients.In the present study all the patients weremonitored clinically in the intraoperative period. Pulserate, systolic blood pressure and diastolic blood pressure was monitored at regular intervals. Theincidence of hypotension was noticed in four patients of group A and in only two patients ofgroup B. Hypotension was corrected by administration of injection mephentermine 5 mg IV inincremental doses, giving IV fluids and foot end elevation. Systolic diastolic blood pressure inboth groups did not vary significantly in other patients. The incidence of bradycardia wasnot seen in any of the patients of either group and there was no significant difference in theonset of sensory and motor blockade and respiratory rate.In our study we found that time for two-segment regression was significantly prolonged inFentanyl group. Liu S *et al.*[8] in 1995, Harbhej Singh *et al.*[9] in 1998, Techanivate A *et al.*[10]in2004 found that two-segment regression was significantly prolonged in patients who receivedintrathecal Fentanyl with bupivacaine and was similar to our studies. Hunt CO *et al.*[11] in1989 conducted a study in 50 patients who received either 0, 2.5, 5,6.25, 25, 27.5 or 50ug offentanyl along with bupivacaine. He noticed that at 60 minutes the number of segmentsregressed was prolonged in 50ug fentanyl groups. But by 120 minutes there were no differences= between groups in the number of segments regressed. In the study, the duration of motor and the sensory block was significantly prolonged in the fentanyl group. Techanivate A *et al.*[10] in 2004 concluded that fentanyl increases the duration andthe intensity of bupivacaine in spinal anaesthesia, whereas Liu S*et al.*[8]in 1995, Harbhej Singh etal[9] in 1998found that addition fentanyl to 0.5% bupivacaine does not prolong the duration ofmotor

blockade but it only increases the time of sensory blockade without prolonging recovery tomicturition or street fitness. In a study conducted by Kuusniemi KS *et al*[12] in 2000 he foundthere was no difference in the duration of motor block among patients who received bupivacaine10mgonly and bupivacaine 7.5ug and fentanyl 25ug, but the duration were prolonged in thethe group which received 10mg bupivacaine and 25ug fentanyl. The duration was shortestamong the group which received 5mg bupivacaine + 25ug fentanyl. Similarly, the duration ofsensory block was maximum in the group which received 10mg bupivacaine and fentanyl 25ugand least in the group which received 5mg bupivacaine 25ug of fentanyl.In our study the meantime for the first request of analgesics in group A was 246 minutes and group B was 333 minutes. This was statistically highly significant. Hunt CO *et al.*[13] in 1987 found in their studies that fentanyl increases the duration of analgesia. Harbhej Singh *et al.*[9] in 1998concluded that intrathecal fentanyl 25 micrograms with 0.5% bupivacaine reduced analgesicthe requirement in the early postoperative period.The visual analogue pain score (VAS) at 3 hours was 0.6 ± 0.8 in group A and 0.1 ± 0.3 ingroup B. At 6 hours it was 4 ± 0.9 in group A and 1.7 ± 0.9 in group B. At 24 hours it was 4.0± 1.3 and 2.6 ± 1.3 in groups A and B respectively. The VAS was lower in group B at all timeintervals, which indicates that the quality of analgesia was better in group B patients even upon24 hours postoperatively. Hunt Co *et al.*[13] in 1987, Techanivate A *et al.*[10] in 2004 found that the use of intrathecal Fentanyl significantly reduces pain scores in the early postoperative period extending upon 12 hours.Hunt CO *et al.*[11] in 1989 found that fentanyl added to bupivacaine increased the quality of perioperative analgesia.

CONCLUSION

The addition of 20ug of fentanyl to 0.5% hyperbaric bupivacaine in spinal anaesthesia, prolongsthe duration of sensory and motor blockade, increase the duration and quality of postoperativeanalgesia 12 – 24 hours without causing any gross haemodynamic disturbances or adverseeffects. Based on the above facts we conclude the addition of fentanyl has many advantages and can be recommended with all spinal anaesthesia techniques.

Abstract

Background: Intravenous regional anaesthesia (IVRA) using Lignocaine is a safe, reliable, and cost-effective technique for providing anaesthesia as well as a bloodless field during upper limb surgery. It has been postulated that the site of action in IVRA is probably by blockade of small nerves or possibly nerve endings and not the major nerve trunks. **Aim:** In this study we evaluated the effects of Paracetamol on the onset of sensory and motor block time, sensory and motor recovery time and the requirement of postoperative analgesia. **Methods:** Sixty patients undergoing upper limb extremity surgeries were randomized into two groups .IVRA was achieved by injecting 10 ml of 2% Lignocaine with 30 ml of Paracetamol to a total of 40 ml in Group 1(n=30) and 10 ml of 2% Lignocaine with 30 ml of Normal saline to a total of 40 ml in Group 2(n=30). **Results:** Onset of sensory and motor block was shorter and sensory recovery time was longer in Group 1 ($p < 0.001$). Intraoperative VAS scores were significantly lower in Group 1 ($p< 0.05$). Intraoperative Fentanyl consumption was 8.33 ± 21.82 mcg in Group 1 and 38 ± 37.82 mcg in Group 2, the number of patients requiring Fentanyl was 4 and 17 respectively ($p< 0.001$). The postoperative analgesic requirement was lower in Group 1 with 9 patients and was 25 patients in Group 2 ($p< 0.001$). **Conclusion:** The administration of Paracetamol as an adjunct to Lignocaine in IVRA was found to be efficacious and it provided significant shortening in the onset of sensory block, a decrease in the intraoperative analgesic requirement and an improvement in the postoperative analgesia with a reduced need for analgesics in the postoperative period.

Key Words: Intravenous regional anesthesia, Lignocaine, Paracetamol, Postoperative Pain

INTRODUCTION

Intra Venous Regional Anaesthesia (IVRA) is a regional anaesthetic technique commonly used in forearm surgeries. It was first introduced by a German surgeon August Gustav Bier in 1908 by injecting Procaine intravenously between twotourniquets[1]. He found that there was a rapid onset of anaesthesia between the tourniquets and a slower onset beyond the distal tourniquet. This technique gained more importance in the late 1960s after its reintroduction by Holmes[2]. There have been many modifications to this technique over time, presently the use of double tourniquet with an injection of drugs distal to the cuffs. Its use has been proved to have an advantage of the faster recovery,

How to site this article: S Sulekha, M S Prasanth Kumar. Efficacy of paracetamol when added as an adjunct to lignocaine in intravenous regional anaesthesia- A prospective randomised double blinded study. *MedPulse International Journal of Anesthesiology.* October 2019; 12(1): 43-47. http://medpulse.in/Anesthsiology/index.php

shorter hospital stays, cost-effectiveness and reduced nursing care requirements making it an ideal choice for Daycare surgeries[3].When IVRA is appropriately performed there is a 96 - 100% success rate[4-6].This technique has the advantage of the rapid return of sensory and motor power at the end of surgical procedure allowing normal functioning of the operated limb and the surgeons are able to assess neurological status after surgery. This rapid recovery facilitates early discharge of patients. IVRA is advantageous being reliable, easy to administer and cost-effective for short operative procedures of the extremities performed on an ambulatory basis3.There are some disadvantages like the delayed onset of action, poor muscle relaxation and rapid onset of pain at the operative site after the tourniquet is deflated[7]. Various additives like Opioids, Muscle relaxants, NSAIDs such as Ketorolac.[8] Tenoxicam[9] and Aspirin[10] have been used to overcome these disadvantages to improve analgesia. There is a risk of local anaesthetic toxicity due to the sudden release of large amounts of local anaesthetic as a result of leakage due to high venous pressure or accidental tourniquet failure past the inflated tourniquet. Due to the above-mentioned effects it is desirable to limit the amount of local anaesthetic to a minimum[11].In previous studies, IVRA with Paracetamol was shown to improve the overall quality of the block, early onset of motor block, reduced tourniquet pain, delayed recovery of motor and sensory block, low intraoperative pain scores and decreased analgesic requirements both during the intraoperative and postoperative period. The ideal IVRA solution should have a rapid onset of action, require less amount of local anaesthetic, reduce tourniquet pain and prolong post-deflation analgesia. This may be achieved by the addition of adjuncts to the localanaesthetic. Paracetamol added as an adjunct to Lignocaine has been shown to provide decreased tourniquet pain, increased anaesthesia quality and decreased postoperative analgesic consumption.

AIM

To determine the efficacy of Paracetamol when added as an adjuvant to Lignocaine for IVRA.

MATERIALS AND METHODS

This randomized double-blinded study was conducted in the Department of Anaesthesiology, PSG Institute of Medical Sciences, Coimbatore in ASA I and II patients posted for upper limb surgeries from August 2013 – March 2015.The study group patients were assigned into two groups as Group 1 and Group2, comprising of 30 patients each. IVRA was performed using 10 ml of 2%Lignocaine with 30 ml of Paracetamol in Group 1 patients and 10 ml of 2%Lignocaine with 30 ml of Normal saline in Group 2.

Inclusion Criteria:

ASA I and II patients, aged between 20-60 yrs, Upper limb extremity surgeries of duration not exceeding 60 minutes. Exclusion Criteria: a history of allergy to local anaesthetics, expected duration of surgery more than 60 minutes, Raynaud's disease, Sickle cell anaemia, Coagulation disorders. Simple randomization was done and assigned into two groups (with 30 patients in each group as Group -1 and Group - 2). According to ASA starvation guidelines patients were kept nil per oral status overnight and pre-medicated with Tablet Ranitidine 150 mg and Tablet Diazepam 5 mg the night prior to surgery and on the morning of surgery. Anaesthesia machine safety checklist including resuscitation equipment, emergency drugs and tourniquet equipment were kept ready before the patient arrived in the operating room (OR). Starvation status and surgical consent confirmed in the preoperative room before the patient was shifted inside the operating room. Preinduction monitors like ECG leads, Noninvasive blood pressure (NIBP)cuff and pulseoximeter were connected and baseline readings noted. All the patients were explained about the Visual Analogue Scale (VAS) prior to the start of the procedure. Vital signs like MAP, HR, and SpO2 were recorded before and after application of a tourniquet and monitored continuously during the procedure at 5, 10, 15, 20, 30,40, 50 minutes interval till the release of a tourniquet. The pain was assessed using a 10cm visual analogue scale. If the patient reported a VAS > 4, rescue analgesic of 1 mcg/kg Fentanyl was intravenously given and the requirement for analgesics was recorded.

RESULTS

In this study, 60 patients were selected after considering the inclusion and exclusion criteria. Consent was obtained from all the 60 patients and was divided into2 groups with 30 patients in each group. Group 1 received 30 ml of Paracetamol and 10 ml of 2% Lignocaine (preservative-free (PF)). Group 2 received 30 ml of Normal Saline and 10 ml of 2% Lignocaine (preservative-free (PF)). In our study, after reviewing the literature we selected the study group in the age between 20 – 60 years. The mean age distribution in our study was 42.87±11.57 in Group 1 and 39.37±13.04 in Group 2. Out of 60 patients in our study, the sex distribution was 18:12 (Male: Female)in Group 1 and 16:14 (Male: Female) in Group 2.In our study, we used a double pneumatic tourniquet placing the first tourniquet on the proximal portion of the extremity to be operated and the second tourniquet distal to the proximal one. Group 1 patients in our study had very negligible intraoperative pain / discomfort during the procedure, but

Group 2 patients reported with pain intraoperatively, presumably tourniquet pain. In our study, the meantime of onset of sensory block was 5.60± 1.58 minutes in Group 1 and 7.13± 1.59 minutes in Group 2 patients. The p-value<0.001 shows there is a statistically highly significant difference between the two groups in terms of the time of onset of sensory block. In our study amongst patients in Group 1, the average onset of motor block time was 8.70± 2.52 minutes and in Group 2 it was 12.27± 2.79 minutes. The p-value<0.001 shows that there is a statistically significant difference among the two groups in terms of the time of onset of motor block. In our study, the sensory recovery time was 7.60± 1.102 minutes in Group 1and 5.60± 1.610 minutes in Group 2. The p-value<0.001 showed that there is a statistically highly significant difference with regard to the onset of the sensory recovery time between the two groups. In our study, the motor recovery time was 8.90± 2.13 minutes in Group 1 and10.37 ± 2.498 minutes in Group 2. The p-value 0.018 showed that there is a statistically significant difference between the two groups in terms of motor recovery time. In our study, 4 patients out of 30 required Fentanyl consumption intraoperatively in Group 1 and 17 patients out of 30 in Group 2 and proved to be statistically significant. In our study, the mean Fentanyl consumed was 8.33±21.82 micrograms in Group 1 and 38±37.820 micrograms in Group 2, p-value<0.001 showed that there is a statistically significant difference between the two groups in terms of Fentanyl consumption as rescue analgesic intraoperatively. The mean VAS pain score intraoperatively was 2.17±1.62 in Group 1 and3.80±2.36 in Group 2. The p-value 0.003 showed that there is a statistically significant difference in the intraoperative VAS score between the two groups. Out of 30 patients in each group in our study, 9 patients required analgesia following tourniquet deflation in Group 1 and 5 patients in Group 2; which was statistically significant between the two groups with p-value< 0.05.Out of 30 patients in each group in our study, surgeon satisfaction grade was excellent in 14 patients in Group 1 and 6 patients in Group 2. The grade was good in16 patients of Group 1 and 24 patients of Group 2. There was a statistically significant difference between the two groups as the p-value is 0.028 (which is < 0.05) with regard to surgeon satisfaction in our study. Out of 60 patients in our study, 7 patients from Group 1 and 2 patients from Group 2 gave excellent grading (Grade 1), 18 patients from Group 1 and 14 patients from Group 2 gave good grading (Grade 2) and 5 patients from Group 1 and 14patients from Group 2 gave moderate grade (Grade 3).There was a statistically significant difference between the two groups as p is0.023 (<0.05) with regard to patient satisfaction in our study.

DISCUSSION

In our study, we investigated whether the addition of Paracetamol to IVRA solution decreased tourniquet pain, intraoperative use (Fentanyl) and enhanced the sensory and motor block duration by increasing the quality of IVRA. However, in our study we also demonstrated a decrease in postoperative pain score and analgesic requirement. Elhakim M and Sadek RA[12] carried out IVRA on patients between 25 – 55years. Palecha S *et al*[13] used IVRA on patients above 20 years of age. Sanjay Kherde *et al*[14] used the age group of 15 – 55 years in his study. Tourniquets are used in IVRA to restrict the drugs from entering beyond the cuff into the systemic circulation causing untoward consequences. It is also used to provide analgesia and motor blockade distal to the tourniquet. Chandrashekara PM *et al*[15] used single rubber latex bandage as a tourniquet above the site of surgery. He noted the tourniquet pain and discomfort in surgeries that prolonged for more than 40-50 minutes. Holmes C *et al*[1], Sorbie C and Chancha P[16] and Janardhan *et al*[17] used double tourniquet with the second tourniquet placed on the anaesthetized portion of the extremity distal to the proximal one to prevent tourniquet pain and discomfort. Intravenous regional anaesthesia technique is successful when there are proper tourniquet placement and adequate exsanguination1.Holmes C *et al*[1] and Chandrashekara PM *et al*[15] achieved exsanguination either by simple gravity draining method or by using Esmarch bandage and combined both in some cases. Blond L *et al*[18] showed there was a 69% reduction in blood volume in the limb after exsanguinations using Esmarch bandage. The observation of the present study is in accordance with regards to the meantime of onset of the sensory block by Myoung Jin Ko and Jeong Han Lee *et al*[19]. He reported a similar statistically significant difference in his IVRA study, in patients who received 40 ml of 0.5% Lignocaine in one group and 0.5% Lignocaine diluted with intravenous Acetaminophen 300 mg to a total volume of 40ml. The observation of the present study is in accordance with the observations of Sen H, Kulahci Y *et al*[20] who stated the similar statistically significant difference in theirs tudy population with the meantime motor block onset, mean time of sensory block recovery time, mean time of motor block recovery time. This observation was in accordance with observation obtained in Sen H *et al*[20]where intraoperative VAS scores were seen at 20 and 30 minutes were significantly lower in Group 2 which was 10 ml 3mg/kg Lignocaine with 300mg Paracetamol similar to the present study. Post deflation analgesic requirement in a study done by Sen H *et al*[20] and Myoung Jin Ko *et al*[19] where they showed a statistically significant difference between the two groups with a p value <0.005 using Diclofenac and Tramadol respectively.

CONCLUSION

To conclude from our study, that the administration of Paracetamol as an adjunct to Lignocaine in IVRA, was found to be efficacious and it provided significant shortening in the onset of sensory block, a decrease in the intraoperative analgesic requirement and an improvement in the postoperative analgesia with a reduced needf or analgesics in the postoperative period.

Abstract

Laryngoscopy and endotracheal intubation is accompanied by sympathomimetic stimulation resulting in increase in Heart Rate and Arterial blood pressure. These hemodynamic adverse effects are minimized by multiple non pharmacological methods and pharmacological agents including alpha 2 agonists such as Dexmedetomidine. Dexmedetomidine has a shorter duration of action and effectively attenuates the hemodynamic response of laryngoscopy and endotracheal intubation during the peri operative period. The aim of our study is to compare two doses (0.6mcg/kg and 1mcg/kg) of the drug in effective attenuation of the sympathetic stimulation. **M**ethod 80 patients assessed under ASA 1 – 2 between the age group 18-60 years of both genders were included in this study and randomly divided into two groups namely GROUP A – 0.6mcg/kg Dexmedetomidine and GROUP B – 1mcg/kg of the same drug 10mins before induction. Heart rate, Systolic Blood pressure, Diastolic blood pressure, Mean arterial pressure and SpO_2 were recorded at various intervals. Result In both groups, HR, SBP, DBP and MAP reduced significantly. During intubation, 1 and 3 minutes following intubation there was minimal rise in blood pressure in Group A while in Group B the decrease in pressure was marked and continuous. Conclusion Both doses of Dexmedetomidine (0.6mcg/kg and 1mcg/kg) attenuated the stress response of laryngoscopy and intubation effectively. The reduction in heart rate, Systolic blood pressure, Diastolic blood pressure and Mean arterial pressure was more in 1mcg/kg group. Hence Dexmedetomidine at a dose of 0.6mcg/kg itself is adequate to control the stress response of laryngoscopy and intubation.

Key words: Attenuation; Laryngoscopy; Intubation; Dexmedetomidine.

Introduction

Laryngoscopy and endotracheal intubation is accompanied by intense sympathomimetic stimulation resulting in increase in Heart Rate (HR) and arterial Blood Pressure (BP). This response is very hazardous in patients with reduced myocardial reserve / hypertension / cerebro-vascular insufficiency / raised intracranial or intraocular pressure and may predispose to pulmonary edema / myocardial infarction / cerebro-vascular accident[1,2,3]/ dysrhythmias. To minimize these hemodynamic adverse effects, multiple non pharmacological methods (minimizing mechanical stimuli of laryngoscopy by blind nasal intubation, reducing time of laryngoscopy to < 15 seconds[6]) and various pharmacological agents have been tried which act at different levels of reflex arc[4]. Dexmedetomidine is a lipophilic α methylol derivative which has sedative, anxiolytic and analgesic effects[7]. It is a highly selectiv

Comparison of two doses of intravenous Dexmedetomidine 0.6mcg/kg and 1mcg/kg given prior to induction in attenuation of hemodynamic stress response of laryngoscopy and endotracheal intubation. *MedPulse International Journal of Anesthesiology.* October 2018; 8(1): 24-28.
http://medpulse.in/Anesthsiology/index.php

alpha 2 agonist (1620 times highly selective to α_2 receptor) and has a shorter duration of action. Dexmedetomidine administered at a dose of 1 mcg/kg IV over 10 minutes, 15 minutes prior to the procedure, effectively attenuates the hemodynamic response during the peri-operative period[8,9,10,11] but it is associated with side effects like bradycardia and hypotension. The aim of our study was to compare the efficacy of Dexmedetomidine in reducing the hemodynamic stress response in two different doses (0.6 mcg/Kg and 1 mcg/Kg body weight) which was given prior to laryngoscopy and endotracheal intubation.

Materials and Methods

After getting the institutional ethical committee clearance, the study was conducted in PSG institute of medical sciences and research, Coimbatore. Patients aged 18-60years belonging to both genders, assessed under ASA 1 – 2 with Mallampatti class I- II were included in the study. Patients with hypertension, bradycardia, cardiac disease, coronary artery disease, cerebro vascular disease, difficult airway, BMI > 30 Kg/ m^2, on β blocker therapy or known hypersensitivity to the study drug were excluded. 80 patients who fulfilled the inclusion criteria were included in the study and informed consent was obtained. They were premedicated with Tab. Alprazolam 0.5 mg and Tab. Ranitidine 150 mg on the night before surgery. Patients were randomly allocated to one of the following two groups by random table number generated by computer. The procedure was double blinded wherein the consultant anaesthesiologist prepared the infusion of the study drug in 100ml normal saline and handed over to the resident. Hence, the resident conducting the study and the patient both were blinded to the group of drug. The two study groups were labelled as follows -

Group A: 0.6 mcg/kg Dexmedetomidine

Group B: 1 mcg/kg Dexmedetomidine

After preoxygenation, Inj.Glycopyrrolate 0.2 mg i.v, Inj.Fentanyl 2 mcg /kg i.v was given and induced with Inj.Thiopentone sodium till the abolition of the eyelash reflex. After confirming the adequacy of mask ventilation, inj. Succinylcholine 1.5 mg/kg was given and intubated after a minute. Anesthesia was maintained with Oxygen, Nitrous oxide, Isoflurane 1% and inj. Vecuronium bromide. The duration for laryngoscopy and intubation was recorded. Heart rate, systolic BP, diastolic BP, mean arterial BP and SpO_2 were recorded before and after induction, at the time of intubation (0 minute), 1st min, 3rd min, 5th min and 10th min after intubation. Surgical stimulus was avoided for 10 minutes after intubation. Adverse effects were noted and treated accordingly as follows

- Hypotension – systolic blood pressure < 20% from baseline value, Inj Ephedrine 6mg iv bolus was given
- Bradycardia – heart rate < 50 beats per minute, Inj Atropine 0.6mg iv was given.

Statistical analysis was performed using the statistical software (SPSS) 19.0. Data was expressed as percentages and mean values (with standard deviations). Differences between groups were analyzed with the Independent Sample t-test for continuous variables and Pearson's Chi-square test for categorical variables. Paired sample t-test was used to compare the difference between pre and post values. Results were defined as statistically significant when the *P* value was less than 0.05.

Table 1: Age distribution between two groups

Age in years	Group A		Group B	
	No of patients	Percentage	No of patients	Percentage
< 20	1	2.5	2	5.0
20 – 29	17	42.5	10	25.0
30 – 39	12	30.0	16	40.0
40 – 49	7	17.5	9	22.5
> = 50	3	7.5	3	7.5
Total	40	100	40	100
Mean age in years ± SD	32.65 ± 8.891		34.70 ± 10.16	
p value	0.563			

Table 2: Sex distribution between two groups

SEX	Group A		Group B

Figure 1: Intergroup comparison for heart rate between Group A and Group B; **Figure 2:** Intergroup comparison for SBP between Group A and Group B; **Figure 3:** Intergroup comparison for DBP between Group A and Group B; **Figure 4:** Intergroup comparison for MAP between Group A and Group B; **Figure 5:** Intergroup comparison for SpO_2 between Group A and Group B

Figure 1, In group A, the basal mean heart rate was 81.58 ± 8.86 bpm. The mean heart rate after administration of the study drug at 5 th, 10 th, 15 th, 20 th min, before induction, after induction, at the time of intubation was 77.40 ± 11.06, 74.30 ± 11.31, 72.58 ± 10.69, 71.72 ± 10.41, 71.10 ± 9.76, 69.90 ± 11.65, 77.63 ± 10.89 respectively and showed a significant reduction from mean heart rate (p value <0.05). No change was noted in the 1st and 3rd minute following intubation. The reduction in heart rate started from the 5th minute following intubation onwards (p value < 0.05). In group B, the basal mean heart rate was 82.70 ± 4.48 bpm. The mean heart rate reduced after administration of the study drug at the 5th, 10th, 15th, 20 th min, before induction and after induction. Further fall in the heart rate was noted during intubation and 1st, 3rd, 5 th, 10 th min following intubation (p value <0.05), The baseline heart rate was comparable in both the groups as p value of 0.476. However 5th, 10th, 15th, 20th min, just before and post induction there was no statistical significance as the p value was > 0.05. There was a significant difference in the mean heart rate of the two groups at the time of intubation, 1st, 3rd, 5th, 10th min after intubation (p value < 0.05). Figure 2, In group A, the basal mean SBP was 126.70 ± 12.07 mmHg. The mean SBP after administration of the study drug at the 5 th, 10 th, 15 th, 20 th min, before induction and after induction were 121.20 ± 10.92, 116.05 ± 12.53, 114.13 ± 11.90, 112.20 ± 11.26, 113.83 ± 14.24 and 108.83 ± 14.75 mmHg respectively. There was a subsequent fall in mean SBP following intubation also. (p <0.05) In group B, the basal mean SBP was 127.58 ± 6.33 mmHg. Significant reduction in the mean SBP was seen constantly thereafter till the measurements were noted (p <0.05). The baseline mean SBP was comparable in both the groups (p value - 0.686). There was a significant reduction in the 5th and 10th min following administration of the study drug and at the 1st min after intubation (p value < 0.05). Figure 3, In group A, the basal mean DBP was 75.97 ± 5.96 mmHg. The mean DBP after the administration of study drug at 5th, 10th, 15th, 20th min, before induction and after induction was 72.58 ± 6.79, 70.20 ± 7.30, 67.68 ± 8.31, 66.95 ± 7.17, 68.00 ± 10.44, 64.80 ± 12.36 mmHg respectively. This showed highly significant reduction of mean DBP from baseline (p value 0.000). But at the time of intubation and 1st min after intubation the mean DBP showed no change. However, Statistical significance was noted during 3rd, 5th and 10th min after intubation with p value < 0.05. In group B, the basal mean DBP was 77.18 ± 5.28 mmHg. The mean DBP after the administration of the study drug was constantly less than the baseline (p value 0.000). There was a significant difference in the mean DBP between the two groups at the time of intubation, 1st and 3rd min after intubation (p value less than 0.05). Figure 4, In group A, the basal mean MAP was 92.48 ± 6.83 mmHg. The mean MAP after the administration of study drug at 5th, 10th, 15th, 20th min, before induction, after induction were 89.00 ± 7.68, 86.68 ± 8.81, 84.18 ± 9.47, 83.23 ± 7.73, 84.35 ± 10.25, 80.70 ± 12.94 mmHg respectively and showed a significant reduction of mean MAP (p value < 0.05). There was no statistical significance at the time of intubation and 1st min after intubation, but the mean MAP at the 3rd, 5th and 10th min after intubation were 80.53 ± 11.65, 76.90 ± 10.34, 76.35 ± 9.28 mmHg respectively, suggestive of a significant reduction from baseline (p value 0.000). In group B, the basal mean MAP was 93.78 ± 4.33 mmHg. There was a significant reduction of the mean MAP from the 10th minute onwards following administration of the drug from the baseline value (p value was 0.000). There was a significant difference in mean MAP at the time of intubation and 1st min after intubation in both the groups (p value of less than 0.05). Figure 5, In group A, the basal mean SpO_2 was 98.93 ± 0.69. The mean SpO_2 after the administration of study drug at 5th, 10th min were 98.63 ± 1.33, 98.50 ± 1.21 respectively and showed a significant reduction from baseline value (p value < 0.05). The mean SpO_2 after induction till 10th min was comparable to baseline value with (p value 0.000). In group B, the basal mean SpO_2 was 98.78 ± 1.00. The mean SpO_2 after the administration of study drug at 5th, 10th, 15th, 20th min from baseline and till 10th min post induction showed significant change from baseline value (p value < 0.05). There was no significant difference in mean SpO_2 between two groups (p value >0.05).

[illegible]

Multiple non pharmacological methods and pharmacological agents have been tried before intubation to attenuate the hemodynamic adverse effects of laryngoscopy and intubation that act at different levels of the reflex arc. The commonly used pharmacological agents are iv Fentanyl, Morphine, Lignocaine, Beta Blockers, Calcium channel blockers, Magnesium Sulphate, Alpha 2 Agonists such as Clonidine and Dexmedetomidine. Dexmeditomidine is a highly selective alpha 2 agonist (1620 times highly selective to α_2 receptor when compared to clonidine). In our study we compared the efficacy of Demeditomidine in attenuating the sympathetic stress response to laryngoscopy and intubation in two different doses (0.6 mcg/Kg and 1 mcg/Kg body weight) when given prior to intubation. After administering the study drug, both groups showed a statistically significant fall in heart rate from the baseline till induction. In Group A, the post intubation heart rate increased but not more than the baseline value. In group B, there was a minimal increase in the heart rate during intubation and one minute post intubation while it

Copyright © 2018, Medpulse Publishing Corporation, MedPulse International Journal of Anesthesiology, Volume 8, Issue 1 October 2018

decreased after that. To conclude the fall in heart rate was comparatively more in Group B than group A[12]. The fall in the systolic blood pressure from the baseline (126.70 ± 12.07 mm Hg) following administration of the drug upto 10 minutes post intubation in Group A was associated with a slight increase during intubation (118.03 ± 16.65 mm Hg)[13].While in group B, a significant decrease in the systolic blood pressure (111.58 ± 15.30 mm Hg) from the baseline (127.58 ± 6.33 mm Hg) was noted after administrating the study drug with no increase during intubation (111.13 ± 10.06 mm Hg)[11] {Menda *et al*}. Changes in Diastolic BP following administration of drug in Group A was similar to Systolic BP [14]. The range of increase was 8 mmHg from induction value but not more than baseline value with a significant difference in the diastolic blood pressure from baseline till 10 minutes post intubation. In group B the fall in Diastolic BP was constant[11], statistically significant and more when compared to Group A. A significant fall in the mean arterial pressure from the baseline till 10minutes post induction was recorded in Group A with a mild increase of 9mmHg above the induction value at the time of intubation and 1 minute post intubation. This finding was similar to the study done by Mowafi *et al*[15] who observed that there was an increase in MAP of 5 mmHg from post induction value but less than basal value. The decrease in MAP was continous in Group B[11]. here was significant fall in SpO_2 in both groups during the infusion of the study drug but post induction the SpO_2 increased significantly probably due to pre oxygenation. In both groups, there was a marked reduction in dose requirement of Thiopentone for induction (Group A- 160.00 ± 15.19, Group B- 166.75 ± 23.73) than the usual dose required to anaesthetise patients[16]. In our study, 3 patients in each group developed hypotension and 1 patient in group A developed bradycardia which required pharmacological management.

□□□□□□□□□□

Both doses of Dexmedetomidine (0.6mcg/kg and 1mcg/kg) attenuated the stress response of laryngoscopy and intubation effectively. The reduction in heart rate, systolic blood pressure, diastolic blood pressure and mean arterial pressure was more in 1mcg/kg group. Hence Dexmedetomidine at a dose of 0.6mcg/kg itself is adequate to control the stress response of laryngoscopy and intubation.□

Abstract Pain in the postoperative period is a major concern for anaesthesiologists, which is usually managed by administration of opioids or analgesics. Single shot nerve blocks with additives such as alpha 2 agonists, opioids and glucocorticoids provide adequate analgesia for a longer duration postoperatively when compared to intravenous opioids or analgesics thereby reducing polypharmacy. The addition of glucocorticoids such as Dexamethasone perinerually increases the duration of analgesia but there are concerns regarding potential neural toxicity. Hence, we compared the analgesic duration, onset of sensory block and motor block in patients receiving Dexamethasone 8 milligram perineurally vs intravenously in supraclavicular brachial plexus block to avoid the potential neural toxicity due to perineural injection of the same. **M** d 60 patients assessed under ASA 1 and 2 belonging to both genders aged between 20- 70years posted for upper limb surgeries under Supraclavicular brachial plexus block were randomly allocated into two groups: Group 1 – patients received 8mg Dexamethasone perinerually, Group 2 – patients received intravenous 8mg dexamethasone The onset of sensory blockade, onset of motor blockade, duration of analgesia, requirement of rescue analgesia postoperatively and severity of pain at the time of administration of analgesia was noted. The onset of sensory blockade, motor blockade, duration of analgesia in both the groups were comparable with no statistical significance. Both IV and perineural Dexamethasone similarly prolonged the duration of analgesia in Supraclavicular Brachial Plexus block. Due to the existence of some controversies over perineural use of Dexamethasone, IV Dexamethasone can be used as a safer alternative to prolong duration of analgesia in patients undergoing upper limb surgeries under Supraclavicular Brachial plexus block.

Introduction

Pain is the most common complaint of patients in the post-operative period and its management forms an important component of peri-operative care1.Supplementation of excessive opioids and other analgesics such as Non steroidal anti-inflammatory drugs (NSAID'S) for pain management often becomes necessary in most of the cases. Opioids have their own side effects such as nausea, vomiting, respiratory depression and dependence when used in large doses while NSAID's are contraindicated in patients with renal and liver dysfunction2. Brachial plexus nerve blocks with additives for upper limb surgeries provide superior analgesia, avoid side effects of general anaesthesia and also minimise use of analgesics in the post-operative period[3,4]. Single shot Brachial Plexus blocks provide analgesia in the immediate post-operative period whereas continuous peripheral nerve blocks with the use of catheters provide extended analgesia as post-operative pain can exist for several days[1].Catheter migration, leakage of the local anaesthetic, infection[5,6,7,] lack of expertise to perform continuous peripheral nerve blockade and lack of continuous monitoring are some of the major problems with continuous nerve block catheters. Hence, various additives have been studied in an attempt to enhance the

effect of single shot nerve blockade. These additives prolong the duration of blockade either by producing local vasoconstriction or delaying diffusion of local anaesthetic from the site of injection. Commonly used additives include alpha 2 agonists, NSAID's, opioids, and glucocorticoids[8]. Addition of Dexamethasone with local anaesthetics in peripheral nerve blocks to prolong duration of analgesia is being extensively studied. Although many studies have shown that the addition of Dexamethasone perineurally increases the duration of analgesia, there are concerns regarding potential neural toxicity but the evidences remain inconclusive [9,10]. The use of intravenous Dexamethasone as a safe alternative to perineural Dexamethasone in prolonging the analgesia duration is being studied and investigated recently. In our study we have compared the analgesic duration between patients receiving Dexamethasone 8 milligram perineurally and by the intravenous (IV) route in supraclavicular brachial plexus block. We have also compared the difference, if any between the onset of sensory and motor blockade in both the groups.

□□M□□ □□□□ □□□□□□□

□r□□ □r□□□ □□ □□The aim of the study is to compare the effects of perineural and IV Dexamethasone in the duration of analgesia in adult patients undergoing elective upper limb surgeries under Supraclavicular Brachial Plexus block.

□□□□d□r□□□ □□ □□To find out the difference if any, between the onset of sensory and motor blockade in patients receiving perineural and IV Dexamethasone.

M□□□□□□□□□□ □

The study was done in PSG Institute of Medical sciences and Research, Coimbatore after obtaining clearance from the Institutional Human Ethics Committee and informed written consent from the patients.

Sample size of 30 patients per group was calculated using duration of analgesia as the primary outcome based on previous studies.

□□□□□□□□□□r□□r□□□

- Patient acceptance
- ASA 1 and 2 patients
- Patients aged between 20-70 years
- All patients posted for elective upper limb surgeries under Supraclavicular Brachial Plexus block

□□□□□□□□□□r□□r□□□

- Patients with history of allergy to local anaesthetics
- Patients on steroid therapy
- Patient with Diabetes and Coagulopathies
- Infection at the site of proposed puncture for block
- Neuropathies

Routine pre-operative assessment of the patients was done prior to the surgery and tablet Ranitidine 150 mg was prescribed the night before surgery and on the day of surgery. Starvation guidelines were followed. The patients were randomly allocated into two groups (group 1 and group 2) using the random table method. After shifting the patient to the operating room, monitors were connected and baseline parameters recorded. The consultant in the operating room who was not involved in the study prepared the study drug according to the group in which the patient belonged to. All vital parameters were recorded every 5 minutes. Under aseptic precautions Supraclavicular Brachial plexus block was performed using a nerve stimulator.

□r□□□1 □Patients received 3mg/kg of Bupivacaine and 8 mg (2ml) of Dexamethasone perineurally and 2ml normal saline intravenously.

□r□□□2 □Patients received 3mg/kg of Bupivacaine and 2 ml of normal saline
perineurally and 8mg (2ml) of Dexamethasone intravenously.

The time of injection of the local anaesthetic, onset of complete sensory and motor blockade was noted and recorded. Patients were followed up post-operatively and the time of administration of first analgesic was recorded. The severity of pain at the time of administration of analgesic was graded with the verbal analogue scale.

□ □□□□□□□□□□□Onset of sensory blockade was defined as the time interval between the end of local anaesthetic administration to loss of sensation to needle prick. In our study this was tested using needle prick method. Onset of motor blockade was defined as the time interval between the end of administration of the local anaesthetic to inability to move the fingers. In our study it was tested using the modified Bromage score. Duration of sensory blockade was defined as the time interval between the completion of injection of local anaesthetic to the administration of first analgesic to the patient.

Modified Bromage Scale:

GRADE 0	Normal motor function with flexion/ extension of elbow wrist and fingers
GRADE 1	Decreased motor function with ability to move fingers or wrist only
GRADE 2	Complete motor blockade with inability to move fingers

□

Type Of Pain	Score
No pain	0
Mild pain	1
Moderate pain	2
Severe pain	3

The data was entered in Microsoft excel 2010 and statistical analysis was performed using the software SPSS version 23.0. Data was expressed as percentages and mean values with standard deviations. Differences between both the groups were analysed using the independent sample 't' test and the Pearson's chi square test. Results were defined as statistically significant if the 'p' value was less than 0.05.

Demographic Distribution Of The Two Groups

AGE IN YEARS	GROUP 1		GROUP 2	
	No. of Patients	Percentage	No. of patients	Percentage
30 and below	5	16.6	9	30
31-40	5	16.6	3	10
41-50	9	30	8	26.6
51-60	7	23.3	7	23.3
61-70	3	10	1	3.3
>70	1	3.3	2	6.6
TOTAL	30	100	30	100
Mean ± SD	45.7± 7.87		43 ± 9.07	
'p' VALUE	0.685			

Table 2:

GENDER	GROUP 1		GROUP 2	
	No. of patients	Percentage	No. of patients	Percentage
MALE	19	63.33	20	67.3
FEMALE	11	36.66	10	33.3
TOTAL	30	100	30	100
MALE	0.861			

For statistical purpose, the onset of sensory blockade was segmented into two categories according to the mean and median values. According to the statistical analysis mean sensory onset in both groups was 14.47 with a median value of 15. Hence the grouping was done as sensory onset less than 14 minutes and more than 15 minutes. In group 1, 33% of patients had a sensory onset below 14 minutes and 66% of patients had sensory onset more than 15 minutes. The mean sensory onset in group 1 was found to be 15.23 In group 2, 36.6 % of patients had sensory onset less than 14 minutes and 63.3%of patients had a sensory onset of more than 15 minutes. The mean sensory onset in group 2 was found to be 14.45. When the sensory onset in both the groups were compared, there was no significant statistical difference according to the 'p' value of 0.861.

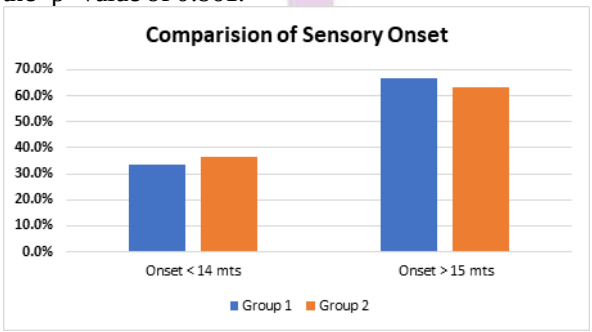

Figure 1: Comparision Of Sensory Onset In Both Groups

For statistical purpose, the onset of motor blockade was segmented into two categories according to the mean and median values. According to the statistical analysis mean sensory onset in both groups was 17.14 with a median value of 17. Hence the grouping was done as motor onset less than 17 minutes and more than 18 minutes. In group 1, 58.62% of patients had a motor onset of less than 17 minutes and 43.33% had a motor onset of more than 18 minutes. In group 2, 48.3% of patients had a motor onset of less than 17 minutes and 56.6% of patients had a motor onset of more than 18 minutes. The mean motor onset was 17.21 in group 1 and 17.34 in group 2. According to the 'p' value of 0.240 there was no significant statistical difference in onset of motor blockade between both the groups.

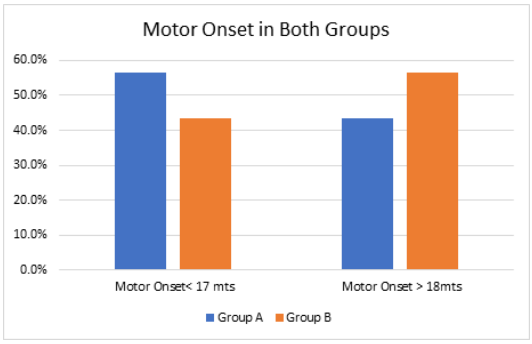

Figure2 : Comparision Of Motor Onset In Both Groups

□□ □□r□□□□□□ □□ □r □□□□□ □□ □□□□□□□□Duration of analgesia was segmented into two, based on the mean and median values. According to statistical analysis the mean duration of analgesia was 35 hrs and the median was 36 hrs. In group 1, 36.6 % of patients had analgesia for less than 36hours and 63.3 % of patients had analgesia for more than 37 hours. The mean analgesic duration in group 1 being 38.89 hours. In group 2, 60% of patients had analgesia duration of less than 36 hours and 40% of patients had analgesia more than 37 hours. The mean analgesia duration in group 2 was 34.39 hours. When duration of analgesia was compared between the two groups, there was no significant statistical difference according to the 'p' value of 0.240.

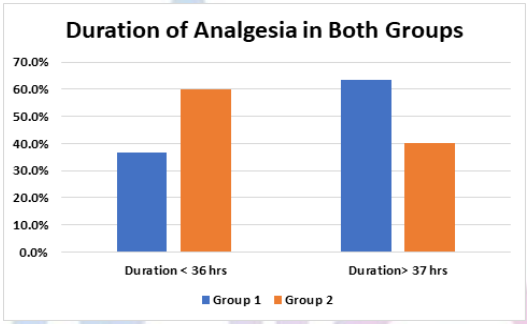

Figure 3: Comparision Of Duration Of Analgesia

□□□□ □□□□ □□

Post- operative pain is the commonest complaint in patients undergoing upper limb surgeries. Administration of multiple analgesics in the post-operative period often may result in a number of adverse effects. Single shot brachial plexus nerve blocks often fail to provide extended analgesia in the post-operative period, hence the use of additives with local anaesthetics to prolong the duration of sensory blockade is practiced[11]. Many additives have been used with local anaesthetics to prolong analgesic duration and improve the quality of the regional block[5,10]. The addition of glucocorticoids with local anaesthetics in brachial plexus supraclavicular blocks significantly prolongs analgesia without much side effects[12,13]. The analgesic effect of Dexamethasone added to local anaesthetics in the perineural route has been studied. The mechanism of action of locally administered Dexamethasone is probably by increasing the activity of inhibitory potassium channels on nociceptive 'C' fibres. It also causes some amount of vasoconstrictor effect[14,15]. The route of administration of Dexamethasone for prolonged analgesia in Brachial plexus Supraclavicular block remains a controversy. It is shown that perineural Dexamethasone may cause potential neurotoxicity but is not proved and evidences are also inconclusive [10]. The use of IV Dexamethasone for prolonged post-operative analgesia is being studied recently. Analgesic effect of systemically administered Dexamethasone could be due to decreased production of inflammatory mediators and increased production of anti-inflammatory mediators as a result of binding of cytoplasmic glucocorticoid receptors to glucocorticoid response elements in the DNA[10,17]. Very few studies have been done comparing the analgesic effect of Dexamethasone administered IV vs perineurally in Brachial Plexus block. In our study we have compared the duration of analgesia with 8 milligram of Dexamethasone administered IV and perineurally in 60 patients undergoing elective upper limb surgeries under supraclavicular Brachial plexus block. In our study the demographic variables like, age, gender and weight were comparable between both the groups and no significant difference occurred between them in both the groups.

The onset of sensory blockade was comparable between both the groups. The mean sensory onset in group 1 was found to be 15.23 minutes and that in group 2 was 14.45

minutes. Our results matched with the results of the study done by Parveen *et al*[2] in 2015 who also inferred that no significant statistical difference occurred between the onset of sensory blockade in the IV and the perineural group. The studies conducted by Desmet *et al*[1] and Rosenfeld *et al*[10] also did not show any significant difference in the onset of sensory blockade between the two groups. The onset of motor block was compared in both the groups. The mean motor onset in group 1 was found to be 17.21 minutes and the mean motor onset in group 2 was 17.34 minutes with no statistical significance similar to the findings of Abdallah *et al*[16]. Alarasan *et al*[17] compared the effects of perineural Dexamethasone in supraclavicular block and showed that the Dexamethasone group had a shorter onset of motor blockade than the control group. The mean duration of analgesia in group 1 was found to be 38.89 hours and that in group 2 was found to be 34.39 hours. Though the mean analgesia duration in group 2 was lower than the mean analgesia duration in group 1 there was no significant statistical difference in the analgesia duration between the two groups. Our study results matched with the results of the study conducted by Abdallah *et al*[16] who also inferred that both IV and perineural Dexamethasone had the same duration of analgesia when added in Supraclavicular brachial plexus block. Kawanishi *et al*[18] compared the effects of Dexamethasone 4mg with interscalene brachial plexus block using Ropivacaine and concluded that only perineural Dexamethasone prolonged analgesia duration when compared to the control group.

□□MM□□□□

A study titled "Comparison of IV and perineural Dexamethasone in prolonging duration of analgesia in Supraclavicular Brachial plexus block" was carried out in PSG Institute of Medical Sciences and Research. The study included 60 patients randomly divided into two groups of 30 patients in each group. One group received Dexamethasone 8 mg perineurally with supraclavicular block and the other group received Dexamethasone 8mg IV along with supraclavicular block. Parameters such as onset of sensory and motor blockade and duration of analgesia was noted. All data were entered in Microsoft excel 2010 and were analysed in SPSS software version 23.0. Demographic variables such as age, gender and weight were comparable between both the groups and no significant difference existed between both the groups. The onset of sensory and motor blockade was similar in both the groups and showed no significant statistical difference. Theprimary outcome of the study was duration of analgesia. The mean duration of analgesia was less in the IV group as compared with the perineural group but the results were not statistically significant.

□□□□□□□□□□

Both IV and perineural Dexamethasone similarly prolonged the duration of analgesia in Supraclavicular Brachial Plexus block. The onset of sensory and motor blockade showed no difference between the two groups. The mean duration of analgesia in the perineural group was slightly higher as compared to the IV group but the results were not statistically significant. Due to the existence of some controversies over perineural use of Dexamethasone, IV Dexamethasone can be used as a safer alternative to prolong duration of analgesia in patients undergoing upper limb surgeries under Supraclavicular Brachial plexus block.

Key words:

Post dural puncture headache, Quincke spinal needles, Lower Segment Caeserean Section, Spinal anesthesia

A B S T R A C T

Background: The most common, nagging and inconveniencing complication of spinal anesthesia is Post Dural Puncture Headache, which is very distressing and debilitating for the patient. Onset is usually within three days and worsens when the patient assumes erect posture. Pain is usually occipital or frontal, occasionally nuchal, radiating to neck and shoulders and dragging in nature. Headache is usually self limiting and disappears within a week. The aim of this study was to compare the incidence, intensity and severity of PDPH with different size Quincke spinal needles (25 G, 26 G and 27 G), in parturients undergoing elective Lower Segment Caesarean Section under Spinal anesthesia. **Methodology:** 150 patients belonging to ASA I and II in the age group 20 to 35 years, undergoing elective LSCS were included in the study. They were randomly allocated into 3 groups, depending upon the size of the spinal needle used - Group I-25G, Group II-26G, Group III-27G. The number of attempts made to locate the subarachnoid space was noted. The patients were followed up in the ward till discharge and the incidence, intensity and severity of PDPH was assessed. **Results:** The intensity of pain was assessed by Visual Analogue Scale in patients with symptoms suggestive of PDPH. The incidence, severity and intensity of PDPH were recorded and statistically analysed using 't' test and Chi square test. From our study, we find that in young obstetric patients, the incidence of PDPH is more with large bore spinal needles and multiple dural punctures. **Conclusion:** We conclude from our study the incidence, intensity and severity of Post dural Puncture Headache are more with large bore Quincke spinal needles. Hence we recommend the use of fine bore needles of 27 G or less for caesarean sections to minimize the incidence of PDPH.

INTRODUCTION

Spinal anesthesia was developed in the late 1800's with the work of Wynter, Quincke and Corning. In 1898, it was the German Surgeon Karl August Bier who introduced spinal anesthesia into clinical practice. Bier also gained first hand experience of the disabling headache related to dural puncture by trying spinal on himself.

The most common, nagging and inconveniencing complication of spinal anesthesia is Post Dural Puncture Headache (PDPH), which is very distressing and debilitating for the patient. This untoward complication is a challenging and frustrating task for the anaesthesiologist.

In 1902 it was Sicard, who suggested the leakage of Cerebrospinal fluid (CSF) into the extradural space might be the cause of Post Dural Puncture Headache. PDPH is used conventionally to denote "after" puncture[1], but the term "Post dural" mimics the word "peridural" and should mean "behind the dura[10]. The synonyms for PDPH are

1. Post spinal Headache
2. Post spinal Cephalagia

PDPH may occur after deliberate or accidental dural puncture with epidural needle. Onset is usually within three days and worsens when the patient assumes erect posture i.e. sits or stands. Pain is usually occipital or frontal, occasionally nuchal, radiating to neck and shoulders - dragging in nature and associated with stiffness of the neck[8]. The temporal and vertex areas are reported less commonly as a site of discomfort.

The headache has been described in various forms such as a feeling of heaviness, constricting band, vacuum like and lead weight, searing and spreading like hot metal. Cranial nerve palsies are not uncommon. The causative leakage of CSF into epidural space is 10 ml/hr and healing may take place up to 3 to 4 weeks. 90 % of headaches will occur within three days of the procedure and 66 % start within the first 48 hours. Rarely the headache develops between 5 and 14 days after the procedure. Headache is usually self limiting and disappears within a week.

Aim

The aim of this study was to compare the incidence, intensity and severity of PDPH with different size Quincke spinal needles (25 G, 26 G and 27 G), in parturients undergoing elective Lower Segment Caesarean Section (LSCS) under Spinal anesthesia.

MATERIALS AND METHODS

After obtaining ethical committee clearance from the institution and informed consent from the patient the study was done. 150 patients belonging to ASA I and II in the age group 20 to 35 years, undergoing elective LSCS were included in the study. They were randomly allocated into 3 groups, depending upon the size of the spinal needle used - Group I -25 G, Group II - 26G, Group - III - 27G.

Inclusion criteria

1. All parturients belonging to ASA I and ASA II
2. Parturients with no systemic diseases like hypertension, diabetes, thyroid

Exclusion criteria

1. All patients who had general contraindications for spinal anesthesia
2. Patients with previous history of headache of any etiology were excluded

All parturients undergoing elective LSCS were premedicated with Tablet Ranitidine 150 mg and Tablet Metoclopromide 10 mg orally the previous night and 2 hours before surgery. An intravenous access was established with 18 G cannula in the preoperative room and the patients were preloaded with 10 ml/kg body weight Ringer's lactate solution over 20 to 30 minutes prior to spinal blockade. The patients were monitored with baseline readings of ECG, non invasive blood pressure, pule rate, oxygen saturation and urine output when shifted inside the operating room and continuous monitoring was done.

The parturient was positioned in right lateral position; sterile draping was done after cleaning back with 10% povidone iodine and 70% alcohol and Subarachnoid blockade was attempted. The bevel of the Quincke spinal needle was kept facing the ceiling. After establishing the free flow of CSF, 0.5 % Bupivacaine Heavy 2 ml was injected intrathecally. Patients were turned supine and oxygen supplementation given with Hudson's mask till the delivery of the baby. Systemic hypotension was treated with intravenous fluids and vasopressors when indicated.

The number of attempts made to locate the subarachnoid space was noted. Any attempt to redirect or reposition the needle after one or more attempts to locate the subarachnoid space with the spinal needle was considered as multiple attempts. Intra operative vital signs were recorded and the patients were shifted to the recovery room after the completion of the procedure. The hydration status was maintained in all the patients and they received Inj. Ketorolac sodium eighth hourly and Inj.Pethidine hydrochloride 10 mg when needed for post operative pain relief.

The patients were followed up in the ward till discharge. At each visit the following questions were asked:

1. Do you have headache, if yes where is it located - occipital or frontal?
2. What is the nature of the headache /
3. Is it relieved on lying down?
4. Any posture like sitting, standing or erect posture aggravating the headache?
5. Does it worsen on coughing, sneezing or straining?
6. Is it accompanied by any other symptoms?
7. When did you first sit up after surgery and when was the ambulation started?

Patients were diagnosed to have PDPH when the following criteria are present,

1. Onset within 3 days
2. Site-Occipital or Frontal
3. Dragging type pain
4. Aggravating factor-sitting, standing, erect posture, coughing, straining or sneezing
5. Relieving factor-lying down or supine posture
6. Associated symptoms-nausea, dizziness, neck stiffness, tinnitus, auditory and visual hallucinations

For the patients who complained of symptoms suggestive of PDPH, the intensity of pain was assessed by Visual Analogue Scale (VAS) as mild, moderate and severe. The scale was graded from 0 to 10, which measures the subjective intensity of pain the patient experiences. The incidence, severity and intensity of PDPH were recorded and statistically analysed using 't' test and Chi square test.

Score	Intensity of pain	Features of PDPH
0 -3	Mild	• Slight restriction of physical activity • Patient not confined to bed • Occipital or frontal headache with postural variation • No associated symptoms*
4 - 6	Moderate	• Restricted physical activities which forces the patient to be confined to the bed for part of the day • Associated symptoms not usually present*
7 - 10	Severe	• Patient bedridden for the whole day and makes no attempt to raise her head or is unable to stand • Associated symptoms present*

*Associated symptoms include:

- Nausea, vomiting, nuchal pain, neck stiffness and paraesthesia
- Ocular disturbances - double vision, blurring of vision, difficulty in focusing and photophobia
- Auditory disturbances - dizziness, tinnitus and reduced hearing

OBSERVATIONS AND RESULTS

The study was undertaken on 150 ASA Grade I and II parturients undergoing elective LSCS with different size Quincke spinal needles and the incidence, intensity and severity of PDPH were noted.

DISCUSSION

The etiology of PDPH is still unclear, but is attributable to the loss of CSF through the hole in the duramater made by the spinal needle leading to lowering of CSF pressure and CSF hypotension[6]. PDPH could be due to the downward traction of the structures of CNS and blood vessels that are attached to the pain sensitive structures in the duramater and cranium or Loss of cushioning effect of the brain[6]. Recent evidences indicates that arachnoiditis or a local inflammatory process might be the etiology for these symptoms and may be associated with urinary and faecal incontinence.

Occurrence of PDPH seems to be related to several factors such as younger patients, females, large gauge spinal needle, design of needle tip, multiple punctures made through the duramater, pregnancy and early ambulation[17]. Atypical presentations of PDPH have been reported. Spielman (1982) mentioned, the stress of labour, changing hormonal level and dehydration to be the factors responsible for an increased incidence of PDPH in obstetric patients.

Ocular symptoms include double vision, blurring of vision, photophobia and difficulty in focusing. The reason being the sixth cranial nerve abducens has a long intracranial course and is more susceptible to low pressure paralysis. The auditory symptoms include decreased hearing and tinnitus, due to endolymphatic expansion secondary to perilymphatic hypotension. The CSF closely resembles perilymph and the pressure changes in the perilymph.

From our study, we find that in young obstetric patients, the incidence of PDPH is more with large bore spinal needles and multiple dural punctures. Choi *et al*[3] reported PDPH 1 in 67 parturients. Statistically there was no significance in the age groups of the parturients as similar with Rasmussen *et al*[14] studies.

From table 2, we infer that successful subarachnoid puncture made was 66% in first attempt (99 out of 150), 27.3 % in second (41 out of 150), 6 % in third (9 out of 150) and 0.66 % in fourth attempt (1 in 150). In all the three groups, no one developed PDPH with single puncture, but the incidence was 14.28 %, 16.6 % and 33.3 % in Group I, II and III respectively with second attempt and successive attempts and was statistically significant at p 0.05 level with close association between multiple punctures and the incidence of PDPH. Seeberger *et al*[19] also found that repeated puncture significantly increases the incidence of PDPH. Costigan *et al*[4] reported similar results in his study.

The overall incidence of PDPH was 11.32 % which was similar to studies from choi *et al*[3] with incidence ranged from 1.5 % to 11.2 %. In our study, 16 % (8 out of 50) in Group I, 12 % (6 out of 50) in Group II and 6 % (3 out of 50) in Group III developed PDPH. The probable reason could be majority of the case was done during summer season and the other one could be the young parturient. Statistical analysis showed a close association between the gauge of the needle and the PDPH incidence by Chi square test significant at p value 0.01. Choi *et al*[3] found that once dural puncture headache occurred, the risk of PDPH was 52 %; but the size of the needle was not mentioned. Flatten *et al*[5] stated 6.7 % developed PDPH with usage of 26 G fine needle, but no PDPH with 29 G. Schultz *et al*[18] concluded that the incidence was less with fine bore

needles and it was not affected by the type of the needle chosen.

The intensity of headache experienced by the patients on different days was measured by VAS and was found to be not statistically significant. The duration of headache was for a maximum period of 6 days in our study. None of our patients had the headache beyond the first week. The largest follow up of PDPH is still that of Vandam and Dripps[20] who reported that 72 % headaches resolved within 7 days and 87 % had resolved in 6 months.

In our study, majority of patients had the onset of PDPH within 24 - 48 hours which was similar to Reynolds *et al*[16] with 90 % onset of headache within three days of the procedure. Leibold[9] *et al* in their study showed 66 % headache started within first 48 hours.

The severity of PDPH was graded as mild, moderate and severe according to our study and the reason for increased severity in Group II (26 G) as compared to Group I (25 G) may be due to patient factors and multiple punctures attempted in this group[12]. Pan *et al*[13] reported an incidence of 4% and 3.9% of PDPH respectively after spinal anesthesia for postpartum tubal ligation with 26-G Atraucan. With 27 G needles in Group III patients all patients had only mild headache. From the statistical analysis, p value is significant at 0.01 level and we infer that there was a strong association between the severity of PDPH and the use of large bore needles.

The intensity and severity of the PDPH was statistically analysed using 't' test and chi square test respectively and was concluded that the intensity of pain experienced between25 G and 27 G was much significant. The severity of pain was much significant at 48 - 72 hrs using chi square test and this indicates that there is an association between the large bore needles and severity of pain.

Mihic DN[11] in his review on PDPH in relation to the direction of the needle bevel hypothesized that splitting rather than cutting the longitudinally directed duramater fibres resulted in lower incidence of PDPH. Recent electron microscopic studies by Reina *et al*[15] showed that the dural fibres doesn't run longitudinally but they are criss-cross; hence the direction of the bevel of the needle does not really matter at all while making the lumbar puncture.

In our study, the patients having PDPH were treated with simple conservative measures like strict bed rest, supine or comfortable position , liberal intake of fluids, intravenous fluids and analgesics. None of the patients with PDPH required epidural blood patch. Jones RJ[7] states that there is no clinical evidence to support the maintainence of supine position before or after the onset of the headache as a means of treatment.[2] Though prone position has been advocated, it is not a comfortable position to lie down by the patient. The prone position raises the intra abdominal pressure which is transmitted to the epidural space and this is said to reduce the CSF leak from spinal space into epidural space, thereby reducing the headache.

CONCLUSION

We conclude from our study the incidence, intensity and severity of Post dural Puncture Headache are more with large bore Quincke spinal needles. Hence we recommend the use of fine bore needles of 27 G or less for caesarean sections to minimize the incidence of PDPH.

Abstract

Background: The gold standard and ideal position for laryngoscopy is sniffing position. Trauma life support guidelines recommend the use of Manual In Line Stabilization or a rigid collar to stabilize the spine in suspected cervical spine injury patients. The gold standard for intubation in patients with cervical spine injury is fibre-optic bronchoscopy. But its use is restricted by lack of expertise, availability and time requirement. C-MAC blade and McCoy blade have been independently compared with Macintosh laryngoscope in simulated difficult airway. Aim: In our study, we compare C-MAC D blade and McCoy blade laryngoscope in simulated cervical spine injury using Manual In Line Stabilisation (MILS). **Materials and methodology:** 100 patients of age group between 18 – 65 years belonging to ASA 1 & 2 posted for elective surgeries under general anesthesia with endotracheal intubation participated in this study. Patients were randomly allocated to one of the two groups by computer generated random table number. Group C - Endotracheal intubation done using C-MAC D blade video laryngoscope and Group M - Endotracheal intubation done using McCoy blade laryngoscope. Observation and results: Baseline characteristics were presented as mean ± S.D. Two-sided unpaired t-test and chi-square test was applied to analyze the data and p value less than 0.05 were considered as significant. **Conclusion:** C-MAC video laryngoscope requires less time for laryngoscopy, provides better visualisation of glottis, lower IDS score with similar duration of intubation and haemodynamic responses when compared to McCoy laryngoscope in patients with simulated cervical spine injury.

Key Word: C-MAC blade, McCoy blade, laryngoscopy, simulated cervical spine injury, manual in line stabilization

INTRODUCTION

The gold standard and ideal position for laryngoscopy is sniffing position. The sniffing position aligns the oral, pharyngeal and laryngeal axes and provides better glottic visualization.[2] The sniffing position produces flexion of the lower cervical spine, extension of the upper cervical spine and extension of the atlanto–occipital joint.[3] Trauma life support guidelines recommend the use of Manual In Line Stabilization (MILS) or a rigid collar to stabilize the spine in suspected cervical spine injury patients.[4] MILS prevents head extension and neck flexion which is necessary for optimal alignment of three airway axes.[5]

How to site this article: S Rohini, R Arun Kumar, G Dhanabagyam. Comparison of C-MAC blade and McCoy blade for laryngoscopy in adult patients undergoing tracheal intubation for elective surgeries with simulated cervical spine injury using manual in line stabilization. *MedPulse International Journal of Anesthesiology.* August 2019; 11(2): 129-135. http://medpulse.in/Anesthsiology/index.php

The presence of collar can worsen the laryngoscopic view and makes the intubation difficult with conventional laryngoscope.[4] To overcome this various devices and options like direct laryngoscope with the aid of gum elastic bougie, fibre-optic bronchoscopy, airway scope, McCoy laryngoscope, Intubating laryngeal mask airway, C-Trach and Bullard laryngoscope has been recommended by many authors.[6] The gold standard for intubation in patients with cervical spine injury is fibre-optic bronchoscopy. But its use is restricted by lack of expertise, availability and time requirement.[4] The McCoy levering laryngoscope is a modification of the standard Macintosh blade.[6] It has a hinged tip and the angle of the hinged portion can be altered by a lever attached to the handle.[7,8] Depression of the lever towards the handle elevates the tip.[8] The hinged tip aids in improving the Cormack and Lehane laryngoscopic view by 1 grade in comparison to Macintosh blade in patient with cervical spine injury. The blade is available in size 3 and 4.[4] The latest generation C-MAC video laryngoscope has several distinct improvements.[8] It has external light source and small digital camera at the distal third of the blade, which extends to a video display monitor.[9] It provides optimum view of the glottis by direct and indirect view.[9] C-MAC laryngoscope can accommodate Macintosh blade 2, 3 & 4. A special D blade with greater curvature is designed to facilitate intubation of the difficult airways.[8] Both the devices have been independently compared with Macintosh laryngoscope in simulated difficult airway. Only a few studies are available comparing C-MAC and McCoy laryngoscope.[4] This study was carried out to compare the efficacy of C-MAC D blade and McCoy blade laryngoscope in simulated cervical spine injury.

AIM

To compare C-MAC D blade and McCoy blade laryngoscope in simulated cervical spine injury using Manual In Line Stabilisation (MILS) with the following parameters.

Primary Aim:

- Duration of laryngoscopy
- Duration of intubation
- Total duration of intubation
- Ease of intubation - Intubation Difficulty Scale (IDS score)

Secondary Aim:

- Haemodynamic responses

MATERIALS AND METHODOLOGY

A study titled "Comparison of C-MAC D blade and McCoy blade for laryngoscopy in patients with simulated cervical spine injury" was done in PSG Institute of Medical Sciences & Research, Coimbatore. This study was done after obtaining ethical committee clearance and informed written consent from all the patients participated in this study. It was a prospective and randomised study. 100 patients of age group between 18 – 65 years belonging to ASA 1 & 2 posted for elective surgeries under general anesthesia with endotracheal intubation participated in this study.

Inclusion criteria

- Patient's acceptance
- Patients aged between 18 – 65 years
- ASA 1 and ASA 2 patients
- Patients undergoing elective surgery under GA with endotracheal intubation

Exclusion criteria

- Anticipated difficult airway
- Risk of aspiration
- Hypertensive patients
- Patients on β-blockers, Clonidine.
- Duration of intubation exceeding 120 sec
- Change in laryngoscopy during intubation
- Emergency surgeries

Routine pre-operative assessment was done and the patients were kept nil per oral from 10 pm the day prior to surgery. Informed written consent was obtained. All the patients were pre-medicated with tablet Ranitidine 150mg orally at night the day prior to surgery and at 6 am on the morning of surgery. Patients were randomly allocated to one of the two groups by computer generated random table number.

Group C: Endotracheal intubation done using C-MAC D blade video laryngoscope

Group M: Endotracheal intubation done using McCoy blade laryngoscope

Parameters recorded

Duration of laryngoscopy - defined as the time taken from insertion of the blade between the teeth until the anaesthetist obtained the best possible view of the vocal cords

Duration of intubation - defined as the time taken from when the anaesthetist indicate the best view at laryngoscopy until the tracheal tube was placed through the vocal cords, as evidenced by visual confirmation by the anaesthetist.

Total duration of intubation - It is the sum of the duration of laryngoscopy and the duration of intubation

Ease of intubation - Intubation Difficulty Scale (IDS score). It includes the following:

1. Number of intubation attempts
2. Number of operators
3. Number of alternative technique used
4. Glottis exposure – CL gradin
5. Lifting force required

6. Necessity for laryngeal pressure
7. Vocal cord mobility

Haemodynamic responses - Heart rate, systolic BP, diastolic BP, mean arterial BP after 1st min, 3rd min and 5th min of intubation. The intubation difficulty scale (IDS)[37] : In 1997 Frederic Adnet *et al* evaluated and proposed an Intubation Difficulty Scale (IDS) score characterising the complexity of endotracheal intubation in both the prehospital and operating room settings to assess the degree of difficulty. The Intubation Difficulty Scale (IDS) score is a function of seven parameters, resulting in a progressive, quantitative determination of intubation complexity and they are as follows:

Parameters	Definition		
N^1-The number of intubation attempts	An attempt is defined as one advancement of the tube in the direction of the glottis during direct laryngoscopy	N^1 = 0 if only one attempt	Every additional attempt adds one point
N^2-The number of supplementary operators	It represents the number of additional persons directly attempting intubation	N^2 = 0 if only one operator	Every additional operator adds one point
N^3-The number of alternative techniques used	Change in approach - oral intubation to blind nasotracheal intubation, change in material – blade, endotracheal tube, addition of stylette	Change in approach	Each alternative technique adds one point
N^4-Glottic exposure	defined by the Cormack grade minus one	GradeI (N^4 = 0) GradeII(N^4 = 1) GradeIII(N^4= 2) GradeIV(N^4=3)	Glottic exposure is evaluated during the first attempt by the first operator
N^5- Lifting force applied during laryngoscopy	If little effort is necessary If subjectively increased lifting force is necessary	N^5 = 0 N^5= 1	
N^6- Necessity for external laryngeal pressure for optimizedglottic exposure	If no external pressure is applied If external laryngeal pressure is necessary	N^6= 0 N^6= 1	
N^7- Position of vocal cords during intubation	if vocal cords are in abduction if the vocal cords are in adduction	N^7= 0 N^7= 1	

The degree of difficulty is described according to IDS score as follows

IDS Score	Degree of difficulty
0	Easy
1 – 5	Slightly difficult
>5	Moderate to major difficulty
Infinity	Impossible intubation

Patients were connected to ASA standard monitors – ECG, Non invasive blood pressure(NIBP) and pulse oximeter (SpO_2) and baseline readings recorded. Intravenous line started and patency of the vessel checked. Patients were pre oxygenated with 100% Oxygen for 3 minutes and Induced with Fentanyl 2mcg/kg, Lignocaine (preservative free) 20mg and Propofol 2mg/kg intravenously. After ensuring adequate mask ventilation, patients were paralysed with Inj. Succinylcholine 1.5mg/kg. Pre intubation heart rate, systolic BP, diastolic BP, mean arterial BP were recorded. After 1 minute MILS was achieved by an anaesthetist, standing to the side of the patient, using fingers and palms of both hands to stabilize the patient's occiput and mastoid process and gently counteract the forces created by the intubator. Laryngoscopy was done by another anaesthetist who is experienced with both the techniques. Laryngoscopy was done with C-MAC D blade laryngoscope in group C and McCoy blade laryngoscope in group M. After visualization of the cords, patients were intubated with appropriately sized endotracheal tube with stylet bent to hockey stick shape. During intubation the duration of laryngoscopy, the duration of intubation and the ease of intubation (IDS scoring) were recorded. After securing the endotracheal tube, the tube position was confirmed with stethoscope and $ETCO_2$ monitoring, anaesthesia was maintained with Oxygen & Nitrous oxide 40:60 with 6 litres fresh gas flow, Sevoflurane 2% and Inj.Vecuronium (loading dose 0.1mg/kg). Heart rate, systolic BP, diastolic BP, mean arterial BP were recorded after 1st min, 3rd min and 5th min of intubation.

Statistical analysis: Data were statistically analysed with the SPSS version 17.0 software. Baseline characteristics were presented as mean ± S.D. Two-sided unpaired t-test and chi-square test was applied to analyze the data and p value less than 0.05 were considered as significant. A repeated measure of ANOVA was applied for the two groups to know the with-in subject variability in Ease of intubation and $p < 0.05$ was considered to be significant.

5th min	75.8 ± 8.3	78.2 ± 11.4	0.231

DISCUSSION

Approximately 2-5% of trauma patients will have cervical spine injury. Patient with cervical spine injury may require airway management for airway protection, to prevent hypoxia and hypoventilation.[1] In our study, we have compared the efficacy of C-MAC D blade and McCoy blade laryngoscope in simulated cervical spine injury by comparing duration of laryngoscopy, duration of intubation, total duration of intubation, ease of intubation (IDS score) and haemodynamic response. In our study the demographic variables like age, gender and BMI were comparable between both the groups. The mean duration of laryngoscopy when compared between two groups, it was shorter in C-MAC group (12.5 seconds) than McCoy group (14.47 seconds) and it was statistically significant. The mean duration of intubation when compared between two groups, it was longer in C-MAC group (13.85 seconds) than McCoy group (12.07 seconds) and it was statistically significant. The mean total duration of intubation was comparable between C-MAC group (26 sec) and McCoy group (26.55 sec) and statistically not significant. Even though the time taken for laryngoscopy was shorter in C-MAC group, the time taken for successful intubation was prolonged. So the

mean total duration of intubation was comparable and statistically insignificant between the groups. Our results of duration of laryngoscopy, duration of intubation and total duration of intubation were similar with the study done by Jain *et al*.[4] comparing McCoy and C-MAC video laryngoscope in simulated cervical spine injury. The ease of intubation was observed in our study using IDS scoring. In our study 48 patients in C-MAC group and 44 patients in McCoy group were intubated in the first attempt and were comparable. This results were similar to study by Jain *et al*.[10,11] who compared the conventional C-MAC and the C-MAC D blade with direct laryngoscopes in simulated cervical spine injury (manikin study) and observed that out of 33 patients, 30 patients were intubated in first attempt using C-MAC D blade and 24 patients using McCoy and was not statistically significant. 50 patients in group C and 47 patients in group M required single operator and all the patients were intubated using single technique in our study. In C-MAC group 47 patients had CL grade 1 and 3 patients had CL grade 2. In McCoy group 34 patients had CL grade 1 and 16 patients had CL grade 2. Hence the glottis exposure was better with C-MAC group than McCoy group and it was statistically significant which was similar in studies by Jain *et al*.[4] and Sabry *et al*.[8] Jain *et al*.[4] compared McCoy laryngoscope and C-MAC video laryngoscope in simulated cervical spine injury and observed that out of 30 patients, 29 patients in C-MAC group and 16 patients in McCoy group had CL grade 1 and was statistically significant. Sabry*et al*.[8,12] compared C-MAC D blade and McCoy laryngoscopes during cervical immobilization and observed that out of 30 patients, 16 patients in C-MAC group and 4 patients in McCoy group had CL grade 1 and was statistically significant. The McCoy group (18 patients) needed more lifting force for visualisation of glottis than C-MAC group (5 patients) and it was statistically significant. 14 patients in C-MAC group needed external laryngeal pressure during intubation compared to 8 patients in McCoy group, but it was not statistically significant. The IDS score between both the groups was found to be statistically significant. The use of C-MAC resulted in more number of easy intubation when compared to McCoy[13]. This was similar to a study by Jain *et al*.[4] comparing C-MAC and McCoy laryngoscopes where C-MAC resulted in lower IDS than McCoy group. In our study the heart rate, systolic BP, diastolic BP and mean BP recorded at all times were comparable between C-MAC, McCoy group and was statistically insignificant. This was similar to study by Jain *et al*.

CONCLUSION

In our study though there was a statistical significance in duration of laryngoscopy and duration of intubation, the total duration of intubation was comparable and insignificant. Because with C-MAC the time taken for successful intubation was prolonged though the duration of laryngoscopy was shorter. The C-MAC group had better glottic visualisation, needed optimal lifting force and clinically insignificant external laryngeal pressure with lower IDS score when compared to McCoy group. To conclude C-MAC video laryngoscope requires less time for laryngoscopy, provides better visualisation of glottis, lower IDS score with similar duration of intubation and haemodynamic responses when compared to McCoy laryngoscope in patients with simulated cervical spine injury.

Abstract

Background: Airway management with cuffed endotracheal intubation is an integral part of an anaesthesiologist's responsibilities. Local irritation and inflammation caused by prolonged inflation of the cuff can result in minor sorethroat to more serious transglottic complications inherent to the usage of cuffed endotracheal tube. Many studies have been performed and published exploring the measures to minimize or eliminate post-intubation morbidities. **Aim:** The aim of our study was to evaluate the efficacy of intravenous administration of Dexamethasone in reducing the incidence and severity of postoperative sore throat in patients receiving general anaesthesia with cuffed endotracheal intubation. **Materials and methodology:** 100 patients of age group between 18 – 65 years belonging to ASA 1 and 2 of both the sexes posted for elective surgeries under general anaesthesia with endotracheal intubation participated in this study. Patients were randomly allocated to one of the two groups, 50 in each by using envelope method. **Group C:** Control group was given 2 ml Normal Saline Intravenously and **Group D:** Dexamethasone group was given 2 ml Dexamethasone 8mg Intravenously. **Observation and Results:** Statistical analysis was done using SPSS PC (11.5) version. Student's t-test was used to compare the mean difference in quantitative variables and Chi-square test was used to study the association among qualitative variables. p value < 0.05 was considered statistically significant. **Conclusion:** The conclusion of our study is that single dose of 8 mg prophylactic Dexamethasone given intravenously reduces effectively the incidence and severity of sore throat after general anaesthesia with cuffed endotracheal intubation.

INTRODUCTION

Airway management with cuffed endotracheal intubation is an integral part of an anaesthesiologist's responsibilities ensuring adequate ventilation and preventing aspiration of secretions. In addition, the wastage of anaesthetic gases and pollution of the operation theatres are also reduced substantially. However, local irritation and inflammation caused by prolonged inflation of the cuff can result in minor sorethroat to more serious transglottic complications (like vocal cord problems and subglottic stenosis), inherent to the usage of cuffed endotracheal tube. The minor sequelae of sore throat from the use of cuffed endotracheal tube results in up to 90% incidence in the postoperative period. Several factors like trauma to laryngopharyngeal mucosa during laryngoscopy, contact of tracheal tube with the vocal cords and pharyngeal wall resulting in oedema, pressure affecting the tracheal mucosal capillary perfusion, cuff design, oral suctioning, placement of nasogastric tube, mobility of the tube

How to site this article: K Chandra Mohan, R Arun Kumar, A T Sathiya Vinotha, D Dhatchinamoorthi. Efficacy of dexamethasone in reducing the severity of postoperative sorethroat after endotracheal intubation. *MedPulse International Journal of Anesthesiology.* November 2019; 12(2): 155-160. http://medpulse.in/Anesthsiology/index.php

inwards, outwards or sideways can contribute to sorethroat. After general anaesthetic one may develop a sore throat which can range between minor discomfort to a more severe continuous pain. One may also have a very dry throat or feel pain on speaking or swallowing and the symptoms may disappear after a few hours but may take a two days or more to settle down completely. Many studies have been performed and published exploring the measures to minimize or eliminate post-intubation morbidities, viz,

- Use of high volume-low pressure cuffed endotracheal tubes[6]
- Use of smaller sized endotracheal tubes[1]
- Inhalation of steroids[4]
- Topical application of lubricant jellies[20], Local anaesthetic (2% Lignocaine) jellies[8] and Steroids like Betamethasone gel[1]

Dexamethasone is a potent corticosteroid with anti-inflammatory, analgesic and antiemetic properties and has been reported to reduce the postoperative pain and swelling following oral surgeries.[2,3,13]

AIM

The aim of our study was to evaluate the efficacy of intravenous administration of Dexamethasone in reducing the incidence and severity of postoperative sore throat in patients receiving general anaesthesia with cuffed endotracheal intubation.

MATERIALS AND METHODS

A study titled "Efficacy of Dexamethasone in reducing the severity of postoperative sore throat after endotracheal intubation" was done after obtaining ethical committee clearance from the institution and informed written consent were obtained from all the patients who participated in this prospective and randomised study.

100 patients of age group between 18 – 65 years belonging to ASA 1 and 2 of both the sexes posted for elective surgeries under general anaesthesia with endotracheal intubation participated in this study.

Inclusion criteria

- Patients belonging to ASA grade 1 and 2
- Age group between 18-66 yrs
- Body weight between 40-75 kg
- Surgery duration lasting for more than 1 hr

Exclusion criteria

- History of recent respiratory infection
- Risk factors for post operative aspiration
- H/o smoking
- Obesity
- Pregnancy
- Prior treatment with analgesics
- Use of corticosteroids
- Neuromuscular diseases
- Those requiring more than two attempts
- Presence of blood on endotracheal tube or on oral suction after extubation

Routine pre-operative assessment was done and the patients were kept nil per oral from 10 pm the day prior to surgery. Informed written consent was obtained. All the patients were pre-medicated with Tab. Pantoprazole 40 mg and Tab. Alprazolam 0.25mg at night the day prior to surgery and at 6 am on the day of surgery. Patients were randomly allocated to one of the two groups, 50 in each by using envelope method.

Group C: Control group was given 2 ml Normal Saline iv

Group D: Dexamethasone group was given 2 ml Dexamethasone 8mg iv

Patients were connected to ASA standard monitors – ECG, Non invasive blood pressure (NIBP), pulse oximeter (SpO_2) and baseline readings recorded. An 18 G Intravenous catheter was inserted and intravenous fluids started. Preoxygenation was done with 100 % Oxygen for 3 minutes and general anaesthesia was instituted with intravenous Fentanyl 2mcg/kg, Lignocaine (preservative free) 20mg and Propofol 2mg/kg intravenously for induction. Mask ventilation was done for 3 mins and Endotracheal intubation was facilitated with 0.5 mg/kg Atracurium besylate. High volume low pressure endotracheal tube from the same manufacturer (Rusch Inc.) were used for all patients from both groups. Male patients received 8 and 8.5 mm and female patients received 7 and 7.5 mm inner diameter endotracheal tubes respectively. Intubation was performed with a standard MacIntosh curved blade size 3 or 4. Application of external laryngeal pressure to aid endotracheal intubation and number of attempts at laryngoscopy were recorded. The cuff was inflated with air just to achieve an airtight seal in the presence of intermittent positive airway pressure ventilation. Intra cuff pressure was adjusted as required every 30 minutes to 25 – 40 cm H_20 (18 – 30 mm Hg) using a cuff pressure monitor to limit nitrous oxide related intracuff pressure increase. Anaesthesia was maintained with oxygen and nitrous oxide in a ratio of 33:66 in isoflurane. Muscle relaxants and analgesia were repeated when required at regular intervals. Ventilation was adjusted to maintain normocarbia (35 – 40 mmHg). Oral or nasal airways were not placed in any patient. Coughing or bucking on the ETT if any, were recorded. At the end of the surgery, Ondansetron 0.1mg/kg i.v was administered and muscle relaxation was reversed with a combination of Neostigmine 0.05 mg/kg and Glycopyrrolate 0.01 mg/kg. Oropharyngeal suction before extubation was done under direct vision to avoid trauma

to pharyngeal mucosal tissues as well as to confirm that secretions were completely removed. Presence of blood in oropharyngeal suction or on the endotracheal tube after extubation excluded these patients from the study. In the Post anaesthesia care unit, presence of soreness of throat was evaluated by a trained observer who, along with the patient, was blinded to the study group assignment. The assessment was done using visual analogue scale (linear 10 cm, starting from 0 = no pain to 10 = worst imaginable pain) at rest and with effort (swallowing movement) at one hour, three hour, six hour, 12 hour and 24 hour periods.

Statistical analysis: Our randomized double blind placebo controlled prospective study comprised of 100 patients, 50 in each group.

Group C-Control Group (n=50)

Group D- Dexamethasone (n=50)

Statistical analysis was done using SPSS PC (11.5) version. Student's t-test was used to compare the mean difference in quantitative variables and Chi-square test was used to study the association among qualitative variables. p value < 0.05was considered statistically significant.

OBSERVATION AND RESULTS

Table 1: Demographic details - Group C and Group D

Parameters		Group C		Group D		p- value	Results
1.Age distribution	Age in years Mean (in yrs)±S.D	38.62±11.54		39.56±9.97		0.66	NoStatistical Significance

Blood on endotracheal tube after extubation or on oropharyngeal suction	Nil	Nil

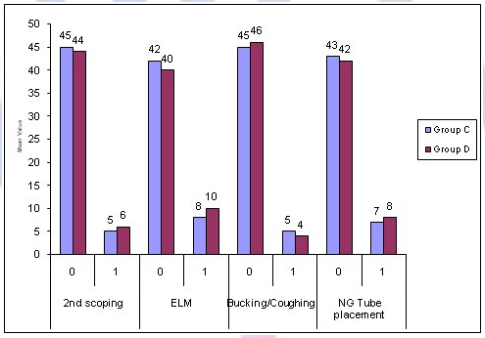

Figure 1: Incidence of 2nd attempt, External laryngeal pressure, Bucking/Coughing on ETT between groups

DISCUSSION

Sorethroat though a minor complaint following endotracheal intubation, is one of the most common and irritating complaints similar to Post operative nausea and vomiting (PONV); and if associated with cough, it increases the pain and oozing when there is abdominal or thoracic wounds. Postoperative sore throat is a symptom caused by many factors, such as the intubation procedure, cuffed endotracheal tube, intracuff pressure and the use of stylets or lubricants. Stenqvist O *et al*[16]in his studies showed the incidence of postoperative sore throat does not necessarily reflect damage caused by the endotracheal cuff only. In our study, Dexamethasone group had a statistically significant reduction in the incidence (18% Vs 54%) and severity of sore throat after general anaesthesia with endotracheal intubation compared to the placebo group. Contrarily the occurrence of sore throat was similar between the two groups, in respect to the duration of surgery, the number of laryngoscopic attempts and intracuff pressure. In our study, patients from both groups had their intracuff pressure checked every half hourly and maintained within acceptable limits. Jenson PJ *et al*[6], El Hakim *et al*[4] and Mc Hardy FC *et al*[9] in three different studies concluded that the incidence of sorethroat ranges from 6.6 – 90%, a wide spectrum. 54% with sorethroat in our study is indicating that every alternative patient had postoperative sore throat. Stout DM *et al*[17] showed a higher incidence of sore throat caused by larger size endotracheal tube compared with smaller size tube. The size of the endotracheal tube in

both age groups was similar in both groups, not letting the size affect the incidence of sore throat. The duration of surgery did not alter the incidence of sore throat in our study, in contrast Jensen PJ *et al*[6] where they found a direct relation with the length of cuff – tracheal contact. In respect to the cuff design and lubrication, Loeser EA *et al*[7] in their study demonstrated high volume low pressure cuffs were associated with higher incidence of sore throat due to the larger area of contact with the tracheal mucosa but we did not have any such increase in the incidence of sore throat in spite of using high volume low pressure cuffs (Rusch AVT Ind. Ltd.,) in our study, which is possibly explained by the improvement in the endotracheal tubes and cuff designs over the last three decades.Stanley TH *et al*[15]showed a significant increase in cuff volume and cuff pressure after use of nitrous oxide intraoperatively and this has been blamed for increase in the incidence of sorethroat. But in our study, though the cuff pressure and cuff volume increased due to the use of nitrous oxide, it was monitored every 30 minutes by a cuff pressure monitor and brought back to acceptable limits, thus not allowing it to affect the incidence of sore throat. 64.5% of postoperative sore throat was reported by Monroe MC *et al*[11] in patients with blood tinge of airway instruments like endotracheal tube tip, compared to those 30.9% without blood tinge, due to improper suctioning which was wrongly attributed to the increased sore throat incidence. None of our patients from either group had any blood staining. Sang-Hyan Park *et al*[12]concluded prophylactic administration of 0.2 mg/kg body weight Dexamethasone significantly decreased the incidence and severity of sore throat and hoarseness 1 hour and 24 hours after tracheal extubation of a double lumen tube. We have used Dexamethasone 8 mg IV, as the exact dose is not known and the results of our study agree with the above study. Hamelberg W *et al*[5] found insignificant decrease in the incidence of sore throat when 1% hydrocortisone ointment was applied to the endotracheal tube. Stride[18] used the same method together with standardized anaesthesia and direct questioning technique and concluded that hydrocortisone ointment was ineffective in the prevention of postoperative sore throat due to the presence of additive substances which are irritating to the tracheal mucosa. Dexamethasone being better anti-inflammatory agent compared to hydrocortisone probably explains better results in reducing sorethroat.Dexamethasone being a steroid may produce complications like gastritis, avascular necrosis, delayed wound healing, glucose intolerance and susceptibility to infection, but a single bolus dose of intravenous dexamethasone does not produce these complicationsas evidenced by Melby JC *et al*.[10] The results of our study very well correlates with the findings of Wang *et al*[19] which primarily studied the effect of dexamethasone on postoperative nausea and vomiting (PONV) and these results were consistent with the study by Siji Thomas *et al*.[14] Postoperative sore throat is a symptom caused by many factors, such as the intubation procedure, cuffed endotracheal tube, intracuff pressure and the use of stylets or lubricants. Methods to minimize sore throat will bring patient satisfaction, less pain and less oozing, thereby promoting early discharge from the recovery room and hospital. One such method is using intravenous Dexamethasone.

Draw backs of this study

- This study was conducted only in ASA I and II patients and not in other groups
- We did not use humidity moisture exchanger in gas delivery circuit, and dry airway gases have been implicated in the development of sore throat Loeser*et al*[42]
- Our study was not conducted in patients with difficult airway
- The dose of Dexamethasone required for the prevention of postoperative sore throat and exact time of administration is not known

CONCLUSION

The conclusion of our study is that single dose of 8 mg prophylactic Dexamethasone given intravenously reduces effectively the incidence and severity of sore throat after general anaesthesia with cuffed endotracheal intubation. Dexamethasone minimizes two of the minor, but irritating postoperative problems of general anaesthesia with endotracheal intubation i.e. PONV and postoperative sore throat and hence it may be recommended in patients undergoing surgery under general anesthesia.

A clinical audit on cancellation of elective surgery on a scheduled day in a teaching institution

R Arun Kumar[1*], C Ganesan[2]

[1]Associate Professor, [2]Professor and HOD, Department of Anaesthesiology, PSG Institute of Medical Sciences and Research, Peelamedu, Coimbatore-641004, Tamil Nadu, INDIA.
Email: shivaaniarun76@gmail.com

Abstract

Background: Cancellation of surgery on the scheduled date poses physical, psychological and emotional disturbances not only to the operating surgeon, but it also includes the perioperative physician as well as the patients. The most common cause of cancellation of elective surgery on a scheduled day in a teaching institution includes lack of operating time in theatre. The reasons to quantify the cancellation list is usually vivid and difficult. **Aim:** The objective of this audit was to find out the prevalence and the reasons for cancellation of elective surgery on the scheduled day and to find out the clinical quality indicator with regard to effective theatre utilization time on a scheduled day. **Materials and Methods:** This retrospective analysis was included for one year duration in a tertiary teaching hospital. We coined the cancellation of the elective surgery as any proposed surgery which was listed and planned the previous day; and subsequently not done on the scheduled day of surgery. The source of audit was the documentation maintained in cancellation records in the anaesthesia department and these data were analyzed. The most common cause for cancellation of surgery was categorized as Patient related, Pre operative (or Surgical) preparation related and Facility related factors. Observations and **Results:** All the data were entered in the Microsoft excel spreadsheet and a Pareto chart was constructed to prioritize the reasons and analyzed using Epi info software version. Out of 10,306 patients during the scheduled period in our audit, 532 (5.16%) patients had cancellation on the elective list. **Conclusion:** Appropriate pre operative assessment, better inter departmental coordination, adequate optimization prior to surgery, improving man power availability and increasing the operation theatre utilization time help to avoid cancellation of surgery on the scheduled day.

Key Words: Cancellation, elective surgeries, scheduled day, teaching institution

INTRODUCTION

Surgery is the primary modality of treatment in specified diseases and it requires a multi disciplinary team work approach in the operating room. Pre anaesthetic assessment, adequate preparation and optimization of the surgical patient prior to the elective surgery, avoids the major catastrophic events perioperatively and also decreases the morbidity and mortality of the surgical patients. Cancellation of surgery on the scheduled date poses physical, psychological and emotional disturbances not only to the operating surgeon, but it also includes the perioperative physician as well as the patients.[19] The prevalence and the cause for cancellation of elective surgery on a scheduled day is diverse and vary from one institution to another. The incidence of cancellation is between 10% and 40% among the booked elective list in various institutions[1,6,15,16,17]. The most common cause of cancellation of elective surgery on a scheduled day in a

How to site this article: R Arun Kumar, C Ganesan. A clinical audit on cancellation of elective surgery on a scheduled day in a teaching institution. *MedPulse International Journal of Anesthesiology.* November 2019; 12(2): 161-165.
http://medpulse.in/Anesthsiology/index.php

teaching institution includes lack of operating time in theatre[1,2,16,17,18] (running beyond the scheduled hours), poorly optimized surgical patients due to varied medical conditions or the administrative reasons[1,7,16,17,18]. Delayed start of elective list, unanticipated anaesthetic or surgical problems or shortages of the operating staff also contribute an pivotal role in cancellation[10]. The reasons to quantify the cancellation list is usually vivid and difficult. Hence the simplest approach is to evaluate the cause for cancellation of surgery and the specified issues needs to be focused preventing the postponement of the elective surgery.

AIM

The objective of this audit was

1. To find out the prevalence and the reasons for cancellation of elective surgery on the scheduled day and to focus on improving the quality of health care
2. To find out the clinical quality indicator with regard to effective theatre utilization time on a scheduled day and thereby offering better utilization of theatre services and resources

MATERIALS AND METHODS

This audit was a retrospective analysis and an observational study conducted in a NABH accredited, ISO certified 1300 bedded tertiary teaching hospital PSG Institute of Medical Sciences and Research, Coimbatore. The audit study period was included for one year duration from 1st October 2017 to 30th September 2018. The elective operating list scheduled for the next working day was planned by the concerned operating surgeon by 3 pm the day prior to operation and the list is printed and displayed in the department. The operating list included the complete elective surgery list on the scheduled day and the cancellation list were maintained in a separate registers along with a detailed note mentioning the details of cancellation. Our hospital comprises of 10 operating room in the main Operation Theatre block involving surgeries with various specialities like General surgery, laparoscopic surgery, obstetrics and gynecology, orthopedic surgery and neuro surgery on all days; with a separate theatre in labor ward and 2 cardiothoracic theatre functioning exclusively separately. Speciality surgeries like pediatric surgery, ENT, plastic surgery, hepato-biliary surgery, surgical gastroenterology, urology and transplant surgery with allocation for three days in a week for elective surgery. The scheduled elective surgery operating duration list was included between 8 am and 5 pm in our institution, with exceptions working on Sundays and public holidays. We coined the cancellation of the elective surgery as any proposed surgery which was listed and planned the previous day; and subsequently not done on the scheduled day of surgery. The source of audit was the documentation maintained in cancellation records in the anaesthesia department and these data were analyzed. The most common cause for cancellation of surgery was categorized as Patient related, Pre operative (or Surgical) preparation related and Facility related factors. All the data were entered in the Microsoft excel spreadsheet and a Pareto chart was constructed to prioritize the reasons and analyzed using Epi info software version. Although the audit was done for improving departmental work under quality assurance, this study received ethical committee approval (Ref No: PSG/IHEC/2018/Appr/Exp/207/ Proposal No.18/202 dated 13.08.2018).

OBSERVATIONS AND RESULTS

Table 1: Cancellation of cases Month wise from October 2017 to September 2018

Month	Number Of Cases (n)	Cancelled Cases (n)	Case Cancelled (%)
October 2017	775	52	6.70
November 2017	900	70	7.77
December 2017	851	50	5.87
January 2018	754	38	5.03

DISCUSSION

The National Health Service (NHS), UK through its Modernization Agency Theater Program has defined case cancellation as those that occur after the patient has been notified of operation date[8]. Few define it as the procedures that were cancelled either on the day on which the surgery was scheduled, or cases which appeared in the definitive scheduled list but ultimately was not performed. Out of 10,306 patients during the scheduled period in our audit, 532 (5.16%) patients had cancellation on the elective list. Rakesh Garg *et al*[5,17] in a north Indian government hospital reported 30.3 % cancellation list followed by, Ezike *et al*[7] stated 25.3 % cancellations, Rajendra Kumar *et al*[16] in an government hospital showed 17.6 % cancellation, Abderrazak Sahraoui and Mohammed Elarref *et al*[2] observed 13.4 % and JimEnez *et al*[9] noted with 3.9 % as cancellation comparable to a study in a Jordanian hospital[11] with 3.6% cancellation on the elective list respectively. The cancellations at a teaching hospital in south india was found to be 4.4 % which was in accordance with our study (5.16%). In our audit, the frequency of cancellations was pronounced more in pre operative or surgical preparation related factors accounting for 265 patients (49.81%), followed by facility related factors in 142 patients (26.69%) and 125 patients (23.49%) in patient related factors respectively. On categorizing Surgical (or pre operative) preparation related factors which includes patients presenting with active respiratory infections, acute exacerbation of any medical conditions, electrolyte disturbances, uncontrolled blood sugar or blood pressure; the overall cancellation was maximum with abnormal laboratory values (21%) on the day of surgery. URI-related cancellations was reported by Palomero Rodriguez *et al*[13], however this decreased from 12.9% in 2001 to 7.2% in 2003 through enhanced communication of simple and appropriate information to parents resembling with 7.54% in our audit. Knox *et al* reported a significant reduction in medical-related surgical cancellations after the establishment of a preoperative assessment clinic (P = 0.013).[12] Patients unwillingness for surgery accounted for 53% with regard to patient related factors for cancellation of surgery. Patients not willing for surgery at the last moment prior to surgery were due to fear, unfavorable conditions existing in the family or unawareness about the importance of surgeries. Female patients who were menstruating on the day of surgery were also considered in our study. Study by Fayed *et al* showed that 9% of patients decided not to undergo elective surgery on the day of surgery[4]. Being a teaching medical institution, few reasons for lack of operating time such as teaching and training the junior residents and interns could not be avoided. There was no issues with administrative or logistic causes such as power failure in operating room, failure of air conditioners, availability of oxygen source, usage of anaesthetic drugs, availability of blood and blood products, suture materials, linen, supply of water, bed availability and hospital workers strike in our audit. Cancellation by Insurance sanctioning availed by government scheme and private insurance peaked maximum cause due to delayed clearance or failure of obtaining the insurance. In general, surgeons took longer than estimated time to finish the procedure and was especially true for less-experienced surgeons and trainees. Surgeons are sometimes too optimistic and aware of the long waiting lists, but they want to operate as many patients as possible. This reason can be avoided by a better internal organization of work as well as planned use of staff breaks and the adequate preoperative preparation of the patients. Patient non compliance regarding medication regimens. Schofield *et al*[18] reported bed availability and theatre time management as a main reason for cancellation; which was not an issue in our audit. Pandit JJ, Carry A[14] estimated that over-booking of operation list is the common cause for postponement due to waiting list pressures. Windokun *et al*[20] reported surgeon's un-availability as main reason. Dufek *et al*[3] recommended the improvement in protocol for pre-op patients' evaluation to address these problems. Most of the reasons for cancellation were debatable as an issue of health care quality and was avoidable by judicious scheduling of lists and careful planning by the team involved in surgeries. We justified with improving following recommendations in our institution :

- Calm, smooth, pleasant and noiseless pre operating assessment room can avoid missing major clinical findings
- Closed loop communication and good rapport with the patient helps to instill confidence preventing the patient's bias regarding the anesthesia and surgery
- Follow appropriate pre operative instructions to improve the health care system avoiding major issues on the day of surgery
- Alleviation of the psychological distress of cancelling the surgery
- Early start of the first case in the operating room
- Surgical patients were adequately counseled, optimized their medical condition, appropriate continuation of medications and obtained informed consent regarding all relevant procedures
- Inter departmental coordination in managing complicated and high risk cases
- Increased utility of operating time in the theatre complex during the working hours

- Following the medical ethics and to practice in accordance with the law

LIMITATIONS

Our study was related to inherent bias in categorizing the cancellation of cases due to varied reasons on behalf of multi factorial components leading to cancellation. The study was confined only to our institution and may not be standardized since the hospital policies varies in other teaching institutions.

CONCLUSION

Although cancellations were only 532 (5.16%) out of 10,306 patients of total elective surgeries, this can even be reduced by implementing and following the recommendations as per guidelines proposed, so that the potential causes can be avoided. To improve the better quality of life we recommend that the cancellations of surgeries can be reduced by improving pre operative assessment, requesting patient information on inter current illnesses between preadmission and surgery, better inter departmental coordination and adequate optimization prior to surgery, improving man power availability, availability of adequate resource sources and increasing the operation theatre utilization time to avoid cancellation of surgery on the scheduled day. Frequent conduct of audits, rectifying the pitfalls in the institution will definitely improve the better healthcare facility in the teaching hospital.

Infra umbilical surgeries

ABSTRACT

Background: Central neuraxial blockade is the most widely used form of regional anesthesia in surgeries involving abdominal, urological, obstetric, gynaecological and lower limb. The nerve blocking properties of the R and S-enantiomers were similar but that the S-enantiomer was less cardiotoxic. The aim of our study is to compare the efficacy and haemodynamic response between intrathecal hyperbaric 0.5% Bupivacaine with isobaric 0.75% Ropivacaine using Fentanyl as adjuvant in patients undergoing infra umbilical surgeries.

Materials and Methods: 60 patients of age group between 25 – 65 years belonging to American Society of Anaesthesiologist (ASA) 1 and 2 posted for general surgical, urological, orthopaedic and gynaecological procedures involving lower abdominal surgeries under spinal anaesthesia divided into two groups of 30 each and randomly allocated to one of the two below mentioned groups:
Bupivacaine group (Group B) n=30; Ropivacaine group (Group R) n=30

Observation and Results: Chi-square test and Student's 't' test were used to analyse the results. The sensory block in Bupivacaine group B was significantly higher compared to Ropivacaine group R attaining statistical significance. The 3 minutes motor block, incidence of hypotension was denser and higher in Bupivacaine group compared with Ropivacaine group. Incidence of bradycardia was not significantly different between the two groups. Although the onset of motor blockade was denser in Bupivacaine group, the total duration of motor blockade was similar between the groups.

Conclusion: We conclude from our study that 0.75% isobaric Ropivacaine produces similar duration of efficacy with stable haemodynamics, as compared with 0.5% hyperbaric Bupivacaine.

1. Introduction

Central neuraxial blockade is the most widely used form of regional anesthesia in surgeries involving abdominal, urological, obstetric, gynaecological and lower limb. The advantages being well established, widely accepted, ease of subarachnoid puncture and studies suggest that spinal anaesthesia may be superior to general anesthesia. The endocrine - metabolic response to surgery is blunted when spinal anaesthesia is employed compared to the response during general anaesthesia (GA).[1]

Various local anaesthetic agents such as cocaine, procaine, etidocaine, tetracaine, lignocaine, bupivacaine and ropivacaine were tried for sub arachnoid blockade. Bupivacaine was marketed as a long acting local anaesthetic, its advantages compared to Lignocaine being long duration of action and differential sensory-motor block; but untoward adverse effects like arrhythmias, prolonged duration of sensory and motor blockade require a need to overcome these problems. Hyperbaric 5% Lidocaine has been reported to be associated with transient radicular irritation following single-dose of spinal anaesthesia and is not being used much now-a-days.

In 1977, the propyl derivative of the pipecoloxylidides was less toxic than the butyl derivative (Bupivacaine). The nerve blocking properties of the R and S-enantiomers were similar but that the S-enantiomer was less cardiotoxic. Thus Ropivacaine a single (S) stereoisomer was chosen for further development.[2] Ropivacaine, structurally resembling Bupivacaine, is a relatively new amino-amide local anaesthetic agent, similar in chemical structure to Bupivacaine, having various advantages like early onset and shorter duration of action and having lesser cardio toxicity. Ropivacaine relieves the psychological distress of being immobile for a longer period of time after lower abdominal surgeries. In view of the above context, the present study was undertaken to compare these two drugs.

2. Aim

The aim of our study is to compare the efficacy and haemodynamic response between intrathecal hyperbaric 0.5% Bupivacaine with isobaric 0.75% Ropivacaine using Fentanyl as adjuvant in patients undergoing infra umbilical surgeries.

3. Materials and Methods

A study titled "Comparing the efficacy and haemodynamic response between intrathecal hyperbaric 0.5% Bupivacaine with isobaric 0.75% Ropivacaine using Fentanyl as adjuvant in patients undergoing infra umbilical surgeries" was done in PSG Institute of Medical Sciences and Research, Coimbatore, after obtaining institutional human ethical committee clearance and informed written consent from all the patients who participated in this study.

This is a randomized, single blind study where the person assessing the response (observer) was blinded to the group the patient belonged to and the person administering the spinal was aware of the drug he is administering. 60 patients of age group between 25 – 65 years belonging to ASA 1 & 2 posted for general surgical, urological, orthopaedic and gynaecological procedures involving lower abdominal surgeries under spinal anaesthesia were included in the study.

60 patients were divided into two groups of 30 each and randomly allocated to one of the two below mentioned groups as Bupivacaine group (Group B) n=30 and Ropivacaine group (Group R) n=30. The Inclusion criteria in our study includes ASA Grade 1 and 2 patients, age ranging from 25 to 65 years, procedures done under spinal anesthesia and patients posted for general surgery, urological, orthopaedic and gynaecological procedures expected to last not more than 3 hours. Exclusion criteria includes patient denial, absolute contraindication for regional anesthesia, inability to communicate with the patient, combined spinal and general anesthesia, pregnancy, patchy or failed spinal.

All patients were premedicated orally with Tablet Pantoprazole 40 mg and Tablet Alprazolam 0.25 mg the previous night and 2 hours prior to surgery. In the receiving room an 18G intravenous cannula was inserted and an infusion of Ringer's lactate solution started at 2ml/ kg/ hr. On arrival in the operation theatre Electocardiogram, Non invasive blood pressure and pulsoxymeter were connected as pre-induction monitors and recording of these parameters started after noting the baseline values. The patient was placed in lateral position, sterile painting and draping done and spinal puncture was made in L_3L_4 interspace with 26G Quinke spinal needle. After establishment of free flow of Cerebrospinal fluid, intrathecal administration of 2.6ml 0.75% Ropivacaine with Fentanyl 25 μg or 2.6ml 0.5% Bupivacaine with Fentanyl 25 μg was given over a period of 30 seconds as per the random allocation and patient was turned supine post spinal injection. No tilt was given to any patients.

The haemodynamic parameters were monitored. Hypotension when Systolic Blood Pressure recorded < 90mmHg was treated with Intravenous (IV) crystalloids and Vasopressors Injection Ephedrine or Mephentremine 6 mg IV bolus, as and when needed if there was persistent hypotension. Bradycardia was noted when the Heart rate was <50 beats per minute and treated with Injection Glycopyrrolate 0.02mg per kilogram IV bolus, as and when needed. The density and recovery of the motor blockade were monitored using Bromage scale and the height of sensory level was determined bilaterally using loss of sensation to pin prick.

Description of the bromage scale

Grade	Criteria	Degree of block
I	Free movement of legs and feet	Nil (0%)
II	Just able to flex knees with free movement of feet	Partial (33%)
III	Unable to flex knees, but with free movement of feet	Almost complete (66%)
IV	Unable to move legs or feet	Complete (100%)

Assessment of motor blockade was done three minutes after intrathecal injection, after completion of surgery, every 15 minutes till the patient completely recovers, during discharge in recovery room.

3.1. Statistical analysis

The observations and results were compiled and analysed by Chi-square test and Student's 't' test to see if there was any significant difference in the onset and density of motor blockade between the two groups. Haemodynamic parameters like hypotension, bradycardia, nausea, vomiting and ventricular arrhythmias (ectopics) were also compared and analysed statistically.

Qualitative variables like sex, ASA gradings, incidence of hypotension, bradycardia, arrhythmia, nausea and vomiting were compared between the two groups using Chi-square test and Quantitative variables like age, weight, height, duration of surgery, Bromage score and total duration of motor blockade between the two groups were compared by using Student's 't'test.

4. Observation and Results

Table 1 to Table 5.

5. Discussion

The first clinical report of spinal anaesthesia was made in the year 1899 by Dr August Bier, who described the intrathecal administration of cocaine.[3] The greatest challenge of the technique is to control the spread of the local anaesthetic through the cerebrospinal fluid (CSF) in order to produce a block that is adequate for the proposed surgery without producing a needless extensive spread.

Subarachnoid block is a commonly employed anaesthetic technique for performing lower abdominal and lower limb surgeries. It is a safe, inexpensive and easy-to-administer technique which also offers a high level of post–operative satisfaction with good pain relief to the patients. The technique is simple, has rapid onset and the risk of general anaesthesia including mishaps due to airway management are avoided by this technique.

The selection of the local anaesthetic to be used for spinal anaesthesia is usually based on the expected duration of surgery and need for early patient discharge. Though cardiotoxicity is not a concern in subarachnoid block, the quality of sensory blockade, motor blockade, hemodynamic changes and side effect profile are some considerations in selecting a drug for spinal anaesthesia.

The use of long acting agents is associated with a lower risk for transient neurologic dysfunction.[4–7] Bupivacaine is the local anaesthetic used routinely for surgeries because of its high potency and minimal neurological symptoms. The efficacy and safety of intrathecal administration of both plain and hyperbaric solutions of Ropivacaine have been evaluated in different clinical settings including orthopaedic,[8] urological surgery,[9] caesarean section and labour pain.[10,11]

Ropivacaine, a S-enantiomer of Bupivacaine is being increasingly used for spinal anaesthesia and the advantages claimed are shorter duration of motor block with similar sensory block properties and lesser cardiotoxic property compared to Bupivacaine; thus it minimizes the psychological discomfort of being immobile for a long time.

In our study, a single blinded clinical trial was undertaken to compare the duration and density of motor blockade and haemodynamic instability between intrathecal hyperbaric 0.5% Bupivacaine and isobaric 0.75% Ropivacaine using Fentanyl as adjuvant in 60 patients between the age group of 25 to 65 years of age either gender, belonging to ASA Grade I and II scheduled for general surgical, gynaecological and orthopaedic procedures (Infra umbilical surgeries).

Demographic data such as age, sex, weight and height between the two groups were comparable and there was no statistical significance since p value was > 0.05 between the two groups. The duration of surgery was 57.67±34.16 mins in Ropivacaine group and 48.17±19.49 mins in Bupivacaine group and p value 0.191 was found to be statistically insignificant.

In our study, maximum cephalad spread is assessed after 3 minutes of injection of local anaesthetic by using loss of sensation to pinprick T10 level. In Bupivacaine group (B) the mean sensory level was T4 to T6 (4.93± 0.828) which is higher when compared to Ropivacaine group (R) where the mean level was T5 to T8 (5.70± 1.055). This is in contrast with the study conducted by Jean-Marc Malinovsky et al[12] (Mean level for Bupivacaine: T7 & Ropivacaine: T9), Whiteside et al[13] (Mean level for Bupivacaine: T5 & Ropivacaine: T7). A study by Koltka k et al[14] reported spread of sensory block was higher in Bupivacaine than Ropivacaine. we infer that the maximum cephalad spread or height of sensory level was significantly lower in Ropivacaine group in out study.

The 3 minutes motor block was denser in Bupivacaine group than Ropivacaine group with statistical significance. The difference in motor blockade between both the group was statistically significant since p < 0.05 and this score was comparable with the study by Mantouvalou et al[15] & Erturk E et al[8] who reported onset of motor block was significantly faster in Bupivacaine group. The total duration of motor blockade was similar in both the groups and there was no statistical significant difference in the discharge time of the patient.

Miller C G et al[16] determined level of sensory (cold sensation) and motor blockade (Bromage) and measured heart rate, blood pressure and oxygen saturation. With the exception of maximum spread of sensory blockade, there was no difference with regard to demographics, sensory or motor blockade and hemodynamic variability.

Mc Namee DA et al[17] recorded the onset and duration of sensory block at dermatome level T10, maximum upper and lower spread of sensory block and the onset, intensity and duration of motor block. Onset of motor and sensory block was rapid with no significant differences between the two groups. But the median duration of complete motor block (modified Bromage Scale 3) was significantly shorter in the Ropivacaine group compared with the Bupivacaine group (220±22.67 versus 228±32.09 mins) in our study.

Y.Y.Lee et al[18] used Fentanyl 15 μg as an adjuvant in both Ropivacaine and Bupivacaine group and achieved sensory block to the T10 dermatome or higher at 15 min after intrathecal injection revealing the duration of complete

Group R	220±27.67			

motor block shorter in the Ropivacaine group compared with the Bupivacaine group. But in our study we used 25 μg as an adjuvant and had similar results, which was also similar to Erturk et al[8] studies who had used 20 μg fentanyl with Ropivacaine or Bupivacaine.

Koltka K et al[14] performed his study in Ropivacaine and Bupivacaine with Fentanyl 50 μg to make 3 ml total spinal fluid volume. The primary outcome, the duration of motor block, was significantly shorter in the Ropivacaine group as compared with our study. No patient had pruritus, eczema, shivering, respiratory depression intraoperativelyNausea and Vomiting

5.1. Definition

Nausea is the sensation of being about to vomit. Vomiting, or emesis, is the expelling of undigested food through the mouth. ..... Click the link for more information. In our study, none of the patient had residual neurological deficit, post-dural puncture headache or transient neurological symptoms at the postoperative follow-up.

In our study the hypotension was a significant statistically in consistent with the study conducted by Lopez-soriano F et al,[5] Whiteside et al,[19] Mantouvalou et al[6] & Erturk E et al.[8] In their studies it is shown that there is increased incidence of hypotension and higher requirements of vasoactive drugs in Bupivacaine group than in Ropivacaine group of patients. This can be attributed to the higher cephalad spread of hyperbaric Bupivacaine causing more sympathetic blockade than isobaric Ropivacaine. Incidence of hypotension is higher in Bupivacaine group compared to Ropivacaine group.

The increased incidence of nausea and vomiting in group B can be explained due to higher incidence of hypotension and maximum cephalad spread. The study by Mantouvalou et al[6] showed occurrence of nausea and vomiting is equally distributed between the two groups, thereby not agreeing with our study.

In our study, the incidence of bradycardia is similar between two groups. 9 patients in each group had bradycardia and were treated with anti-cholinergics. This is in contrast with the study done by Kessler P et al,[12] Boztug N et al[2] and Koltka k et al[10] which reported no significant bradycardia between the two groups (Bupivacaine and Ropivacaine). Regarding intra-op arrhythmias only 2 patients in Bupivacaine group had ectopics and was not statistically significant.

In our study, total duration refers to the time after intra-thecal injection to the complete recovery of the patients from motor block. In Bupivacaine group, the mean duration was 228 minutes whereas in ropivacaine group it was 220 minutes. P value is 0.305 and is statistically insignificant. This is in complete agreement with the studies done by Gautier PE et al,[19] Liu et al,[20] Jean-Marc Malinovsky et al[7] andKessler P et al[12] compared isobaric Ropivacaine and Bupivacaine, which showed similar motor blockade between the two groups.

In our study, there was no failed spinal cases and there was no need for supplementation with general anesthesia.

6. Conclusion

We conclude from our study that 0.75% isobaric Ropivacaine produces similar duration of motor blockade with stable haemodynamics, as compared to 0.5% hyperbaric Bupivacaine producing denser motor blockade with hypotension when Fentanyl is used as adjuvant in both the groups.

Subarachnoid blockade

ABSTRACT

Background: The most common nagging and inconveniencing complication of spinal anesthesia is intra operative shivering. Central neuraxial blockade blunts the thermoregulatory mechanism by restricting vasoconstriction, resulting in shifting of central heat to the periphery from the trunk. Various pharmacological and non pharmacological methods are used for the control of intraoperative shivering.
Aim: The aim of our study was to compare the efficacy of Tramadol, Ketamine and Dexmedetomidine in the prevention of intra operative shivering in patients undergoing surgeries under subarachnoid blockade.
Materials and Methods: 90 patients of age group between 20 to 65 years belonging to ASA 1 and 2 posted for elective surgery under spinal anaesthesia will participate in this study. The patients were randomly allocated into 3 groups of 30 each and were named as by computer generated random table number. Group T received Tramadol 0.5 mg/kg in 100 ml NS over 10 – 15 mins**;** Group K Ketamine 0.25 mg/kg in 100 ml NS over 10 – 15 mins and Group D Dexmedetomidine 0.5 μg/kg in 100 ml NS over 10 – 15 mins.
Observation and Results: Data were statistically analysed with the SPSS version 22.0 software using two-sided unpaired t-test and Chi-square test. A repeated measure of ANOVA was applied for the three groups to know the with-in subject variability in prevention of shivering following subarachnoid blockade and p value < 0.05 was considered to be significant.
Conclusion: The conclusion of our study is that Dexmedetomidine at the dose of 0.5 μg/kg decreases effectively in the prevention of intra operative shivering in patients undergoing surgery under subarachnoid blockade when compared with Tramadol and Ketamine.

1. Introduction

Subarachnoid blockade or spinal anesthesia is the commonest regional anesthesia technique performed for surgeries involving lower abdomen, pelvis and lower limb extremities. The most common nagging and inconveniencing complication of spinal anesthesia is intra operative shivering which is very distressing experience causing physiological stress both to the patients as well as the perioperative physicians and operating surgeon.

Shivering is the involuntary recurrent muscle action of skeletal muscles, is a normal thermo regulatory mechanism and the reported occurence is wide varied ranging from 40 – 70 % from the literature.[1,2] Central neuraxial blockade blunts the thermoregulatory mechanism by restricting vasoconstriction, resulting in shifting of central heat to the periphery from the trunk (below the level of subarachnoid block).[3,4]

Hypothermia worsens in perioperative period insulting in major adverse cardiac events and it doubles to triples the requirement of oxygen consumption, rising the metabolic

rate by 100 to 600%, thereby increasing the catecholamine production resulting in lactic acidosis, which is very detrimental in poor cardio respiratory reserve patients.[5] Shivering can produce motion artifacts in anaesthesia monitors showing erroneous values.[2]

Various pharmacological and non-pharmacological methods are dealt for the management of intraoperative shivering.[5] Pethidine have been used for many years as the treatment modality for shivering.[6] In our study, we have used Tramadol, Ketamine and Dexmedetomidine to study the effect of preventing the intra operative shivering in patients undergoing surgery under spinal anesthesia.

2. Aim and Objectives of the Study

The main aim is to compare the efficacy of Tramadol, Ketamine and Dexmedetomidine in the prevention of intra operative shivering in patients undergoing surgeries under subarachnoid blockade. This study also focuses on effects of drugs on intra operative haemodynamics, monitoring the temperature, comparing the level of sedation and other undesirable effects.

3. Materials and Methods

A study titled "Comparing the efficacy of Tramadol, Ketamine and Dexmedetomidine in the prevention of intraoperative shivering in patients undergoing surgery under subarachnoid blockade" was done in PSG Institute of Medical Sciences & Research, Coimbatore. This study was done after obtaining Institutional Human ethics committee clearance from the institution and informed written consent from all the patients who participated in the study. It is a prospective randomised control study and the sample size was calculated using 95% confidence interval and power of the study being 80%. The sample size was 30 in each group with allocation ratio being 1:1:1.

90 patients of age group between 20 to 65 years corresponding to ASA 1 and 2 posted for elective surgery under subarachnoid blockade will participate in this study. The patients were assigned at random with 30 participants in each group and were called as Group T receiving (Tramadol 0.5 mg/kg), Group K (Ketamine 0.25 mg/kg) and Group D (Dexmedetomidine 0.5μg/kg). Patients were randomly allocated to one of the three groups by computer generated random table number (numbered from 1 to 90) and the corresponding number was represented with the concerned group of the study drug. It is a double blinded study and the performer is also unaware of the group of the drug till the end of the trial.

Patients aged between 20 – 65 years belonging to ASA 1 and ASA 2 undergoing elective surgery under spinal anaesthesia < 150 minutes duration with surgeries involving lower abdomen, urological, gynaecological, orthopaedic and lower limb extremity was considered the inclusion criteria for our study. Patient denial, absolute contraindications for subarachnoid blockade, inability to communicate with the patient, combined spinal and general anaesthesia, known drug intolerance or proven allergic reactions to study drugs, baseline core temperature >37.5ºC or < 35.5ºC, blood transfusion during surgery, pregnancy and lactating mothers were excluded from the study.

Routine pre-operative assessment was done and the patients were kept nil per oral from 10 pm the day prior to surgery. Informed written consent was obtained. All the patients were pre-medicated with tablet Pantoprazole 40 mg and Alprazolam 0.25 mg orally the day prior to surgery at night and Pantoprazole 40 mg at 6 am on the morning of day of surgery. Patients were assigned individually to one among the three groups by computer generated random table number.

Group T: Tramadol (n=30) 0.5 mg/kg in 100 ml NS over 10 – 15 mins

Group K: Ketamine (n= 30) 0.25 mg/kg in 100 ml NS over 10 – 15 mins

Group D: Dexmedetomidine (n=30) 0.5 μg/kg in 100 ml NS over 10 – 15 mins

In the pre operative room, an 18G intravenous cannula was inserted and an infusion of Plasmalyte solution started at 2ml/ kg/ hr. On arrival in the operation theatre, pre induction monitors like ECG, NIBP and SpO_2 were connected and monitoring of these parameters started after noting the baseline values. The operating room ambient was continued at 25ºC. The patient was placed in right lateral posture and under standard universal precautions, sterile painting draping done. After skin infilteration with 2 ml of 2% Lignocaine, spinal puncture was attempted in L_3L_4 or L_4 L_5 interspace with 26G Quincke spinal needle. After establishment of free flow of CSF, intrathecal administration of 15mg 0.5% Bupivacaine Heavy was given over a period of 30 seconds as per the random allocation and patient was turned supine post spinal injection. No tilt was given to any patients. The study drug was infused by the blind observer. Oxygen delivered at a rate of 5L/min using Hudsons mask and injection Ondansetron 4 mg was supplemented to all patients. Surgery was commenced when the spinal blockade level reached T7/T8 and Patients were observed for 120 minutes or until the end of the surgery; considering the longer duration among them.

The haemodynamic parameters were monitored. Hypotension (Systolic BP <90mmHg and Diastolic BP < 50 mm Hg was treated with intravenous fluids ± vasopressors – Injection Ephedrine or Mephentremine 6 mg IV bolus SOS. Bradycardia (Heart rate <50/min) was treated with injection Glycopyrrolate 0.004 mg/kg IV bolus SOS. Intra operative temperature monitoring and level of sedation was also assessed. The patients who developed shivering intra operatively were supplemented with injection Pethidine 0.25 mg/kg as rescue drug.

Shivering was observed by a grading system as described by Wrench

Grade 0 : No shivering

Grade 1 : One or more of the following – Piloerection peripheral vasoconstriction peripheral cyanosis but without visible muscle activity.

Grade 2 : Visible muscle activity confined to one muscle group.

Grade 3 : Visible muscle activity in more than 1 muscle group.

Grade 4 : Gross muscle activity involving the whole body Sedation was assessed by a four point scale as per Filos et al.

Grade 1 : Awake and alert.

Grade 2 : Drowsy, responsive to verbal stimuli.

Grade 3 : Drowsy, arousable to physical stimuli.

Grade 4 : Unarousable.

Data were statistically analysed with the SPSS version 22.0 software using Chisquare and ANOVA. Baseline characteristics were presented as mean ± S.D. Two-sided unpaired t-test and Chi-square test was applied to analyze the data and p value less than 0.05 were considered as significant. A repeated measure of ANOVA was applied for the three groups to know the with-in subject variability in prevention of shivering following subarachnoid blockade and $p < 0.05$ was considered to be significant.

4. Result and Discussion

Homeothermic mammals maintain a uniform isothermal characteristics internally and the central temperature varies between 36.5℃ and 37.5℃ in humans. Anterior hypothalamus incorporates the thermal inputs from various tissues of the body and differentiates peripheral information with a set point to reach or approach the temperature lower than this set point; resulting in responses to warm the body, while higher temperatures will initiate reflexes to cool the body.[2]

Autonomic thermoregulation is attenuated during central neuraxial blockade resulting in decrease in central or core temperature. Central neuraxial blockade decrease the shivering and vasoconstriction thresholds cephalad to the level of the neuraxial block by 0.6^0C. The concept of postanaesthesia shivering resembling like seizures or tremors remains still unproven. The postulates suggest that the decrease in reflex response in the descending spinal reflexes due to central neuraxial blockade could be the cause for tremors.[3] The two variants of tremor patterns noted could be either a tonic pattern resembling normal shivering with 4 – 8 cycle/min waxing and waning model or a phasic pattern with 5 to 7 Hz shattering pattern similar to pathologic clonus response. The net effect of this tonic and phasic patterns are due to thermoregulatory responses superseding with drop in temperature and arteriovenous shunt vasoconstriction.[7]

The consequences of hypothermia and shivering includes reversible coagulopathy, increased blood loss necessating blood transfusion, impaired wound healing, delayed drug metabolism, altered mental status, cardiac arrhythmias and ischaemia, increased risk of infection, myocardial oxygen consumption and basal metabolic rate.[4]

Treatment of shivering includes both non pharmacological methods like use of forced air warmers, warmed blankets, warmed intravenous fluids, use of plastic sheets and surgical drapes and maintaining warmed humidified operating room; and pharmacological methods that includes usage of drugs like pethidine, tramadol, meperidine, clonidine, ketamine, magnesium sulphate, dexmedetomidine, alfentanyl and nefopam.

In our study, extremities of population like paediatric, pregnancy and geriatric patients were not chosen due to variable confounding factors in relation to their age. Demographic profile in all the groups are comparable but statistically insignificant.

The primary objective in our study was about the drugs in causing decreased incidence of shivering in the desired study group population.[8] Dexmedetomidine had better prevelance in decreased incidence of intra operative shivering compared to Tramadol and Ketamine as only one patient had shivering at 30 minutes following subarachnoid blockade in close equivalent with Lim fern et al[9] studies with similar outcome. 6 patients at 15 minutes and 11 patients at 30 minutes in Tramadol group had the highest incidence of shivering with shivering grade more than two and showed statistical significance with p value 0.045 and 0.003 respectively. Only one patient in Ketamine group had shivering at 30 mins. Mittal et al[10] in his study compared dexmedetomidine with tramadol supplementing the drug after the onset of shivering and concluded that both drugs were equally efficacious and dexmedetomidine had a faster onset of action. Bozgeyik et al[11] used dexmedetomidine and tramadol compared with a placebo and commented both drugs were equally similar in the prevention of shivering. Dhimar et al.[12] in his study used Tramadol 100 mg in all patients which showed variation in their results while comparing with our study. Though the shivering was seen in all the groups at 45 and 60 minutes, with varying grades statistically it was insignificant. Statistical insignificance was noted at 90 and 105 mins since none of the patient had shivering. Prophylactic low dose Ketamine was found to be effective in preventing postoperative shivering in Gecaj-Gashi et al[13] and similar results were seen in our study also. Yong shin et al[14] in their study used 0.75 with 1 μg/kg and found to be effective against 0.5 μg/kg in our study. Genopadhyay et al.[15] concluded that pethidine, tramadol and ketamine effectively prevent shivering following spinal anaesthesia, prove ketamine was smart and effective alternative over two drugs due to the better haemodynamic stability and less adverse effect.

Dal et al,[16] in their study found that the number of patients shivering on arrival in the recovery room, and at 10 and 20 min after operation were significantly less in Groups P (pethidine 20 mg) and K (ketamine 0.5 mg kg) than in Group S (normal saline) and concluded that use of Prophylactic low-dose ketamine was very useful in preventing postoperative shivering.

The secondary objective of the study was sedation[17] and all our used study group drugs can produce drowsiness to a certain extent; hence none of the study population were supplemented with sedatives, hypnotics or anxiolytics. Dexmedetomidine showed good sedation score of 3 within 5 minutes in majority of the population comfortably lasting for about 90 minutes without producing haemodynamic disturbances comparing with other two drugs. Initiation of sedation was slow in onset, peaking around 15 minutes for a sedation score of 2 in 40% in Tramadol group. Ketamine had a sedation score superior to tramadol, almost similar

to dexmedetomidine with peak effect within 15 minutes producing good sedation score but lacked in awakening state. Mittal et al[10] in his studies concluded sedation due to dexmedetomidine provides additional comfort to the patient. Bozgeyik et al[11] also reported similar results of sedation within 5 minutes about dexmedetomidine in his study. Usta B et al[18] showed higher sedation scores in dexmedetomidine group providing conveniencing sedation for the patient. Dexmedetomidine sedated population followed oral commands and maintained in a tranquil state as seen in Elvan et al[19] studies. Bradycardia was reported in 3 patients and hypotension in 2 patients only in dexmedetomidine group necessating conservative treatment but proved statistically insignificant similar to Usta B et al.[17] There was no incidence of respiratory depression, nausea, vomiting and headache in all the three groups. No statistical significance was noted in the axillary temperatures measurement in all the 3 groups.

The limitations noted in our study are ideal Dexmedetomidine dose needs to be evaluated to produce negligible haemodynamic instability.[20] Tramadol used at 0.5mg/kg seemed to be inconclusive necessating the work up of optimal dose to prevent shivering.[21] Dosage of 0.25mg/kg Ketamine as studied by Kose et al.[22] was used in our study and needs reconsideration.

To summarise Dexmedetomidine was more effective in the prevention of shivering when compared with Ketamine and Tramadol with an added advantage of adequate reliable sedation and stable haemodynamics without any detrimental adverse effects.

5. Conclusion

The conclusion of our study is that Dexmedetomidine at the dose of 0.5 μg/kg decreases effectively in the prevention of intra operative shivering in patients undergoing surgery under subarachnoid blockade when compared with Tramadol and Ketamine.

ABSTRACT

Background and Aims: To compare and evaluate the efficacy of Single Level Paravertebral Block (SLPVB) with Caudal Block (CB) using 0.2% ropivacaine. **Materials and Methods:** A prospective study was performed for 40 children aged 2-8 years, undergoing paediatric inguinal hernia repair. They were divided into 2 groups, of 20 patients each, and SLPVB or CB was administered. They were followed up for 24hours and assessed for efficacy of the block in terms of duration of analgesia and quality of block as assessed by FLACC score. The amount of rescue analgesia used, parent satisfaction, and complications if any were also noted. The data collected was analyzed using SPSS software version 17 and a P value of <0.05 was considered significant and appropriate tests were applied. **Results:** The mean duration of action was found to be 1001.25±564.34 minutes (Median 1440 and IQR 975 minutes) in CB and 1440 minutes (Median 1440 IQR 0) in the PVB. This was statistically significant (P value = 0.03). The efficacy of the block as assessed by the FLACC score was comparable in the two groups. Rescue analgesia was required in 8 patients in the CB as compared to none in the PVB. The parent satisfaction levels were also significantly higher with PVB as compared to CB. No complications were noted with PVB. Failure of block occurred in 1 patient with CB, and there was complaint of urinary retention in 3 patients in the same group. **Conclusion:** SLPVB has been demonstrated to be superior to CB to provide postoperative analgesia children undergoing inguinal hernia surgery.

Key words: Analgesia, Caudal, Inguinal, Lumbar, Paravertebral, Ropivacaine

INTRODUCTION

Introduction of regional anaesthetic techniques into modern pediatric anaesthesia has revolutionized pain management. Regional anaesthesia also reduces general anaesthesia requirement, thereby reducing the potential risks associated with deeper planes of anaesthesia[1].

Surgeries through inguinal approach like orchidopexy, orchidectomy and especially inguinal hernia repair are fairly common surgeries in paediatric population. This type of surgery can cause significant discomfort postoperatively and CB is often used to provide pain relief[2]. However single shot CB has the disadvantage of short duration of action with more children needing supplementary analgesia in the immediate postoperative period.

Paravertebral block has been used for postoperative analgesia in children since1992. It provides excellent pain relief following both continuous and multi-level nerve stimulator – guided techniques[4]. Through this study we evaluated if a single level, single injection paravertebral block can provide longer duration of analgesia with lesser requirement to supplement analgesia than single shot caudal block for children undergoing inguinal surgery.

This study compared the effect of caudal block versus SLPVB using 0.2% Ropivacaine following inguinal surgery in children in terms of postoperative analgesia and complications encountered during the study.

MATERIALS AND METHODS

This prospective randomized study was conducted in a tertiary care Centre and Institutional ethics committee clearance was obtained.

Forty Children of the age group of 2 years to 8 years, posted for inguinal hernia repair surgery were enrolled for the study over a period of 1 year. Written informed consent was taken from the parents of the children.

Inclusion Criterion included children who were American Society of Anaesthesiologists (ASA) grade 1 and posted for inguinal hernia surgery. Children with history of allergy to local anaesthetics, coagulation abnormality or bleeding disorders or with infection at the site of the block or any abnormality or disease of the spine were excluded from the study.

A detailed pre anaesthetic check up was carried out in all the cases.

Patients were randomly allocated by computer generated random tables into two groups of 20 patients each namely, group P, where SLPVB was administered and group C, where caudal block was administered.

Before the surgery, premedication was done with oral midazolam (0.5mg/kg). Patient was taken up in the operative room and standard monitoring devices (electrocardiogram, pulse oximetry and non invasive arterial blood pressure) were attached to the patient. Anaesthesia was induced with 6-8 % sevoflurane by facemask and maintained with N2O:O2 50:50 in 0.5 to 2.5% sevoflurane. After securing intravenous access injection fentanyl (2mcg/kg) was administered and appropriate size Proseal LMA was inserted according to the age of the patient and connected to Mapleson F modification of Ayre's T piece. No neuromuscular blocking drugs were given and the spontaneous ventilation was assisted as required. Fluid administration was as per standard protocol.

All patients in group C received CB. As per the technique mentioned by Suresh et. al[5], with the child in lateral position, flexion of hips was done. Sacral cornua was located either by palpating near the cephalad margin of the gluteal crease or by palpating the posterior superior iliac spine and taking the line between them as one side of an equilateral triangle. The depression inferior to the cornua, that is, the sacral hiatus was then identified and caudal needle inserted at an angle of 45 degrees. While advancing the needle a decrease in resistance to needle insertion was felt as it pierced the sacrococcygeal membrane. At this point 0.2% ropivacaine (1ml/kg) was given after aspiration.

Patients in-group P were given PVB as per the technique described by Berta et al[6]. With the patient in lateral decubitus position, and under all aseptic precautions, needle insertion was made at an easily palpable second lumbar vertebrae (L2) lateral to the spinal process with the distance from the midline being about 1-2cm as per the formula given by Lonnqvist et. al[7],. A 19 gauge epidural needle was inserted perpendicular to the skin in all planes until contact with the transverse process was made. The needle was then withdrawn to the subcutaneous tissue and angled to walk off the cranial edge of the transverse process. The needle was then advanced under the transverse process and the paravertebral space identified by loss of resistance to air. After aspiration, a bolus of 0.2ml/kg ofropivacaine (0.2%) was injected.

After completion of the surgery, 100% oxygen was administered and proseal removed. In both the groups, assessment was done at 30mins, 1hour, 1hour 30mins, 2, 4, 8, 12 and 24 hours in postoperative ward by an independent observer who was blinded to which group the patient belonged.

Complications were noted and compared in the above two groups.

Efficacy of the block: Assessed by duration of analgesia and FLACC SCORE Face, Legs, Activity, Cry and Consolability (FLACC) score[8] was used to evaluate the effectiveness of the block (supplementary Table 1).

Table 1: Age and weight distribution in the two groups (C = caudal group, P = paravertebral group)

Groups	Mean Age (years)	Mean Weight(kg)
Group C	5.60 ±2.46	17.15±7.15
Group P	4.90± 2.13	15.50±4.84
C VS P (P value)	0.171(NS)	0.199(NS)

Rescue Analgesia: The time and required dose of rescue analgesia was noted and compared. If a FLACC score >2 were recorded, the child was first managed by non-pharmacological means (tactile stimulation, change of position, warming etc). If no response was noted within 5-10 minutes, intravenous tramadol (1mg/kg) was administered. Patients were also attended whenever the child experienced pain even if that was not the assessment time of the study and analgesia was provided as per the protocol. If rescue opioid was needed within the first two postoperative hours, the block was considered a failure.

Parental satisfaction to treatment given was evaluated based on the child's comfort and activity level. Parents were asked to rate their degree of satisfaction and scored as very satisfied (3), acceptably satisfied (2), somewhat satisfied (1) or dissatisfied (score 0).

Any events like bladder hesitancy, postural hypotension, prolonged motor blockade leading to delayed ambulation, epidural spread or any other of the rare complications like nerve injury, intravascular injectionand pneumothorax were noted.

Researchers have recorded the mean duration of analgesia in C group as 4.52±2.02 hours as compared to 21.67±5.61 hours in the P group[3,9,10]. Assuming these as reference values, the minimum required sample size at 5% level of significance and 95% power is 3 patients in each group. We have taken 20 patients in each group considering the influx of patients in our hospital and the duration of study.

For quantitative data (pain score, parent satisfaction score), for comparison b/w the two groups, difference between the two means was observed by t-test for normally distributed data and Mann Whitney test (non parametric) for non normal distributed data.

Chi square or Fischer test was used for computing consumption of analgesics and other categorical variables.

RESULTS

A total of 40 patients were enrolled, 20 in each group and all the patients were included and analyzed.

The data collected was analyzed using SPSS statistical software version 17 and p-value<0.05was considered statistically significant. A total of 40 patients were studied with 20 patients in each group. The incidence of inguinal hernia was found to be more in males as compared to females and more common on the right side as compared to the left.

All the subjects were ASA grade 1. The two groups were comparable in terms of age and weight (Table 1).

The mean duration of action, as determined by the time to rescue analgesia was found to be 1001.25 ±564.34 minutes (Median 1440 and IQR 975 minutes) and1440 minutes (Median 1440) in the paravertebral group (Patients were followed up only for 24hrs) and this difference was found to be statistically significant (P value = 0.03) by Mann Whitney U test.

The efficacy of the block as assessed by the FLACC score was comparable in the two groups (Table 2).

Rescue analgesia was required in 8 patients in the caudal group as compared to none in the paravertebral group. This was statistically significant (P = 0.003). Rescue was provided with inj. Tramadol 1mg/kg i.v. None of the patients required rescue analgesia for more than once in 24 hrs.

In PVB group, 90% parents were completely satisfied with the postoperative comfort of their children compared to

Table 2: Comparison of FLACC score between the two groups at different time intervals

FLACC score median (IQR)	30min	1hr	1.5hr	2hr	4hr	8hr	12hr	24hr
C	0 (1.5)	0 (0)	0 (0)	1 (1)	1 (1)	1 (1)	0 (0)	0 (0)
P	0 (0)	0 (0)	0 (1)	0 (0)	0 (0)	0 (0)	0.5 (0.5)	0 (0)
C vs. P (p-value)	0.18	0.41	0.50	0.20	0.44	0.09	0.49	0.99

Group C: caudal epidural block group; Group P: paravertebral block group

only 45% in the CB group (Table 3). This was statistically significant (P = 0.011)

Table 3: Comparison of parental satisfaction score between the two groups

Parent satisfaction score	C		P	
	Frequency	%	Frequency	%
0 (dissatisfied)	0	0	0	0
1 (somewhat satisfied)	4	20	0	0
2 (acceptably satisfied)	7	35	2	10
3 (very satisfied)	9	45	18	90
Total	20	100	20	100
Mean±S.D	2.25±0.79		2.90±0.31	
p-value	0.01			

No complications were noted in the paravertebral group. Failure of block occurred in 1 patient in the caudal group, and there was complaint of urinary retention in 3 patients in the same group. No other complications with the local anaesthetics or blocks were noted.

DISCUSSION

Inguinal hernia repair is the most common surgery performed worldwide and has the potential of being performed on an outpatient basis. The spectrum of regional anaesthetic techniques extend from CB and lumbar epidurals[1] to various other techniques like combined ilioinguinaliliohypogastric[4] nerve block, field blocks to wound infiltration with local anaesthetic agents in children.

CB is an established technique for providing postoperative analgesia. The technique of CB is easy to perform, however large volumes of drug are required and there is always a risk motor paralysis, subarachnoid block, urinary retention and failure of block even in experienced hands.

This prospective study was undertaken to compare CB and PVB with respect to the effectiveness and duration of block and the complications of the two techniques. The results shows that caudal as well as PVB are effective in decreasing postoperative pain. We found that there was a significant increase in the duration of postoperative analgesia in the group treated with PVB compared to those undergoing caudal. All this was achieved with a dose of local anaesthetic (0.2ml/kg) that was one fifth of the dose of the local anaesthetic used in the caudal group (1ml/kg). Needless to say this would also translate into a lesser incidence of side effects and risk of toxicity associated with local anaesthetics.

Though the technique of PVB requires some expertise it was noted that the location of the transverse process very well corroborated with the formula given by Berta and Lonnqvist et al6, thus making the technique easiest to master. Besides none of the 20 patients had a block failure. In our study none of the patients in the paravertebral group required supplemental analgesia. The mean duration of analgesia (as described by the time to rescue analgesia) was noted to be 1440 minutes i.e., 24 hours in the paravertebral group as compared to 1001.25±564.34 minutes in the caudal group. We found that majority of the children had maximum pain in the first 24hrs following which they were discharged with oral analgesic medication. Therefore, a technique, which can provide analgesia for 24hours without any need for supplemental analgesia, is certainly more desirable.

This finding has been corroborated by previous studies by Tug et. al[3], who gave PVB in children and found the mean duration of action in the paravertebral group to be 1300 minutes. Akcaboy et al reported that PVB obtained very long and effective analgesia compared with spinal block in adult patients[10]. A comparison study between PVB (using 2%lidocaine) and field block (using 0.5% bupivacaine and 1%lidocaine) by Wassef et al in children also showed that the PVB had a higher success rate in terms of frequency of pain relative to surgical manipulation of spermatic cord, hernia sac and also in terms of supplementing analgesia using local anaesthetics[2]. Various other studies by Naja et al and Berta et al in children have also reported the effect of PVB to last from 12-48 hours[4,5]. These results support our findings. It was claimed that this results from the relative a vascularity of the paravertebral space and hence the slow uptake of local anaesthetics. Division of the spinal nerves into smaller branches in the paravertebral space also enables better penetration of the local anaesthetic[5].

We did not encounter any complications with PVB in our study. However, we had failure of block in one patient in the CB group and 3 patients also complained of urinary retention. Because of the inherent nature of the PVB and the lesser amount of drug required, there is negligible risk of damage to the spinal cord, lower limb weakness, urinary retention and widespread sympathetic blockade.

Previously, multiple level paravertebral blocks had been used to provide adequate blockade[5]. Since the psoas muscle enveloped each lumbar nerve within the paravertebral space, it was considered essential to block each lumbar segment individually to achieve sufficient blockade. However, cadaveric studies have reported that if the dye was injected at L1 level, it was observed that the genitofemoral, iioinguinal, iliohypogastric and lateral cutaneous nerves were stained with dye[3]. This may explain

why the PVB obtained in our study was very effective. Besides, multiple segments PVB also increase the risk of pleural puncture and pneumothorax.

Further research can compare the effectiveness of the block using Ultrasound guidance and the inability to do that is also one of the limitations of our study.

To conclude this study has demonstrated that a single level, single shot PVB has been found to be superior in providing postoperative analgesia in terms of duration of analgesia, quality of analgesia and need for rescue analgesics as compared to CB in children undergoing inguinal hernia repair. It has also been noted to have lesser complications and higher parent satisfaction.

Abstract

This study compares the safety and efficacy of multiple level thoracic paravertebral block and modified Pecs block for postoperative pain relief after Modified Radical Mastectomies.

After Institutional Review Board [IRB] and Human Ethics Committee [HEC approval, the study was conducted on 41 patients who were scheduled to undergo modified radical mastectomy. Written informed consent was taken. Female patients in the age group of 18-75 years who were ASA grade I and II were randomly allocated to two groups to either receive Ultrasound guided Thoracic paravertebral block TPVB at T2 and T4 levels (Group 2) or an ultrasound guided modified PECS block (Group 1) preoperatively in the block room.

Paravertebral block was given at two vertebral levels T2 (10 ml) and T4 level (10 ml) under ultrasound guidance utilising the parasagital in-plane technique. Modified PEC block was administered to patients in the PEC group.10 ml of 0.5% Ropivacaine for Pec1 and 20ml for Pec 2. In all patients surgery was done under GA. Pain was assessed with Numerical Rating Scale (NRS) on a 0 to 10 scale, for 24 hours after surgery, at 0,0.5,1,1.5,2,4,6,12 and 24 hours after surgery by a blinded observer.

Rescue opioid and Paracetamol requirement was recorded. The patients were also monitored for any specific block related complications.

Primary outcome measures were the numerical rating scores for pain and rescue analgesic requirement. Secondary outcome measures was looking for any block related complications. Demographic categorical variables were expressed in frequency and percentage, and the continuous variables were reported in terms of mean and standard deviation. The comparison of pain scores between the thoracic paravertebral nerve block and modified pectoral nerve block was done using Mann-Whitney U test. Mean duration of analgesia and mean 24 hour Morphine, Paracetamol consumption was compared using Student's t test.

There was no statistically significant difference between the two groups with respect to the pain scores at 0,0.5,1,1.5,2,4,6,12,and 24 hours at rest or with movement of the ipsilateral arm. The 24 hour Morphine consumption was not also statistically significant. [pec gp,mean 2.17, SD 1.09, tpvb gp mean 2 SD 0.77, p value 0.752.] Paracetamol consumption in the initial 24 hours after surgery was also not statistically significant between the two groups (pec gp. 36.8% and tpvb gp. 50% patients received paracetamol with a p value of 0.523). We found both the blocks, modified Pecs and multiple level paravertebral block were equally effective in treating postoperative pain.

[illegible]rd Modified pectoral nerve block, Multiple level thoracic paravertebral block, Postoperative analgesia, Modified radical mastectomy.

Introduction

The age adjusted rate and mortality of breast cancer among Indian females is 25.8 and 12.7 per 100,000 women respectively.[11] Modified radical mastectomy, can cause considerable pain in the immediate postoperative period and also has the potential to cause chronic pain[1]. Adequate pain control in the acute postoperative period is of paramount importance for patients' wellbeing, shorter hospital stay and also to prevent chronic pain due to the fact that inadequately treated postoperative pain is an important predictor of chronic pain.[2,3] Many regional anaesthesia options are now available for the anaesthesiologist to choose from for breast surgeries. A proper understanding of the nerve supply and analgesic requirements for various breast surgical procedures is necessary to choose the correct regional technique. In our institution, a tertiary care cancer hospital in South India an average of six breast surgeries are done daily of which 3 to 4 will be modified radical mastectomies. These patients are offered General Anaesthesia with a peripheral nerve block, either paravertebral block or PEC block or local infiltration.

Thoracic paravertebral block (TPVB) has been well researched and has been found to provide not only excellent analgesia in breast surgeries but also has less severe chronic pain and thereby good physical and mental health related quality of life after surgery.[4-7] Pectoral nerve block is an ultrasound guided interfascial plane block as described by Blanco in 2011 for postoperative pain relief in breast surgeries.[8-10] Recently a few studies have compared the safety and efficacy of the two blocks. It was observed that modified Pecs block provides superior postoperative analgesia than

TPVB in radical mastectomies with axillary clearance. (Wahba and Kamal 2013; Kulhari S et al 2016). Our study compares the safety and efficacy of multiple level thoracic paravertebral block and modified Pecs block for postoperative pain relief after Modified Radical Mastectomies.

Materials and Methods

After Institutional Review Board (IRB.No.06/2017/03) and Human Ethics committee (HEC No.14/2017) approval the trial was registered at clinical trials registry of India (CTRI/2018/02/011757 Principal investigator: Dr. Viji S. Pillai Date of registration: 07/02/2018.).The study was conducted on 41 patients who were scheduled to undergo modified radical mastectomy after obtaining written informed consent. Female patients in the age group of 18-75 years who were ASA grade I and II were randomly allocated to two groups to either receive or an ultrasound guided modified PECS block (Group 1) or Ultrasound guided multiple level Thoracic paravertebral block at T2 and T4 levels (Group 2) preoperatively in the block room. Patients were randomised into two groups with computer generated random numbers in sealed opaque envelopes which were opened before administering the blocks. Patients with preexisting local site infection, coagulopathy, morbid obesity (BMI>35), allergy to local anaesthetic were excluded from the study. Patients with other major organ system dysfunction were also excluded from the study. Patients were reviewed in the preoperative day in the ward by one of the investigators. Procedure and Numerical Rating Score is then explained to the patient and informed consent is obtained. All the patients were kept nil per oral for 6 hours before procedure. They received Alprazolam 0.25-0.5mg on the night before and Pantoprazole 40mg on the morning of surgery. Prior to the block patient was monitored using standard ECG, SpO2 and NIBP measurements. After securing an intravenous line they received premedication with 1mg of Midazolam and Fentanyl 30 microgram.

Modified PEC block was administered to patients in the group 1. Under strict aseptic precautions, patient in supine position the probe is placed below the lateral part of the clavicle, similar to the probe position for infraclavicular brachial plexus block and then moving inferolaterally. After recognition of the appropriate anatomical structures, the skin puncture point is infiltrated with 2% lignocaine, then the block is performed by using a 22-gauge Quinke's needle. The needle is advanced to the tissue plane between the pectoralis major and pectoralis minor muscle at the vicinity of the pectoral branch of the acromiothoracic artery, and 10 mL of 0.5% ropivacaine deposited. In a similar manner, 20 mL is deposited at the level of the third rib between the pectoralis minor and Serratus Anterior muscle. Thoracic Paravertebral block with Ropivacaine (0.5%) was given to patients in group 1. Procedure was done with patient in sitting position under strict aseptic precautions. Paravertebral block was given at two vertebral levels T2 (10 ml) and T4 level (10 ml) under ultrasound guidance utilising the parasagital in plane technique. Pleural displacement on injection of the drug is taken as confirmation for correct drug deposition.

After administering the blocks the patient's vitals, heart rate, blood pressure, SpO2 will be monitored continuously. Response to pinprick sensations in the thoracic dermatomes T1 – T6 at 20 minutes and 30 minutes after the block was noted.

Patients in both the groups underwent surgery with general anaesthesia standardized according to our centre's current clinical practice. General Anaesthesia was induced with Fentanyl 2microgm/kg, Xylocard 1.5mg/kg IV, Propofol (titrated to verbal response), Vecuronium 0.1mg/kg for muscle relaxation and trachea intubated with appropriate sized ETT. Anaesthesia maintained with Sevoflorane and Oxygen, Nitrous oxide mixture with 1 MAC., FiO2 0.4 and ventilation titrated to maintain ETCO2 35 - 40mmHg, with low fresh gas flows. Fentanyl 0.5 microgram/kg bolus will be given if the mean blood pressure or heart rate exceeded 20% of the baseline recordings, repeated once more if it does not return to baseline values after 10 minutes. After surgery patients were reversed with Neostigmine 2.5mg and Glycopyrrolate 0.4mg and extubated after good respiratory efforts and stable vitals. Patients were then shifted to the recovery room.

Post-operative pain was assessed in the recovery room and periodically after discharge to the ward until 24 hours postoperatively by another observer who was blinded regarding the block performed. Pain was assessed with Numerical Rating Scale (NRS) on a 0 to 10 scale, where 0 means no pain and 10stands for the maximum pain ever experienced for 24 hours after surgery, at 0,0.5,1,1.5,2,6,12 and 24 hours after surgery.

Morphine 1.5mg bolus was given to treat postoperative pain. Paracetamol 1gm IV was given if pain did not subside after two boluses of Morphine. Rescue opioid and Paracetamol requirement was recorded. The patients were also monitored for any specific block related complications like local anaesthetic toxicity, pleural puncture, vascular puncture, pneumothorax and intrathecal spread of the drug.

Sample size was calculated with Master 2.0 sample size software. Sample size calculation was done based on the 24 hour postoperative Morphine consumption from a previous study by Kulhari et al.

Data was entered in Microsoft Excel sheet. Normality of data tested with P-P probability plot and histogram. Demographic categorical variables were expressed in frequency and percentage, and the continuous variables were reported in terms of mean

and standard deviation. The comparison of pain scores between the thoracic paravertebral nerve block and modified pectoral nerve block was done using Mann-Whitney U test. Mean duration of analgesia and mean 24 hour Morphine, Paracetamol consumption was compared using Student's t test.

Results

Both groups were comparable with respect to age, body mass index, ASA status and the duration of surgery.The post block haemodynamic status remained stable throughout the period of monitoring. (Table 1)

There was no statistically significant difference between the two groups with respect to the pain scores at 0,0.5,1,1.5,2,4,6,12, and 24 hours at rest or with movement of the ipsilateral arm. (Table 2, 3) The 24 hour Morphine consumption was not also statistically significant. [pec gp, mean 2.17, SD 1.09, tpvb gp mean 2 SD 0.77, p value 0.752.] Paracetamol consumption in the initial 24 hours after surgery was also not statistically significant between the two groups (pec gp. 36.8% and tpvb gp. 50% patients received paracetamol with a p value of 0.523). (Table 4)

Time (in hours) to first analgesic was 5.667 (8.84) in the Pecs group and 2.985 (3.55) in the paravertebral group with a p value of 0.335 which was not significant. (Table 5)

There was a significant difference between two groups at the level of T2 dermatome block with 31.6% blocked in the PEC gp. and 80%% in Tpvb with a p value of 0.006.

Forty one patients were recruited into the study of which one patient in the Pecs group had reexploration and was later excluded from the study. One patient in the Tpvb group had wrong sided block who underwent surgery under general anaesthesia, postoperative pain managed with, Morphine and NSAIDS. Thus there were twenty patients in the paravertebral group and 19 in the PEC group.

Discussion

Axillary dissection and nerve injury may play a major role in causing chronic pain after breast cancer surgery.[12-15] Nerve injury can cause central sensitization and trigger the development of chronic pain. Since nerve blocks are capable of preventing central sensitisation we feel the blockade of intercostobrachial nerve, the main nerve supplying the axilla plays a major role in decreasing the incidence of chronic pain after axillary dissection. ICBN is almost always handled by the surgeon and suffers varying degrees of damage.[38] Hence we designed our technique of paravertebral block at two levels T2 and T4 with 10 ml of Ropivacaine at each level to assure adequate block of the intercostobrachial nerve.

The breast receives its innervation from the lateral and anterior cutaneous branches of the second to the sixth intercostal nerves and from the supraclavicular nerves. Axilla is mainly supplied by the intercostobrachial nerve which in turn communicates with other intercostal nerves T1, T3 and T4, and also with nerves from brachial plexus.[20-22] The pectoral muscle forms the anterior axillary wall which is supplied by the medial and the lateral pectoral nerves, serratus anterior muscle supplied by long thoracic nerve forms part of the medial wall and lattissimusdorsi supplied by thoracodorsal forms part of the posterior wall.

The fascia covering the pectoralis major muscle is removed during modified radical mastectomy.[1,40] This contributes to the postoperative pain which can be alleviated by the pectoral nerve blocks. In reconstructive breast surgeries with subpectoral prosthesis, there can be considerable postoperative pain due to pectoralis muscle stretching, for which the Pecs 1 block was originally described.[8,9,25] The pectoral muscles, serratus anterior and lattisimusdorsi are retracted during axillary dissection which can cause intraoperative pain.[1] The long thoracic nerve and thoracodorsal nerve may suffer injury during axillary dissection which can cause motor weakness of the muscles supplied by them.[40] The contribution of these nerves to postoperative pain after axillary dissection has yet to be understood. Sacrificing the intercostobrachial nerve may be required for oncological clearance during surgery which in turn can cause varying degrees of sensory loss in the axilla and medial side of arm.[16,40]

A few previous studies have evaluated the efficacy of PEC and TPVB for surgeries of breast including axillary dissection. Kulhari S[11]et al in their study comparing PEC and paravertebral block found that the PEC block was superior to paravertebral block with respect to the duration of analgesia, 24 hour morphine consumption and postoperative pain scores in the initial two hours after surgery. Wahba et al[12] in a similar study comparing these two blocks had less opioid consumption at 24 hours, longer time to first analgesic with the Pecs group. They had lower pain scores on movement at initial 12 hours and higher pain scores at 18 and 24 hours with Pecsblock. Another randomised double blind trial comparing Pecsblock, TPVB, and local infiltration by KarthikSyal et al had lower pain scores and longer duration of analgesia with the paravertebral block group.[23] Here the blocks were given after surgery under GA before extubation.

It is quite interesting to note that in all these studies the paravertebral block was given at T4 level as a single site injection without a catheter. The authors point out this single site injection of thoracic paravertebral block as a drawback for adequate spread of the local

anaesthetic to the higher dermatomal levels owing to the fact that spread of drug can be variable with this technique. Richardson et al[30] in their study found that 1.5 mg/kg bupivacaine 0.5% produced sensory loss at the level of injection with a mean superior spread of 1.4 (range, 0–4) dermatomes and a mean inferior spread of 2.8 (range, 0–7) dermatomes. Thoracic paravertebral anesthesia does not appear to be gravity-dependent, but there is a tendency for preferential caudal spread of somatic and sympathetic blockade.[26,31-34] Eason and Wyatt[27] found that at least four intercostal spaces could be covered by a single 15-ml injection of 0.375% bupivacaine. Single site injection at the T4 level may not always anaesthetise the cephalad dermatomes, especially at the T2 level. This is more important when there is axillary dissection since it involves much of tissue handling and has major contribution to postoperative pain. The ICBN is a thick nerve compared to the other intercostals and needs to be blocked separately when axillary clearance is done.

Hetta DF[35] et al, in their study on Pectoralis-serratusinterfascial plane block vs thoracic paravertebral block for unilateral radical mastectomy with axillary evacuation concluded that Pectoralis-serratus interfascial plane block was safe and easy to perform and decreased intensity of postmastectomy pain, but it was inferior to thoracic paravertebral block. Kasimahanti R.[36] et al in their study on Ultrasound-guided single vs double-level thoracic paravertebral block for postoperative analgesia in total mastectomy with axillary clearance concludes that patients receiving double-level TPVB had significantly less 24-hour analgesic consumption in the postoperative period than those in the single-level TPVB group. They attribute this could be due to significantly greater number of segments blocked in the double-level TPVB group. This is similar to our study outcome.

The results of the study by Sopena-Zubiria LA[37] et al showed that the combination of the two techniques was associated with a better post-operative analgesic control immediately after surgery: pain level assessed with VAS was significantly lower in the group treated with the combination of pectoral and thoracic paravertebral block 8 hours but not 24 hours after surgery. Combination of the two techniques reported a reduced need for intra-operative sedation.

We had a wrong sided block in one patient in the paravertebral block group who was excluded from the study. Surgery was done under general anaesthesia ad postoperative pain managed with Morphine and Paracetamol. Being a para median block extra precautions has to be exercised to prevent this.

We had similar experience as that of Bakshi et al,[39] with surgeons having difficulty to use electrocautery during axillary dissection in the Modified Pecs group. This was due to the presence of local anaesthetic drug in the tissue planes and they had to use higher currents or resort to bipolar cautery.

Modified Pecs block has the advantage of simple and safe technique with ultrasound whereas paravertebral block is an advanced level block and demands more procedural expertise. Single level paravertebral blocks may not adequately cover all dermatomes always as the spread of local anaesthetic is variable. So in our study we compared paravertebral block at two levels with modified Pecs block and found both techniques had comparable outcomes with respect to numerical rating scales, time to first analgesic request and rescue analgesic consumption.

Conclusion

We found both the blocks, modified Pecs and multiple level paravertebral block equally effective in treating postoperative pain without any statistically significant difference between the two groups. Trials with large sample sizes may bring out differences. We feel that blocking the intercostobrachial nerve with a dedicated T2 level paravertebral block has an important role in perioperative analgesia in breast surgeries with axillary dissection since it is the major nerve supply to axilla and also because it is implicated in chronic pain.

Abstract

Vital capacity rapid inhalation induction (VCRII) results in faster achievement of desired minimum alveolar concentration while reducing the incidence of excitatory phenomenon compared to conventional incremental technique. This study aimed to determine whether the VCRII can achieve faster induction of anesthesia in adults compared to the traditional tidal ventilation (TV) technique. Following the approval from the Institutional Ethics Committee, Amala Institute of Medical Sciences, with an approval No. AIMSIEC/07/2017, on July 1, 2017, 51 adults belonging to American Society of Anesthesiologists physical status I–II, undergoing elective surgery at a tertiary care teaching hospital were prospectively assigned to two groups: 25 in VCRII (38.3 ± 13.3 years old, 20 (80%) females) and 26 in TV inhalation induction (35.2 ± 11.9 years old, 17 (65%) females) using 8% sevoflurane in 66% nitrous oxide. The induction time, such as time (in seconds) to the cessation of voluntary finger tapping, time to loss of eyelash reflex, time to return of regular breathing, the return of conjugate gaze, was measured. The primary outcome was time to induction as defined by time to loss of eyelash reflex. Hemodynamic effects of both methods were compared at baseline and 1, 3, 5, 10, 15-minute intervals from induction. Induction was significantly faster in the VCRII group compared with the TV group in all the measured parameters. Hemodynamic parameters were comparable in both the groups. VCRII resulted in a faster induction time compared to the TV technique in adults.

Key words: adults; excitatory phenomenon; inhalational agent; inhalational induction; minimum alveolar concentration; prospective study; sevoflurane; tidal ventilation; vital capacity

Introduction

With the advent of newer agents, inhalational induction is becoming an attractive alternative to intravenous induction. Because of its non-irritating nature and higher efficacy, sevoflurane is the preferred agent. There is evidence that inhalational induction of anesthesia is increasingly preferred by subjects over intravenous induction.[1] In a meta-analysis, the time to induction with sevoflurane was found to be comparable with propofol while sevoflurane was associated with higher first-time success with laryngeal mask airway insertion.[2] High inspired concentrations of sevoflurane are safe and do not provoke airway reflex responses as shown in a multiple adult and pediatric study.[3]

As required by vital capacity rapid inhalation induction (VCRII), the subject is asked to first take a deep breath followed by maximum exhalation. Afterwards, the anesthetic circuit with facemask is applied, the subject is asked to take a deep breath, hold his/her breaths for as long as possible and then breathe out to residual volume.[4] VCRII technique requires patient education and cooperation for a vital capacity breath and an adequate breath-hold following it. The other technique is tidal ventilation (TV) induction, in which the patient breathes normal tidal volume breaths. TV induction does not require any patient training as it involves the patient taking normal breaths. A comparison of VCRII and TV techniques performed in the pediatric age group has shown that VCRII achieved shorter time to induction and was preferred by the subjects.[5] This study aimed to ascertain whether the VCRII technique can result in faster induction in Asian adults compared to the traditional TV technique and to compare the incidence of adverse events using both the techniques.

Subjects and Methods

An approval from the Institutional Ethics Committee, Amala Institute of Medical Sciences with an approval No. AIMSIEC/07/2017 on July 11, 2017 was obtained. Written informed consent was obtained from all subjects. We prospectively enrolled subjects aged 18 years and above scheduled to undergo elective urological, head and neck, orthopedic, or visceral surgeries at our tertiary care teaching hospital from June 2018 to December 2019 and belonging to the American Society of Anesthesiologists (ASA) physical status I–II. Adults with contra-indications to inhalational induction (gastro-esophageal reflux, myopathy, or familial history of malignant hyperthermia) and those with a history of unstable cardiac disease, neurological disease, obstructive airway disease, and recent acute respiratory illness/infection were excluded. The circuit was primed with 8% sevoflurane (Sevotroy 250, Troikaa Pharmaceuticals Ltd., Ahmedabad, India) in nitrous oxide and oxygen before the application of a mask to the patient's face. Before anesthesia, subjects in the VCRII group were instructed on the vital capacity breath.[4] The concentration of gases used was 8% sevoflurane in nitrous oxide (66%) and oxygen (33%) at a flow rate of 8 L/min in both the groups.

© 2021 Medical Gas Research | Published by Wolters Kluwer - Medknow

In the VCRII group, the subject was asked to exhale forcefully, followed by a maximal inspiration via a face mask connected to the anesthetic circuit. The subject was then asked to hold his/her breath for the maximum time possible and then exhale residual volume. In the TV group, the subject was asked to continue quiet breathing through the facemask. The onset of induction of anesthesia was assessed as the time to the cessation of voluntary finger tapping, time to loss of eyelash reflex, time to return of regular breathing, and time to return of conjugate gaze.[5] Heart rate, peripheral oxygen saturation, systolic, and diastolic blood pressures were compared at baseline and 1-, 3-, 5-minute intervals from induction. The occurrence of stridor, cough, laryngospasm, hypoxemia, and excitatory movements was recorded. All patients received fentanyl 2 μg/kg (Verfen, Verve Pharma, India) 3 minutes before sevoflurane induction. Rescue remedy of intravenous propofol (Troypofol, Troikaa Pharmaceuticals Ltd.) at 2 mg/kg and succinylcholine (Sucol, Neon Pharma, Mumbai, India) 100 mg was prepared for laryngospasm or desaturation. The trial was non-randomized. A trained nurse who was blinded to the group allocation was recording the outcome endpoints. Acceptance of anesthesia induction technique was assessed by the willingness to undergo a repeat procedure using the same method of induction. The trial flow chart showing the distribution of patients is given in **Figure 1**.

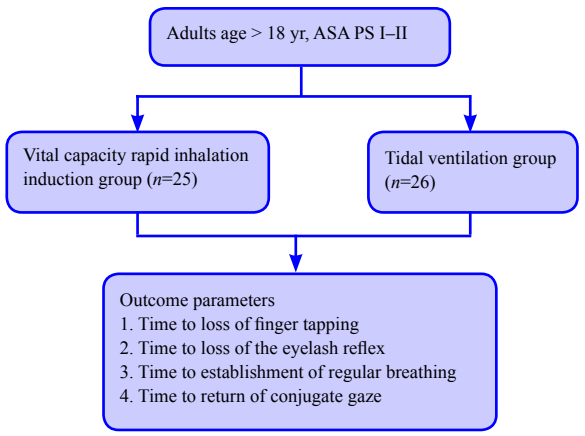

Figure 1: The flow chart.
Note: ASA PS: American Society of Anesthesiologists physical status.

The sample size was calculated according to the results of Yurino et al.[6] A sample size of 23 in each group was calculated for a difference in onset of induction of 11 seconds for a power of 80% and an alpha of 0.01 using SPSS 23 software (IBM, Armonk, NY, USA). All results are expressed as the mean ± standard deviation (SD) or median (range; continuous variables) or as percentages of the group from which they were derived (categorical variables). Continuous variables were compared with the Student's *t*-test for normally distributed variables and the Mann-Whitney *U* test for non-normally distributed variables. Categorical variables were evaluated with the Chi-square analysis or two-tailed Fisher exact test. A value of *P* less than 0.05 was considered significant.

Results

Baseline characters of patients under vital capacity rapid inhalation and tidal ventilation induction with sevoflurane

A total of 51 patients were included in the study, 25 in the VCRII group and 26 in the TV group. The baseline parameters of both groups are depicted in **Table 1**. Age, sex, weight, and ASA status distributions, baseline heart rate, percutaneous oxygen saturation, systolic, and diastolic blood pressures were comparable between the two groups ($P > 0.05$).

Hemodynamic and respiratory outcomes of patients under vital capacity rapid inhalation and tidal ventilation induction

Induction was significantly faster in the VCRII group compared with the TV group. The time to loss of voluntary finger tapping ($P < 0.001$), time to loss of eyelash reflex ($P < 0.001$), time for the establishment of regular breathing ($P < 0.001$) and time to return of conjugate gaze ($P = 0.046$) were all significantly less in the VCRII group than those in the TV group.

To evaluate the cardiovascular effects of methods of induction, a comparison of vital signs was done between two groups before induction, and upon loss of consciousness. Heart rate in the VCRII group was significantly lower compared to the TV group at 3 minutes ($P = 0.015$) and 5 minutes post-induction ($P = 0.012$). Systolic and diastolic blood pressures were comparable between the two groups at all time points ($P > 0.05$; **Table 2**).

No adverse event (cough, laryngospasm, excitatory movements, hypoxemia) occurred in both groups. Patient willingness to return for repeat procedure using the same method of induction of anesthesia was 100% in both the groups.

Discussion

In this study, the VCRII technique using 8% sevoflurane resulted in a faster induction of anesthesia, as estimated by time to loss of finger tapping, loss of the eyelash reflex, establishment of regular breathing, and return of conjugate gaze, compared with the TV technique.

The time for induction of anesthesia was taken as the time from the beginning of the administration of the agent to the loss of finger tapping which is an acceptable outcome in similar studies.[7-9] Though bispectral index monitoring was not done, clinical endpoints for recognition of induction like loss of finger tapping to verbal command are valid surrogates for bispectral index monitoring.[10]

The roadblock to wider acceptance of inhalational anesthesia is the longer time of induction compared to intravenous agents.[11,12] Modification of administration techniques facilitates the speed of induction. VCRII achieves a high alveolar concentration of sevoflurane in a shorter time resulting in smoother induction. Typically, this single-breath technique achieves the 2% alveolar sevoflurane concentration required to tolerate a surgical incision.[2,13] In a study by Lin et al.[14] the use of VCRII inhalational induction in 36 ASA physical status I–II patients resulted in an induction time of 60.6 ± 19.2 seconds which could be shortened to 48.3 ± 17.9 seconds with the use of fentanyl before induction. By contrast, our study employed fentanyl pre-induction in both the groups along with nitrous oxide and hence demonstrated faster induction times. In the

Table 1: Baseline characteristics of patients under VCRII and TV induction

Parameter	VCRII group (*n*=25)	TV group (*n*=26)	*P* value
Age (yr)	38.3±13.3	35.2±11.9	0.39
Female	20 (80)	17 (65)	0.24
American Society of Anesthesiologists physical status (I/II)	2/23	2/24	0.96
Weight (kg)	61.8±8.8	59.8±7.3	0.38
Heart rate (beats/min)	78.8±7.7	80.5±6.5	0.39
Percutaneous oxygen saturation (%)	99.9±0.2	100.0±0	0.313
Systolic blood pressure (mmHg)	126.7±9.3	124.2±8.0	0.302
Diastolic blood pressure (mmHg)	78.3±7.4	78.0±6.4	0.902
Anesthesia induction			
Loss of finger tapping (s)	24.4±4.7	31.7±4.3	0.0001
Loss of eyelash reflex (s)	43.8±8.3	65.0±8.3	0.0001
Establishment of regular breathing (s)	73.7±12.7	86.9±7.5	0.0001
Return of conjugate gaze (s)	108.8±18.2	117.7±12.8	0.046

Note: Data are expressed as the mean ± SD, except female [number (percentage)] and American Society of Anesthesiologists physical status (number). Continuous variables were compared with the Student's *t*-test (for normally distributed variables) or the Mann-Whitney *U* test (for non-normally distributed variables). Categorical variables were evaluated with the Chi-square analysis or two-tailed Fisher exact test. TV: Tidal ventilation; VCRII: vital capacity rapid inhalation induction.

Table 2: Hemodynamic and respiratory parameters after induction of patients under VCRII and TV induction with sevoflurane

Parameter	VCRII group (*n*=25)	TV group (*n*=26)	*P* value
Heart rate (beats/min)

5 min	98.9±0.9	99.6±0.6	0.001

Note: TV: Tidal ventilation; VCRII: vital capacity rapid inhalation induction.

pediatric population, the VCRII technique can produce faster induction as measured by loss of eyelash reflex, which has been preferred over tidal ventilation technique in 73 subjects over the age of 5 years in a randomized controlled trial comparing the two techniques.[5] This pediatric study used sevoflurane 7% in 50% nitrous oxide with oxygen at 6 L/min fresh gas flow along with midazolam premedication, while our study used sevoflurane 8% in 66% nitrous oxide with oxygen at 8 L/min fresh gas flow with fentanyl premedication, which may result in a comparable induction time in both the studies. Another pediatric study showed similar results with VCRII producing fewer adverse events, faster induction and better patient satisfaction compared with TV using 8% sevoflurane.[15] A similar study in adults using sevoflurane and nitrous oxide showed that VCRII, in comparison with stepwise tidal ventilation induction, resulted in an earlier loss of consciousness (54 ± 10 seconds *vs*. 108 ± 19 seconds) but was associated with a higher incidence of coughing.[16] This study used a lower concentration of sevoflurane at 4.5% which explains the longer induction times compared to our study.

The present study shows that inhalational induction is a feasible and effective alternative to intravenous induction in Asian adults. There is emerging evidence that inhalational induction using sevoflurane has better hemodynamic stability, equal patient acceptance, and is cheaper than intravenous induction using propofol.[7] Usage of a single inhalational agent for induction and maintenance reduces adverse events accompanying the use of multiple intravenous agents, such as hemodynamic compromise.[17]

None of the patients in our study had coughing or laryngospasm. This indicates an adequate depth of anesthesia and suppression of airway reflexes. The VCRII technique requires some training but this is easily achieved in all our subjects. The feasibility of achieving adequate VCRII is 95% by 14 years of age as described in a previous study.[18] Besides, there was no difference in patient willingness to return for a repeat procedure under both the techniques, indicating that the VCRII technique was acceptable for the subjects.

The use of inhalational agents especially as maintenance of anesthesia is found to be feasible and cost-effective in ambulatory surgeries.[19,20] Our study also demonstrates the utility and safety of a faster induction technique using the same inhalational agent.

Our study has some limitations. This non-randomized study may be subject to bias. Although the VCRII technique produces a faster induction, this advantage remains small in clinical practice. In this study, intubation times or emergence times

were incomparable between the two groups as we designed primarily for the comparison of induction characteristics of the two techniques.

VCRII rapid inhalational induction technique using 8% sevoflurane with nitrous oxide can result in a faster induction compared to the TV induction technique in adults.

Abstract

Background and objective

A large number of studies describing the clinicoepidemiological features of coronavirus disease-2019 (COVID-19) patients are available but very few studies have documented similar features of the deceased. This study was aimed to describe the clinicoepidemiological features and the causes of mortality of COVID-19 deceased patients admitted in a dedicated COVID center in India.

Methodology

This was a retrospective study done in adult deceased patients admitted in COVID ICU from April 4 to July 24, 2020. The clinical features, comorbidities, complications, and causes of mortality in these patients were analyzed. Pediatric deceased were analyzed

separately.

Results

A total of 654 adult patients were admitted in the ICU during the study period and ICU mortality was 37.7% (247/654). Among the adult deceased, 65.9% were males with a median age of 56 years [interquartile range (IQR), 41.5–65] and 94.74% had one or more comorbidities, most common being hypertension (43.3%), diabetes mellitus (34.8%), and chronic kidney disease (20.6%). The most common presenting features in these deceased were fever (75.7%), cough (68.8%), and shortness of breath (67.6%). The mean initial sequential organ failure assessment score was 9.3 ± 4.7 and 24.2% were already intubated at the time of admission. The median duration of hospital stay was 6 days (IQR, 3–11). The most common cause of death was sepsis with multi-organ failure (55.1%) followed by severe acute respiratory distress syndrome (ARDS) (25.5%). All pediatric deceased had comorbid conditions and the most common cause of death in this group was severe ARDS.

Conclusion

In this cohort of adult deceased, most were young males with age less than 65 years with one or more comorbidities, hypertension being the most common. Only 5% of the deceased had no comorbidities. Sepsis with multi-organ dysfunction syndrome was the most common cause of death.

Introduction

Coronavirus disease-2019 (COVID-19) emerged in China in December 2019 and engulfed the whole world in a very short period of time. Worldwide till now around 95 million patients have been infected and there have been more than 2 million deaths. India is also severely affected. It has infected more than 10 million people in India and has led to more than 1.5 lakh deaths till now.[1]

The clinical spectrum of COVID-19 is varied, ranging from asymptomatic carriers to severe pneumonia, acute respiratory distress syndrome (ARDS) profiles, multi-organ involvement, and death.[2] Nearly 14–15% of patients develop severe disease and 5% become critically ill.[3] Earlier thought to be primarily affecting the pulmonary system, a number of symptoms related to other organ systems have been widely recognized as initial presenting features of COVID-19 infection.[4,5] These extrapulmonary manifestations can lead to complications and increase morbidity. The prevalence of mortality among hospitalized patients with COVID-19 disease varies from 6.3 to 26.85% in different parts of the world.[6] Various studies have looked into and analyzed the risk factors for severe disease and predictors of mortality.[7,8] However, studies regarding the clinicoepidemiological features of the deceased and causes of mortality are sparse. Some

studies of COVID-19 related mortalities from US, China, Italy, and Spain are available;[9–17] however, such descriptive study has not been done from Indian subcontinent so far. This study was aimed to describe the clinicoepidemiological features and the causes of mortality of COVID-19 deceased patients admitted in our hospital during the initial period of the pandemic spread in the country from April to July.

Materials and Methods

This was a retrospective study conducted in the COVID center of AIIMS, New Delhi, after approval from the institutional ethics committee. This study analyzed data of patients who died in the course of treatment in the ICU of COVID-19 center during the study period between April 4 and July 24, 2020. All the patients admitted to the center were moderate to severe confirmed COVID-19 patients whose real-time reverse-transcription polymerase chain reaction assay findings for nasal or pharyngeal swab specimens were positive. Mild cases were admitted in different centers. Criteria for ICU admission were patients with severe disease i.e., tachypnea with respiratory rate greater than 30/minute or SpO_2 less than 90% on room air, patient with hemodynamic instability, encephalopathy or patients with moderate disease who had risk factors for severe disease.

Data Collection

Data related to demography and clinical course of all the patients who died in the ICU during the study period was collected from their electronic medical records, patients' daily progress charts, and nursing notes. Patients' age, sex, comorbidities, complaints at the time of presentation, complications during treatment, duration of hospital stay, and cause of death were noted and analyzed. Data regarding adult and pediatric deceased were analyzed separately. Adult patients were further divided into age-groups of 18 to 50, 51 to 65, and more than 65 years and their clinical characteristics and outcomes were compared.

Statistical Analysis

The data were summarized and analyzed using STATA (Version 14.0) software and expressed as mean ± SD/Median (min, max) and numbers and percentages as appropriate to describe the patient's demographic and clinical characteristics. Wilcoxon–Ranksum test was used to compare the non-normal quantitative values while chi-square/Fisher's exact test was applied for association between categorical variables and for comparison between stratified age-groups. Kruskal–Wallis was used to see the difference in age-groups for the days of stay followed by multiple comparison tests between the groups. A value of p less than 0.05 was considered as statistically significant in the study.

Results

During the study period, a total of 1,420 patients (adult and pediatric) were admitted in the center. The deaths of adults and pediatric age-groups were analyzed separately.

Adult Fatalities

There were 654 adult admissions in the ICU during the study period out of which 247 died. The ICU mortality for adults was 37.7% (247/654).

Among the adult patients who did not survive, the youngest was 18 years old and the eldest was 97 years old. The median age was 56 years [interquartile range (IQR), 41.5–65] and most of them were males (65.9%). Age distribution of adults in various age-groups is given in Table 1.

Most of the adult patients who died (94.74%) had 1 or more comorbidities. Preexisting hypertension was the most frequently seen comorbidity in 107 (43.32%) patients followed by diabetes mellitus in 86 (34.82%) patients and chronic kidney disease in 51 (20.6%) patients. Other comorbidities are tabulated in Table 1. Among the patients with comorbidities, 39% of patients had one comorbidity, 27.5% had two comorbidities, 21% had three, and 6% had more than three comorbidities. The frequency of patients with different numbers of comorbidities is depicted in Figure 1.

Twenty-nine patients had some kind of malignancy, out of which 14 suffered from hematological malignancies and remaining 15 had solid organ tumors. Besides these, other infrequently encountered comorbidities were postrenal transplant, cardiomyopathy, cholelithiasis, complete heart block with pacemaker *in situ*, HIV, ulcerative colitis, sarcoidosis, interstitial lung disease, liver abscess, aspergilloma, shoulder abscess, peripheral vascular disease, parkinsonism, corrosive ingestion, mesenteric ischemia, dementia, depression, aplastic anemia, cervical spondylosis, systemic sclerosis, ulnar, and subclavian artery thrombosis.

The most common presenting symptom among deceased was fever (75.7%) followed by cough (68.8%), shortness of breath (67.6%), and altered sensorium (19.8%) as shown in Table 2. Besides these, other patients presented with chest pain, abdominal pain or distension, generalized weakness, diarrhea, and headache. Approximately 20% of patients presented with nonspecific complaints including myalgia, decreased urine output, jaundice, upper limb pain, generalized edema, epistaxis, and joint pain.

The patients had varying degrees of severity of illness. The initial sequential organ failure assessment (SOFA) score was calculated for 232 deceased, the data were missing for 15 patients. The mean SOFA score was 9.3 with a standard deviation of 4.07. The initial SOFA score was significantly higher in males as compared to females (p = 0.03). Out of 247 deceased, 60 patients were received intubated in our center from the screening area. Patients were given treatment according to the institutional protocol. The patients were initially managed on oxygen by facemask and then as the oxygen requirement increased, they were managed on high flow nasal cannula (HFNC) and noninvasive ventilation (NIV) before invasive ventilation as per SCCM guidelines. Seventy-five patients were intubated in the first 24 hours of admission. The number of patients who received HFNC and NIV are mentioned in Table 3. As the disease advanced, many patients developed multisystem involvement. However, the predominant system involved due to COVID was the respiratory system in 66% of the patients followed by the neurological system and cardiovascular system. One twenty one patients developed acute kidney injury (AKI) and 39 received RRT (Table 3). Repeat SOFA score was calculated on day 4 of admission after 72 hours. Repeat SOFA was available for 133 patients as 99 patients died within 3 days of admission to ICU.

Duration of Stay and Cause of Death

Among the deceased adults, the median duration of hospital stay was 6 days (IQR, 3–11) with maximum stay of 37 days and minimum of 1 day.

The cause of death was analyzed in all the deceased (Table 4). Sepsis with multi-organ dysfunction remained the leading cause of death (55.1%) followed by severe ARDS (25.5%), cardiogenic shock, intracranial hypertension, and suspected pulmonary embolism.

There were 41 patients who died within 24 hours of admission. Among these, 90.24% of them reported a history of one or more comorbidities and majority had respiratory distress at presentation. Most of them were shifted intubated to our center. Four patients received cardiopulmonary resuscitation in the emergency room and were postarrest patients. The cause of death of these patients is depicted in Figure 2.

Age-related Analysis

The study patients were stratified into three age-groups (18–50, 51–65, and >65 years) to find out age-related differences in the number of comorbidities, presenting symptoms, duration of illness, and cause of death (Table 5).

In the study cohort, 42.1% of the deceased were in age-group between 18 years and 50 years, 34.8% in age-group 51–65 years, and 23.1% in the group above the age of 65 years. There was no difference in the male-to-female ratio between the three groups. The percentage of deceased having multiple comorbidities (two or more) was significantly higher in the age-group above 65 years as compared to younger age-groups. Multiple comorbidities were seen in 68.4% of patients above the age of 65 years, as compared to 59.3% in age-group 51–65 years and 44.2% in patients in 18–50 years of age.

The most frequent presenting complaints were similar in deceased of all age-groups with no significant difference. Initial SOFA score and percentage of patients given HFNC and NIV, and patients developing AKI were also similar in all the three groups. However, the duration of stay in the hospital was higher in the elderly deceased population. The percentage mortality was significantly higher in the age-group of more than 65 years as compared to other groups. The percentage mortality in different age-groups was 30.2% in age-group between 18 and 50 years, 43.2% in age-group between 51 years and 65 years, and 51.3% in age-group more than 65 years.

Pediatric Fatalities

There were 46 pediatric admissions during the study period and six COVID-19 related deaths, the ICU mortality among the pediatric age-group being 13% (6/46). The age-group of the deceased varied from 6 months to 16 years as depicted in Table 6. All of these patients had comorbidities including congenital heart disease, tubercular meningitis, endocrine disorders, and hematologic malignancies. Mean hospital duration of stay was 4.33 days. Most common cause of death was ARDS followed by sepsis with multi-organ dysfunction.

Discussion

This study retrospectively analyzed clinicoepidemiological characteristics, course of the disease, and cause of mortality of COVID-19 patients who died in the ICU. Total of 1,420 confirmed COVID-19 patients of all ages were admitted in the COVID center in the study

period. Almost half (49.3%) of the hospitalized patients received ICU care during the course of illness. This figure varies from 5 to 46.8% of hospitalized patients in different studies[9–11] and is related to the availability of ICU resources in that region.

The ICU mortality of COVID-19 patients varies from 8.0 to 66.7% in different studies.[18] In our center, the hospital mortality was 18.2% and ICU mortality was 36.1%. Similar mortality rates have been reported in other studies from US, Spain, Italy, and few studies from China.[9,10,16] However, there are other studies from China[2] which depict lower overall mortality rates. As the pandemic is evolving and our understanding of the disease is increasing, there has been a steady decline in the mortality rate.[19]

Approximately 60% of all admitted patients were males in our center. An almost alike proportion of male patients has been documented in all other studies suggesting male predisposition for this disease across various ethnic and racial groups.[9,10,15] Similarly, among the deceased adults, 66% were males and among pediatric fatalities, all were males except one.

In our study population of adult deceased, 42.1% were of age-group of 18–50 years, 35% in the age-group 51–64 years, and only about 23% were above 65 years age-group. This was a deviation from the studies from other parts of the world where most of the nonsurvivors were from a much older age-group[10,15,20] and could be explained by the majority of the young population in India, the percentage of the elderly population (>60 years) being 6.8%.[21] In our study, 95% of the adults deceased and all of the pediatric ones had at least one comorbid condition. Mortality studies from Spain and Italy[10,15] have reported a similar incidence of comorbidities in nonsurvivors. However, few other studies[11,16] report lesser incidence of comorbidities than ours. In our cohort, hypertension was the most common comorbidity seen followed by DM and CKD. Similarly, worldwide studies have shown hypertension followed by diabetes mellitus and cardiovascular comorbid conditions to be associated with the highest mortality.[12,14,22] Role of ACE-2 receptor in entry of SARS-CoV-2 virus into a host cell is one of the proposed reasons for the highest incidence of COVID-19 in hypertensive patients.[23]

In the present study, the elderly (>65 years old) deceased had more comorbidities than younger deceased suggesting that elderly population with higher number of comorbidities are more susceptible to adverse outcomes following COVID-19 infection, while factors other than number of comorbidities could be a significant variable in younger population.[15] Malignancy was seen in 11.74% of patients in our study which was higher than other reported incidences.[12,13,16]

The most common presenting complaints in our deceased population were fever, cough, and breathlessness similar to the findings of earlier studies.[3,24] Few patients initially presented for unrelated diagnoses and then later tested positive for COVID-19. Nonspecific symptoms were significantly more common in younger deceased.

The median initial SOFA score was 9.3 in our study. This was higher as compared to studies from US and China[11,25,26] reflecting increased severity of COVID-19 at ICU admission in our cohort. High SOFA scores at ICU admission or their progression over 48 hours have been associated with poor outcome of COVID-19.[25,27] Around 24% of our deceased were received intubated from the screening area and another 30% got intubated within the first 24 hours. HFNC was used in 45% of deceased in our study similar to

studies from China where HFNC use among nonsurvivors was 21.1 to 41%.[11,14] Only 18.2% of patients received NIV in our cohort and even in the published literature, proportion of nonsurvivors receiving noninvasive ventilatory support has been variable.[11,14,17] Use of NIV was greater in elderly subgroup of nonsurvivors in other studies[16] unlike our study.

The median duration of ICU stay among deceased was 6 days in our study. There was significant variation in median duration of ICU stay reported in other studies ranging from 6 days to 11.5 days.[12,16] Elderly deceased (>65 years) had significantly longer average duration of hospital stay of 9 days while younger had average 5 days of stay. However, a study in China on deceased patients[28] reported a longer average duration of hospital stay in younger patients. The reason for shorter stay in the younger age-group could be either the patients presented to the hospital late in the disease process or had severe cytokine storm-related multi-organ failure. Ours being a tertiary care center, patients were shifted after deterioration from other hospitals. The incidence of AKI in our study was 48.9 and 15.8% received RRT similar to the study by Ahmed et al. in which AKI incidence was around 10 to 50% in critically ill nonsurvivors and around 10–18.5% received RRT.[29]

Forty-one patients died within 24 hours of admission to ICU. These patients either had severe illness, coexisting decompensated comorbid illness, or were referred from other hospitals. Some were postarrest patients who collapsed in the emergency room, received CPR, and were revived. These patients were more likely to have a poor prognosis and shorter clinical course in the hospital.

Sepsis with multi-organ dysfunction syndrome (MODS) was the most common cause of death in our adult patients followed by severe ARDS and cardiogenic shock. Earlier studies[11,24] have also described multi-organ failure as the most common cause of death in the Chinese population while many other studies reported respiratory failure as the leading cause of death.[12,13,30] The reduced incidence of respiratory failure among the deceased in our study can be explained on the basis that 95% of our study cohort had one or more comorbidities that already compromised other organs. Moreover, all our severely affected patients were given ICU admissions as there were enough ICU beds available and we were able to give rescue therapies like prone ventilation for severe ARDS patients. Our scenario was different from other studies where many patients were not able to get supportive treatment as the number of patients requiring ICU care overwhelmed their medical system. Other rare causes of death were raised intracranial pressure and suspected pulmonary embolism.

Of all the admitted patients, COVID-19 related mortality was much lower (5.6%) in pediatric age-group compared to adults (18.8%). This correlated with the acknowledged low pediatric mortality rates by other authors.[31–33] In pediatric patients, respiratory failure secondary to ARDS was the most common cause of death. Only a few cases of pediatric COVID-19 mortality have been reported in the literature, wherein comorbidities and multi-organ dysfunction are the most common cause.[33]

Limitations

Ours was a retrospective study done in patients who died in ICU. As only data related to the deceased was studied, it is not possible for us to comment on risk factors for more severe infection or death due to COVID-19. Only deaths till July 24 were included in the study. Patients admitted to the hospital during the study duration could have died later during the illness, which has not been included.

Conclusion

In this single-center retrospective study of the deceased, 65.9% of the deceased were males. Most of them (76.8%) were of the age less than 65 years indicative of the majority of young population of India. Nearly all patients had single or multiple comorbidities, most common being hypertension followed by diabetes mellitus and chronic kidney disease. The most common cause was of death was sepsis with MODS followed by ARDS. There were a significant number of patients (16.6%) who presented late in the disease process and died within 24 hours.

ABSTRACT

Background: Novel coronavirus (SARS-CoV-2) infection is associated with hypoxemic respiratory failure. Mechanical ventilation (MV) is reported to have high mortality in SARS-CoV-2 acute respiratory distress syndrome. We aimed to investigate whether awake prone positioning (PP) can improve oxygenation and prevent intubation when employed early. **Methods:** This prospective interventional study included proven coronavirus disease 2019 (COVID-19) patients with room air saturation 93% or less. The primary outcome was the rate of intubation between the two groups. The secondary outcomes included ROX index (SpO_2/FiO_2%/respiratory rate, breaths/min) at 30 min following the intervention, ROX index at 12 h, time to recovery of hypoxemia, and mortality. **Results:** A total of 45 subjects were included (30 cases and 15 controls) with a mean (standard deviation [SD]) age of 53.1 (11.0) years. The age, comorbidities, and baseline ROX index were similar between the two groups. The median duration of PP achieved was 7.5 h on the 1st day. The need for MV was higher in the control group (5/15; 33.3%) versus prone group (2/30; 6.7%). At 30 min, there was a statistically significant improvement in the mean (SD) ROX index of cases compared with that of the controls (10.7 [3.8] vs. 6.7 [2.6], $P < 0.001$). No significant adverse effects related to intervention were noted. **Conclusion:** Awake PP is associated with significant improvement in oxygenation and may reduce the need for MV in subjects with COVID-19.

INTRODUCTION

Coronavirus disease 2019 (COVID-19) has resulted in a significant number of critically ill patients requiring intensive unit care admissions. A systematic review of intensive care unit mortality of COVID-19 reported mortality of 31.1%–79.0% among patients on invasive mechanical ventilation (MV).[1] Among intubated patients

with severe acute respiratory distress syndrome (ARDS), prolonged prone positioning (PP) for at least 12–16 h/day, is associated with significant improvement in oxygenation and mortality.[2] During this pandemic, there is a pressing need to conserve essential resources, and awake PP may be useful to improve oxygenation and reduce the need for MV.[3] There is emerging data on the same, but most studies lack a control group to provide information about the definite utility of this intervention. This study aimed to determine whether the early use of PP combined with noninvasive modalities of oxygen therapy can improve oxygenation and avoid the need for intubation in patients with hypoxemic respiratory failure due to COVID-19.

METHODS

This prospective, interventional study was conducted in Delhi, India, after obtaining approval from the institutional ethics board (IEC-308/27.04.2020, AA-4/08.05.2020). Subjects with nasopharyngeal swab RT-PCR-confirmed COVID-19, having room air pulse oxygen saturation (SpO_2) <94%, were included in the study. We excluded subjects with hypercapnic respiratory failure, hemodynamic instability, altered sensorium; those requiring immediate tracheal intubation; those with duration of hypoxia or hospitalization for more than 12 h; those with obesity with body mass index (BMI) >30 kg/m^2; those with PaO_2/FiO_2 <100 on noninvasive ventilation (NIV)/high-flow nasal cannula (HFNC); and having an intolerance to PP. All consecutive subjects admitted with hypoxemic respiratory failure were screened. The treating team decided the mode of oxygen delivery among conventional oxygen therapy, NIV, or HFNC as per the availability. Subjects who did not allow for PP underwent standard treatment and were included as controls for study purpose. Baseline variables, including age, comorbidities, radiological involvement, symptom duration, and severity of illness, were recorded. The severity of pneumonia was assessed by chest X-ray severity scoring.[4] On chest X-ray, divided into three zones in each lung, a severity score was assigned based on the presence or absence of opacity in each zone (maximum score 6, minimum 0).

The protocol followed for proning has been previously published.[5] Patients undergoing PP were assisted in changing positions. Proning was made comfortable by the use of multiple pillows over pressure points to avoid pain. Prone position was maintained for a minimum of 2 h per session and with a target duration of 8 h/day. A reverse Trendelenburg position of the bed was used to help increase comfort. The PP was stopped if there were patient intolerance, worsening of hypoxia, or the patient has recovered from respiratory failure. In case of any worsening hypoxia with respiratory distress, technical problems were checked and corrected, and prone position was withdrawn. Any respiratory distress with increased work of breathing was monitored, and MV was employed as per the discretion of the treating team. There was no protocolized transition to other noninvasive methods of oxygen delivery so as to avoid any delay in instituting MV. Recovery was defined as sustained improvement in oxygenation defined as more than 93% saturation in room air for at least 2 h following supination. Patients were followed up until hospital discharge or death.

ROX index (SpO_2/FiO_2%/respiratory rate, breaths/min) was monitored for improvement in oxygenation at baseline, 30 min, and 12 h in both the groups. ROX index is simple to calculate at the bedside and gives a summary of the patient's degree of hypoxemic respiratory failure.[6]

The primary outcome was the rate of intubation between the two groups. The secondary outcomes included ROX index at 30 min from the start of the intervention, ROX index at 12 h, days to the recovery of hypoxia (defined as room air SpO_2 >93%), and mortality.

Statistical analysis was done using Stata version 14.0 (StataCorp, Stata Statistical Software: Release 14. College Station, TX: StataCorp LP). Continuous variables were compared with *t*-tests and categorical variables with a Chi-square test. The paired *t*-test was used to compare pre- and post-PP change in oxygenation parameters of cases if normally distributed.

RESULTS

Among 78 subjects with COVID-19-related hypoxemic respiratory failure, 45 were enrolled following the inclusion and exclusion criteria. Among the 45 subjects included in the study, 30 patients received PP, while 15 were in the control group [Figure 1]. The mean (SD) age was 53.1 (11.0) years, with the majority being males. Age, comorbidities, and radiological severity were similar between the two groups [Table 1]. Medical management of both the groups included hydroxychloroquine (83% in cases and 73% in controls, $P = 0.45$) and corticosteroids (methylprednisolone 40 mg twice daily, 86.7% of both cases and controls) for 5 days. Baseline oxygenation, as measured by the ROX index, was similar in both the groups. The median duration of PP on the 1st day was 7.5 h (range, 4–12 h). The need for MV was higher in the control group (5/15; 33.3%) versus prone group (2/30; 6.7%). At 30 min from the initiation of proning, there was a statistically significant difference in the ROX index between cases and controls (10.7 ± 3.8 in cases vs. 6.7 ± 2.6 in controls, $P < 0.001$). At 12 h, both respiratory rate per minute (23.8 ± 3.4 among cases vs. 27.5 ± 4.6 among controls, $P = 0.004$) and ROX index (12.4 ± 4.5 among cases vs. 6.4 ± 3.0 among controls, $P < 0.001$) were significantly different between the two groups. The time to resolution of hypoxia as well as the mortality rate was not different. Adverse events associated with proning were mild and included backache (6.6%)

and bloating sensation (6.6%). There were no episodes of desaturation or hemodynamic worsening. Among cases, the ROX index improved statistically significantly from 8.5 ± 2.3 at baseline to 10.7 ± 3.8 at 30 min ($P < 0.001$). There was also an improvement in heart rate, respiratory rate, and saturation at 30 min and 12 h [Table 2].

DISCUSSION

In this study of COVID-19 patients with hypoxic respiratory failure, there was a lower rate of need for MV as well as a significant improvement in the oxygenation parameters with awake PP as compared to that of the control group.

Table 2: Baseline, 30 min, and 12 h postintervention parameters among cases (*n*=30)

Parameter	Baseline	30 min postprone	*P**	12 h postprone	*P**
Heart rate (beats/min), mean±SD	105.9±11.6	102±12.3	0.03	92.8±11.7	<0.001
Respiratory rate (breaths/min), mean±SD	28.9±3.6	27.1±3.4	<0.001	23.8±3.4	<0.001
Pulse oxygen saturation (%)	92.4 (2.8)	94.8 (1.7)	<0.001	95.3 (2.3)	<0.001

*Compared to baseline. SD: Standard deviation, SpO_2: Oxygen saturation

Proning in COVID-19 hypoxemic respiratory failure has been shown to result in improved oxygenation in multiple small studies.[7-11] PP can improve oxygenation by multiple mechanisms, resulting in improved ventilation–perfusion matching. Most studies have demonstrated an improvement in PaO_2/FiO_2 ratio and the respiratory rate among patients who tolerated a session of PP. The prone sessions reported in these studies were short, partly because of limited patient tolerance. The effects were transient, and respiratory rates and oxygenation parameters often returned to baseline after supination.[9] Most of these studies were limited by their retrospective design and lacked a control group. Our study stands apart as we included a comparison group, though in a nonrandomized fashion. We were able to achieve a longer duration of PP, with a median of 7 h/day.

The ROX index was used as it reflects an objective measure of work of breathing. ROX index was validated for identifying patients requiring intubation in hypoxic respiratory failure treated with HFNC.[12] ROX at 4 h of starting noninvasive oxygen therapy ≥5.37 was significantly associated with a lower risk for intubation in COVID-19 hypoxemic respiratory failure in intensive care admitted patients from a retrospective single-center study.[13]

Caution against early intubation has been raised in COVID-19 ARDS, and assessment of work of breathing is an essential determinant of the same.[14] We included patients early during the respiratory failure as this subgroup of patients are likely to benefit most from PP. Due to the limited sample size, we cannot conclude on the minimum duration of proning, which may be beneficial for crucial clinical outcomes. We also did not find any harm associated with the intervention in terms of mortality or recovery of hypoxia. The reported mortality rate in another prospective study of awake proning in COVID-19 was 43.5% in the prone position group, compared with 28 (75.7%) COVID-19 patients in the nonprone position group.[15]

There are several limitations to our study. It was a nonrandomized study and is subjected to bias. The tolerance of patients to PP was not measured as we excluded patients, not tolerating PP. We did not perform regular ABG, which is considered best to assess oxygenation and used noninvasive surrogates. All patients included were hemodynamically stable and had a similar baseline oxygenation index (ROX), which suggests homogeneity between cases and controls with respect to the severity of hypoxia. The mean ROX index in our study was 8.1, which suggests a milder form of hypoxemic respiratory failure in the included population. Computed tomography depiction of lung involvement has been used in some studies to predict the underlying physiology and determine the utility of PP; however, this was not done in our study due to feasibility issues.[15,16]

CONCLUSION

We conclude that awake PP, when employed early, for patients with COVID-19-associated hypoxemic respiratory failure, improves oxygenation, and may obviate the need for MV. Further randomized controlled trials are needed to assess its effect on mortality, although it may be difficult to perform in such a pandemic situation.

Comparative study between insulin bolus regimen and glucose insulin infusion regimen on effectiveness of intraoperative blood glucose control in patients with type 2 diabetes mellitus undergoing non-cardiac surgery

Parthasarathy Arun[1], Handattu Mahabaleswara Krishna[2]*
Resident Anaesthesiologist[1], Professor[2], Kasturba Medical College, Manipal, Manipal Academy of Higher Education, India.

Background: The surgical rates are comparatively greater among diabetic patients. Surgery, a period of stress, mandates fasting and anti-diabetic medications are skipped on the morning of the procedure. High blood glucose levels in the peri-operative period can lead to ischaemia, infection, acute kidney injury and electrolyte disturbances. Hence, control of blood glucose levels during the peri-operative period becomes important and there are various regimens described. We compared two of the existing regimens, intravenous insulin bolus and glucose insulin infusion regimen, for their effectiveness of intraoperative blood glucose control.

Method: In this randomized, prospective controlled study, 120 patients were enrolled with 60 patients in bolus group and 60 in infusion group. Capillary blood glucose was measured every hour during the intra-operative period. The primary outcome measure was proportion of patients in the target glucose levels between 100 mg/dL and 180 mg/dL and proportion of intra-operative surgery time (in minutes) during which patient was in the target range. Secondary outcome measure was serum potassium levels pre-operatively and post-operatively.

Results: The proportion of patients in the target range in the bolus group was 39 out of 60 as compared to 31 out of 60 in the infusion group (P=0.13). Also, proportion of intraoperative surgery time (in minutes) during which patient was in the target glycaemic range was 41.57% in bolus group when compared to 27.22% in the infusion group (P < 0.05). No hypoglycaemic episodes were seen in any of the patients in the two groups.

Conclusion: As compared with infusion regimen, bolus regimen provides better glycaemic control measured in terms of target blood glucose levels and duration for which the patient remained in the target range.

Keywords: Diabetes mellitus; intraoperative glucose management

Introduction

The rate of surgeries in diabetic patients are more when compared to non-diabetic patients.[1,2] Surgery under general or regional anaesthesia requires patient to be nil by mouth and glucose control medications omitted during this period. Glucose balance in the body can change due to metabolic disturbances occurring as a result of surgical stress.

Continuous high blood glucose levels can predispose to infection post-surgery, ischaemia of brain and impaired wound healing.[3] It is also a risk factor for diabetic emergencies perioperatively, which can lead to negative prognostic consequences. Gastrointestinal derangements induced by drugs, stress and anaesthesia can cause nausea, vomiting and dehydration. Also, osmotic diuresis induced by hyperglycaemia leads to volume contraction. These place the patients at risk for acute kidney injury. Electrolyte imbalance because of altered glucose levels may increase the risk for arrhythmias. Hence, the metabolic profile of these patients who undergo surgery must be attended to perioperatively.[3-6] The focus of these diabetic patients during surgery is prevention of either severely low or high blood sugar levels.[5]

There are many regimens that are described for perioperative blood glucose control each having its own advantages and disadvantages.

Intravenous insulin bolus is simple and reliable method for intra-operative glycaemic control and has been described by Poldermann et al.[7] Intravenous insulin infusion along with glucose is another popular regimen for intra-operative blood glucose management.[8] We compared the intra-operative glycaemic levels between insulin

bolus regimen and glucose insulin infusion regimen. The aim was to compare the intraoperative capillary blood glucose levels between intravenous insulin bolus regimen and glucose insulin infusion regimen in diabetic patients. The primary objective was to compare the intra-operative capillary blood glucose levels in patients managed using insulin bolus and glucose insulin infusion regimen. The secondary objective was to compare the preoperative and postoperative serum potassium levels.

Methods

Trial design

This randomized, prospective study was a single centred trial conducted at Kasturba Hospital, Manipal, Karnataka, India, after obtaining approval of the Institutional Ethics Committee. The study was registered with Clinical Trials Registry India (CTRI/2017/12/011037).

Eligibility criteria

Patients with type 2 diabetes mellitus (diagnosed from pat history or medicine consultation) between 18 and 70 years with preoperative fasting blood glucose value > 150 mg/dL undergoing elective and emergency non-cardiac surgery of at least one hour were eligible for inclusion. Patients scheduled under local anaesthesia were not included. Patients with known history of cardiac, respiratory, renal, hepatic failure (either compensated or decompensated, as indicated by physician's evaluation and laboratory investigations), those having active infection or taking steroids (irrespective of whether on insulin therapy or not) were excluded. Also, pregnant females and those with serum potassium below the reference range (<3.5 mmol/L) were excluded.

Randomization

Consecutive patients scheduled for surgery were considered for enrolment. If eligible, the participants were randomized to one of the two groups, group bolus or group infusion in the study.

We used simple randomization method. Randomization was done with the help of a computer-generated table. The principal investigator generated the random allocated sequence, enrolled participants and assigned them to interventions. Patients and investigators were not blinded for the treatment.

Interventions

During preanaesthetic evaluation the patients were explained about the study methodology and written informed consent for participation in the study was obtained. Preoperative fasting instruction was nil per orally 8 hours for solids and 2 hours for clear fluids (based on local practice guidelines). All patients received acid aspiration prophylaxis with ranitidine 150mg and metoclopramide 10mg orally, on the previous night and on the morning of the surgery. All patients were advised to skip the oral hypoglycaemic agents or insulin injections on the day of surgery. Patients who had received long acting insulin on the night before the surgery were started on 5% dextrose in 0.9% saline infusion with insulin added based on morning value of fasting blood glucose. During fasting period, decision to start on 5% dextrose in 0.9% saline with neutralizing dose of insulin was as per the concerned anaesthesiology consultant in charge of the operating room. This fluid was discontinued in the operating room. The technique of anaesthesia depended upon the requirement of the patient as per the concerned anaesthesiology consultant in charge of the operating room. After arrival of the patient in the operating room and before induction of anaesthesia, random capillary blood glucose was measured (zero hour) and patients with values of >150 mg/dL were included in the study.[15] Subsequently capillary blood glucose was measured every hourly using glucometer (Accu-Chek Performa and Accu-Chek Performa glucose strips; error of measurement is ±15% of the measured glucose values when compared with standard laboratory values) until the end of the surgery.

For the patients in *group bolus*, intravenous insulin - Monocomponent Human Insulin, biosynthetic r-DNA origin – Human Actrapid® (manufactured by Torrent Pharmaceuticals Ltd, Indrad 382 721, Dist: Mehsana, India, under license from Novo Nordisk India Private Ltd. Whitefield, Bangalore) was administered as given in Table 1.[7]

This regimen was adapted from a trial published by Poldermann et al, converting mmol/L to mg/dL using multiplication factor 18 for conversion of mmol/L to mg/dL (1mmol/L = 18 mg/dL), since the common mode of blood glucose measurement in our practice is in mg/dL.[7]

Table 1: Bolus insulin regimen

Glucose measurement (mmol/L)	Glucose Measurement (mg/dL)	Insulin bolus (IU)
4-8	72-144	-
8-9	145-162	2
9-10	163-180	3
10-11	181-198	4
11-12	199-216	5
12-13	217-234	6
13-14	235-252	7
14-15	253-270	8
15-16	271-288	9
>16	>288	10

In an event of hypoglycaemia (blood glucose level < 70 mg/dL), treatment was provided as bolus 100ml 5% dextrose in water (D5W) rapidly followed by repeat blood sugar level after 15mins. For the patients in *group infusion*, insulin was administered as infusion in 100ml of D5W taken in a burette set as given in Table 2.[8] Before the start of infusion, 10ml of 5% D5W + 1 IU insulin was added and mixed well in the burette, flushed through the tubings and discarded. After measuring the blood glucose value, burette was filled with the 100ml of infusing solution and according to Table 2 insulin was added to the burette through the side arm using an insulin syringe. The blood glucose measurements were performed when the burette got empty at the end of one hour, using a glucometer.

Patients in both the groups received 0.9% saline to meet their fluid requirements. In both the groups, preoperative serum potassium value was compared with the postoperative serum potassium level measured after 1 hour of surgery.

Outcome measures

The primary outcome measures were (a) The proportion of patients in the target glucose levels between 100mg/dl and 180mg/dl and (b) proportion of intraoperative surgery time (in minutes) during which patient was in the target glucose range. The secondary outcome measure was serum potassium level.

Sample size

With 80% power and a difference of 10% of patients who could be maintained in the target glucose level (100-180mg/dl) between the two studied regimens considered clinically significant, the sample size was estimated to be 360. Since the estimated sample size was relatively large with 360 patients, provision was made during the study design phase for two interim analyses i.e. when 120 patients and then 240 patients were enrolled. Interim analysis was done when two arms had a sample size of 60 each. It was found that the desired power and effect was achieved.

Table 2: Insulin infusion regimen

Blood glucose (mg/dL)	Treatment
<70	Stop insulin infusion if any. Rapidly infuse 100ml of D5W. Measure blood sugar after 15 min.
71 to 100	Stop insulin if any. Infuse 100ml/h of D5W
101 to 150	1 U of insulin in100ml of D5W/h
151 to 200	2 U of insulin in100ml of D5W/h
201 to 250	3 U of insulin in100ml of D5W/h
251 to 300	4 U of insulin in100ml of D5W/h
More than 300	1 U of insulin for every 1–50mg >100mg/dl in 100ml of NS/h

D5W - 5% dextrose in water; NS - normal saline

Statistical methods

The proportion of patients in the target glucose levels between 100mg/dl and 180mg/dl and the proportion of intra-operative surgery time (in minutes) during which the patient was in the target range were analysed with Chi square test. The secondary outcome measure (serum potassium level compared between preoperative value and postoperative value within the group) was tested with t test. Other statistical tests were used appropriately as required. SPSS 19 for Windows was used for statistical analysis.

Results

Patient characteristics and duration of surgery are given in Table 3. CONSORT flow chart is given in Figure 1. Comparison of proportion of patients in the target glycaemic range showed that 39 patients (65%) in bolus group and 31 patients (51.66%) in infusion group remained in the target glycaemic range in the intraoperative period. This was comparable (P=0.138, Chi square test).

Table 3: Patient characteristics and duration of surgery

	Bolus group (n = 60)	Infusion group (n=60)	P value
Age	53.68 (9.20)	54.76 (8.49)	0.51
Gender (Male/Female)	32/28	37/23	0.36
Duration of surgery (min)	99.58 (35.50)	88.50 (25.75)	0.14

Data are mean (standard deviation) for age and median (interquartile range) for duration of surgery Patients remained in the target glycaemic range for 4440 minutes out of 10680 minutes of surgery in the bolus group and 2940 minutes out of 10800 minutes of surgery in the infusion group. Patients were in the target glycaemic range for a longer period of time (41.57% of the intraoperative period) in bolus group when compared to infusion group (27.22% of the intraoperative period). This difference was significant (P <0.001; Chi square test).

To see if preoperative glucose levels confounded the results, we compared the preoperative blood glucose levels between the two groups (Table 4). It is evident from the table that a greater number of patients in the bolus group were outside the target range before the start of surgery.

Table 4: Blood glucose range in patients before the start of surgery

Blood glucose range (mg/dL)	Bolus group (number of patients)	Infusion group (number of patients)
150-180	10	17
181-210	14	35
211-240	11	6
241-270	15	1
271-300	4	0
>300	6	1

Postoperative serum potassium level decreased in both the groups [from 4.34 (0.55) mmol/l to 4.13 (0.48) mmol/l in bolus group, P<0.001 and from 4.29 (0.48) mmol/l to 4.26 (0.36) mmol/l in infusion group, P=0.54; Data are mean (standard deviation), t test)] but was clinically and statistically not significant.

Discussion

An ideal blood glucose control regimen should give good glycaemic control with least incidence of hypoglycaemia. Optimal blood sugar control is essential not only in preventing untoward complications, but also reflects the quality of health care. In this regard, a simple, easy to use regimen will help in working towards these goals.

In this study, we chose to compare the proportion of patients in the target glucose levels between 100mg/dl and 180mg/dl and the proportion of intra-operative surgery time (in minutes) during which patient was in the target range as primary outcomes rather than comparing the absolute values of blood sugar at different time intervals to be more meaningful clinically. Insulin bolus regimen maintained the patients for longer duration of time in target glycaemic range (41.57% of intraoperative period) as compared to infusion group (27.22%), though there was no significant difference in the proportion of patients in the target range between both the groups. Also, we noted that though a greater number of patients were outside the target blood glucose range preoperatively in bolus group when compared to infusion group, we had better control of blood glucose with the former. This confirms the effectiveness of insulin bolus regimen in management of blood sugars during the intraoperative period, especially in patients with poor preoperative glycaemic control.

The major concern with intravenous insulin boluses is the fear of hypoglycaemia. In the group of patients that we studied, there was no hypoglycaemia with both the regimens. We also compared to see if there was any significant difference in the serum potassium levels between both the studied groups as insulin is known to cause decrease in serum potassium levels. We found that there was no significant difference between both the groups clinically, although it was statistically significant in bolus group.

Prior studies have shown varying results while comparing insulin bolus regimen with infusion regimen.[9,14] But there are no studies to compare between intravenous bolus and infusion regimens in the intraoperative period.

Alberti et al and AAGBI guidelines in 2015 compared glucose control in two sets of diabetic patients and concluded that insulin infusion is a better choice in terms of glycaemic control over subcutaneous regimen.[9,13] ADVANCE trial,[10] study by Berghe et al[11] and ACCORD study[12] were conducted comparing two intravenous insulin regimens with different target ranges of blood glucose levels for the regimens. The above studies thus emphasize the effectiveness of intravenous insulin regimens with additional emphasis on the target blood glucose levels (between 100mg/dl and 180mg/dl).

Our study had some limitations. Blood glucose levels were monitored only once an hour. The fluctuations within this hour could not be captured since there is no monitor for continuous glucose monitoring. The onset time of intravenous human actrapid is immediate and

the peak effect is at 10-15 minutes. So, it is unlikely that these patients could have experienced hypoglycaemia and recovered from the same as well within one hour of monitoring. Markers of stress levels were not monitored in the study. So, despite the absence of baseline dextrose infusion in the bolus group blood glucose levels were maintained. Whether this happened at the expense of catabolism is not clear from this study. Preoperative glycaemic control was not compared between the groups using glycosylated haemoglobin levels.

Conclusion

Intravenous insulin bolus regimen as compared to insulin infusion regimen for intraoperative blood glucose management provides better glycaemic control measured in terms of proportion of intraoperative duration during which the patient remained in the target blood glucose levels. However, the proportion of patients in the target blood glucose levels was similar with both the regimens.

the older CT scanner are not always optimized to suit children. The result is that pediatric patients are being given considerably larger radiation doses than required for an optimum image quality.[13,14]

As children are intrinsically more sensitive to the effects of X-rays than adults, there is an urgent need to optimize CT exposure protocols for pediatric patients. The objective of optimization in CT exposures is to obtain acceptable image quality with minimum dose to the patients; reduction of dose in itself is not the objective of medical exposures. From this point of view, in recent times, much work has been done on optimization of scanning parameters in routine clinical conditions.[15-18] The foundation of optimization is the establishment of diagnostic reference levels (DRLs), first proposed by the ICRP in 1996[19] and later introduced into European[20] and Irish legislation.[21]

ICRP defines DRLs as "a form of investigation level applied to an easily measured quantity, usually the absorbed dose in air or tissue-equivalent material at the surface of (or inside) a simple standard phantom or a representative patient." This definition strongly emphasizes that DRLs are not the dose limits and do not help distinguish between good and poor medical practice. Although dose limits for occupational exposures must not be exceeded, patient DRLs may be exceeded if clinically necessary. DRLs also differ from dose limits for occupational exposure because they are not used to constrain individual patient exposures; this is because a dose higher than the standard dose may be required depending on the patient's body size and weight. DRLs are a tool for identifying facilities with unusually high doses and for promoting the optimization process.

Separate DRLs have been established for each country and/or region because equipment and procedure protocols can vary between different facilities in countries or regions, mainly due to different patient sizes and their weights. It is usually defined for a large collection of data at the 75th percentile. It can be defined at local level for a minimum number of 10–20 patients and preferably for a much larger number. By averaging such data from a large number of hospitals, the national DRLs can be estimated.[22,23] Hence, establishing national DRL would definitely ensure a safer pediatric CT diagnosis from patient's perspective. The purpose of DRLs is optimization of the imaging technique rather than radiation dose reduction to patients. If a justified examination does not provide the necessary clinical information because of too low dose resulting in an inadequate image quality, then the patient has been exposed needlessly to radiation. In clinical practice, it is assumed that the necessary dosage, within stipulated margins, will be used. In this line, it is essential to initially establish zonal DRL, namely, South, North, East, West and central and finally consolidate them to arrive at the pediatric DRL for the country. Thus, the objective of our study was to measure radiation dose for most commonly performed pediatric head, chest, and abdomen procedures in the radiology department in Tamil Nadu hospitals and suggest/derive pediatric DRLs, compare them with the internationally recommended DRLs and to suggest dose reduction methods without disturbing image quality.

Materials and Methods

Selection of computed tomography scanners

When attempting to establish regional CT DRLs which are applicable to all hospitals in Tamil Nadu, it is essential to sample as many hospitals as possible. The hospitals incorporated were equally spread over in the state of Tamil Nadu. This work was performed in thirty CT scanners which include both conventional and multidetector CT (MDCT) types installed at various major cities (Chennai, Coimbatore, Madurai, Salem, Erode, Tirupur, Namakkal, Trichy, Vellore, Dindigul, Dharmapuri, Hosur, Thiruvarur). The selection of the scanners was based on the number of pediatric patients investigated. The average number of pediatric patients scanned each day in the Tamil Nadu region was 3000: From this 1100 for head, 900 for chest and 1000 for abdomen CT procedures were performed. The total number of patients examined each day in the region was approximately 9000. Table 1 summarizes the make and model of the CT scanners involved in this study.

Radiation dose calibration

Before collecting the patient dose data, CT dose index (CTDI) measurements were carried out on all CT scanners by using calibrated 100 mm pencil ionization chamber (DCT10 RS, S/N 1636) and solidose electrometer 400 (S/N 4253) of RTI Electronics, Sweden. For this purpose, polymethyl methacrylate head (10 cm diameter) and body (16 cm diameter) phantoms were used.[24] The dosimetry methods recommended in the European guidelines[20] were followed. The individual approximate patient dose data were estimated from the phantom $CTDI_v$ and DLP measurements. It should be noted that phantom measurements are only a measure of the actual patient dose. Furthermore, it requires correction for different pediatric patient diameter.

Computed tomography dose measurements

Before initiating measurements in hospitals, a questionnaire was prepared to collect data regarding the pediatric CT protocols and clinical practices adopted by the hospitals in Tamil Nadu. These data helped to record the pediatric CTDI values for different scanning protocols adopted by the various departments. Participants were asked to extract from the scanner library, data for twenty patients belonging to each examination type and each age group in thirty CT departments (a total of 120 [20 (patients) × 3 (sites) × 2 (age group)] × 30 = 3600 procedures). In each category of machine, the lowest, highest, and mean physical parameters and operating parameters of both age group of pediatric patients are presented in Tables 2 and 3. Each row in this table refers to the parameters of the scanners mentioned in Table 1 in the same order.

This data abstraction has been done as per "Nationwide Evaluation of X-ray Trends" protocol.[25] The questionnaire contains a number of parameters including (i) make and model of the CT scanner, (ii) patient physical parameters

such as height, weight, lateral diameter and anteroposterior diameter, (iii) indication, (iv) interested organ, (v) phase such as pre- and post-contrast, arterial phase, venous phase, full bladder, and delay phase, (vi) routine scan parameters such as tube potential, tube current, scan time, rotation time, slice thickness, slice beam collimation, pitch, total slices, field of view, start couch level and end couch level, (vii) dose-related data such as displayed volumetric CTDI and DLP.

The majority of the hospitals have followed almost similar exposure parameters for chest and abdomen procedures. However, the newer scanner systems like 64 slice, 128 slice CT machines use AEC/care kV technique for pediatric patients. Some of the CT centers have used larger scan length for routine brain and abdomen procedures. Further, it was noted that individual CT radiographers selected different scan parameters for the same type of pediatric patients.

CT dose experiments were carried out by placing the standard head and body phantom at the isocenter of the CT scanner and applying one axial slice of a clinical head protocol in sequential scan mode. The dose received by the phantom at the five positions for a set of scan parameters was measured by placing the ion chamber in one hole at a time while plugging the rest of holes with acrylic rods.

The CTDI is defined as:[26]

$$CTDI = (1/nT) \int D_z \, dz \text{ (integration limits from } -50 \text{ mm to } +50 \text{ mm)} \quad (1)$$

where, n is the number of data channels in the multiscan CT scanner, T is the slice thickness corresponding to one channel and the integration is done over the length of the pencil chamber (100 mm). The CTDI was measured as per the above definition by the pencil chamber-electrometer system and displayed on the dosimeter unit. CTDI is defined for a single complete rotation of the CT scanner. Using these dose values, the other CT dose indices, namely, weighed CTDI ($CTDI_w$), $CTDI_v$, and DLP were calculated using the following relations:

$$\text{Weighted } CTDI_w = 1/3\ (CTDI_{100,c}) + 2/3\ (CTDI_{100,p}) \quad (2)$$

$$\text{Volumetric } CTDI_v = CTDI_w/\text{pitch} \quad (3)$$

$$DLP = CTDI_v \times \text{scan length} \quad (4)$$

Results and Discussion

Before carrying out the regional dose estimation, complete QA (electrical, mechanical, and radiation checks) was performed for all the machines involved in this work. One among these tests was the measurement of $CTDI_w$ for standard protocol involving tube potential of 80 kV, 100 kV, and 120 kV, tube current-time product of 100 mAs and 5 mm slice thickness. These values were compared with the $CTDI_w$ displayed on the console to ensure that the measured and displayed values agreed as per Atomic Energy Regulatory Board standards (maximum ± 18%).[27]

The CT dose indices were measured based on the five point method proposed by European guidelines using standard CTDI phantoms and suitable detector. The pediatric CTDI phantom was placed on the couch and aligning the central axis of the phantom with isocentre point of the gantry. As per FDA's recommendation the dose is measured at the four peripheral holes as well as the central hole. The measured $CTDI_v$ and DLP of pediatric head, chest and abdomen procedures for

Chest	4-13	5-15
Abdomen	5-14	5-18

both age groups at different CT departments are presented in Figures 1 and 2.

Figures 1 and 2 show that the large variations in CT radiation doses for pediatric head, chest, and abdomen procedures were noted for both age groups. This may be attributed to scans conducted without optimization of tube voltage and tube current-time product (mAs) with respect to the patient anatomy and organ of interest. Out of thirty CT departments, twenty CT departments have followed larger scan length for routine procedures; this will also give rise to an increase in the patient dose. Further, in this work, it was observed that based on the experience and knowledge of the radiographers, the selection of exposure parameters was altered from the default values. Those who have experience, have selected appropriate scan parameters when compared with newer radiographers; this also contributes to minimize radiation dose. Further, in this study, latest advancements and concepts in CT technology and selection of techniques such as detector arrangements, detector size, number of detectors, scan speed, tube rotation time, and type of detector (e.g., stellar detector in Siemens CT) available in recent MDCT scanners have been employed with reduction of radiation dose when compared with older CT scanners for pediatric patients.

Further, using overall calculated $CTDI_v$ and DLP value for both age groups of pediatric patients, the 75th percentile of $CTDI_v$ and DLP for head, chest and abdomen procedures thus calculated was taken as their respective third quartile values for each group of pediatric patients. The pediatric CT DRL proposed for Tamil Nadu region in south India has been compared with DRL recently proposed by EC[28] in Tables 4 and 5 [extracted from Figures 1 and 2].

From Tables 4 and 5, it was observed that the 75th percentile of $CTDI_v$ of pediatric head is lower than European DRL for both age groups. For chest and abdomen procedures, the 75th percentile of $CTDI_v$ is higher than European DRL

for both age groups. This may be attributed to selection of greater exposure parameters for pediatric chest and abdomen procedures as compared to European practice. Following the European regulations, it becomes necessary to take into account the body size and habitus for selection of optimum machine parameters (e.g., tube voltage and mAs) for the

DLP: Dose length product

required diagnostic information with minimum dose to the patient. In addition, it was observed that the 75th percentile of DLP of pediatric head for 0–1 year old patients is higher and for 1–5 years old patients is lower than European PiDRL, and for chest and abdomen procedures was higher than European pediatric DRL for both age groups. This is mainly

[Downloaded free from http://www.jmp.org.in on Monday, March 20, 2017, IP: 115.248.154.247]

because of choosing higher scan length for both procedures and both age groups.

From this study, it is suggested that it is very important to justify CT examinations in advance and once the decision for CT scan is taken, it is mandatory to adopt the ALARA principle strictly. In this line, radiologists should play essential advisory role with referring clinicians. When equal or greater diagnostic yields are expected, CT should be replaced by alternative imaging modalities such as sonography, magnetic resonance imaging, or radionuclide voiding cystography. On the other hand, radiologists should make every effort to reduce the pediatric radiation dose of CT examinations while maintaining diagnostic quality when CT is indicated. Furthermore, minimizing the scan range of CT examinations as required is a straightforward way to achieve this goal. CT radiographer should follow the strategies for pediatric CT dose optimization methods, namely, body size adopted CT protocols, tube current modulation, optimal tube voltage, scan modes, appropriate pitch, appropriate scan length, and field of view to reduce the pediatric CT radiation dose for selected procedures.

Conclusion

This study reports the regional pediatric CT DRLs for head, chest and abdomen procedures for the first time in Tamil Nadu region. More than 3600 individual patients' data were recorded and studied. The experimentally measured $CTDI_v$ and DLP values for all procedures were compared with displayed control console values (maximum ± 18%). Tamil Nadu pediatric CT DRL values have been proposed for $CTDI_v$ and DLP of head, chest, and abdomen procedures for <1 year and 1–5 years age group of patients. These proposed DRL values were compared with the pediatric European DRL values and strategies for pediatric CT dose reduction have been suggested. In this line, all clinicians who request pediatric CT should frequently assess its suitability on a case-by-case basis. When used carefully, CT is a valuable imaging modality for both age groups of children.

Qualitative and Quantitative Assessment of Enhancement and Washout Characteristics of HCC and non HCC Hypervascular Liver Tumours

PRERNA GARG[1], SALIL PANDEY[2], MUTHUSUBRAMANIAN[3], CINDREL[4], B DEVANAND[5], V MAHESHWARAN[6], R RAJAKUMAR[7]

Introduction: The image based diagnosis of Hepatocellular Carcinoma (HCC) relies on assessment of arterial enhancement and venous or delayed phase washout. This assessment is based on visual analysis; however, studies quantifying such enhancement and washout are lacking.

Aim: To qualitative assessment of the imaging characteristics of HCC and non HCC hypervascular liver tumours followed by quantitative assessment of the enhancement and washout kinetics, and also to derive objective values that may help in differentiating HCC from non HCC on Computed Tomography (CT).

Materials and Methods: The present study was carried out in PSG hospitals, Coimbatore, Tamil Nadu, India. Retrospective analysis of hypervascular liver lesions was performed over a study period of four years (January 2012 to February 2016). These lesions were divided into two groups namely; HCC and non HCC. All non HCCs were pathologically proven, while HCC cases included those diagnosed on histopathology or typical imaging findings based on American Association for the Study of Liver Diseases (AASLD) (2010) and Liver Imaging Reporting and Data Systems (LIRADS) (2014) diagnostic criteria along with an elevated Alpha Fetoprotein (AFP) of more than 400 IU/mL.

A qualitative analysis of the enhancement and washout patterns was done followed by quantitative analysis using Regions of Interest (ROI) measurement of attenuation in Hounsfield units (HU). The quantitative parameters assessed were; Mean Attenuation (MA) of lesions in different phases, Attenuation Gain Percentage (AGP) on arterial phase, Arterial Phase Attenuation Change (AAC), Attenuation Loss Percentage in venous and delayed phases (ALP-V, ALP-D), Percentage Attenuation Ratio in venous and delayed phases (PAR-V, PAR-D) and Relative Washout Ratios from arterial to venous/delayed (RWR A-V, RWR A-D) and from venous to delayed phases (RWR V-D). Sensitivity and specificity were calculated for qualitative washout.

For quantitative variables comparative analysis between HCCs and non HCCs was done using Student's t-test. ANOVA was used to compare different categories. ROC curves were drawn for values that were significantly different to establish a cutoff value.

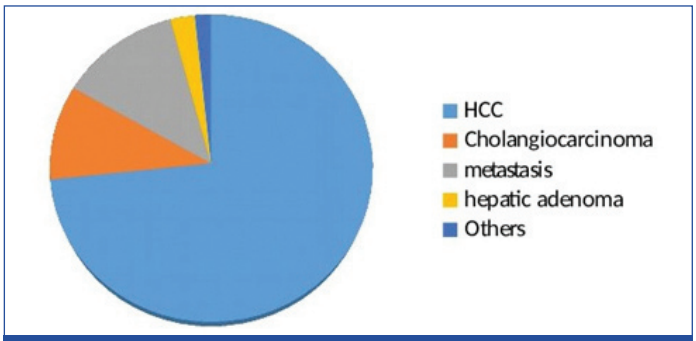
Results: A total of 120 lesions were evaluated consisting of HCCs (n=88) and non HCCs (n=32). Qualitatively majority (81) of HCCs demonstrated arterial enhancement and washout with eight cases of these demonstrating subtle washout requiring settlement by consensus. Washout were absent in seven cases. True mimics of HCC on qualitative analysis were hepatic adenomas, few cases of metastasis and hepatoblastoma were also there. The overall sensitivity of the washout appearance for predicting HCC was 92% while specificity was 78%. On quantitative analysis a PAR-V≥106 has sensitivity of 70% and specificity of 75%, RWR-V-D≥41.79 has sensitivity of 75% and specificity of 70% for HCC detection. Additionally significant difference was seen between RWR V-D of HCC when compared to cholangiocarcinomas (p-value 0.035) and metastasis (p-value 0.026) and also between PAR-V of HCC and metastasis (p-value 0.033).

Conclusion: The qualitative analysis combined with quantitative assessment of washout using percentage attenuation ratio in venous phase and relative washout ratio from venous to delayed phase offers good sensitivity and specificity in image based diagnosis of HCC.

Keywords: Hepatocellular carcinoma, Percentage attenuation ratio, Relative washout ratio

INTRODUCTION

The diagnosis of HCC on imaging relies on subjective assessment of arterial enhancement and venous or delayed phase washout. The arterial phase enhancement is attributed to an increase in intralesional flow with relative reduction in portal flow which occurs as the lesion progresses from dysplastic nodule to HCC [1,2]. Venous or delayed phase washout is decrease in attenuation of the lesion relative to background liver. Factors attributed to washout include early drainage of contrast material as compared to parenchyma and retention of contrast by surrounding fibrotic parenchyma [1-3]. There is ample literature on arterial enhancing mimics of HCC [1,3-7]. Arterial enhancing metastases, cholangiocarcinomas are known, similarly washout, a hallmark of HCC has been described in other tumours [5-7]. According to some studies Intrahepatic Mass-forming Cholangiocarcinoma (IMCC) showing arterial enhancement, was the most common lesion misinterpreted as HCC in preliver transplant imaging work up in recipients [5,9]. In cirrhotic livers lesions like regenerative nodules, dysplastic nodules, arterioportal or venous shunts and confluent fibrosis may also mimic this appearance [2,5-9]. Owing to typical enhancement characteristics of HCC, radiological imaging plays a crucial role in diagnosis and this combined with certain clinical and biochemical characteristics have been adopted as practice guideline for diagnosing HCC over the world. Differentiating HCC from other hypervascular tumours is important since HCC has therapeutic implications and prognostic factors which are very different from other lesions [2,8,10].



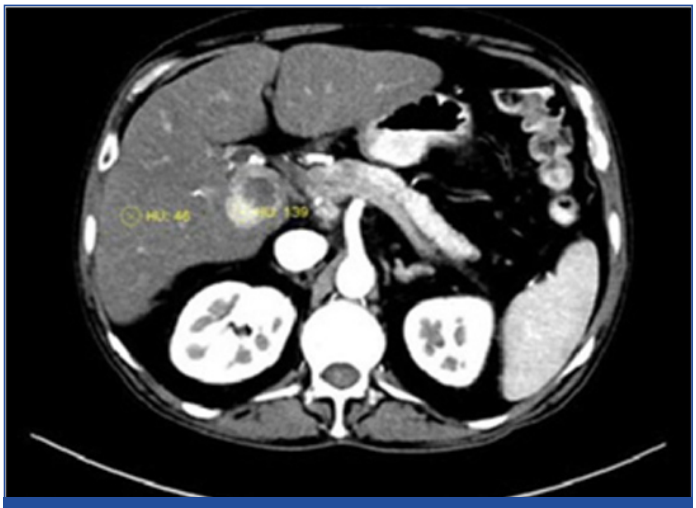
The assessment for hypervascularity of tumours and washout or persistent enhancement relies heavily on radiologist's subjective visual assessment. Only few studies have attempted to quantitate these variables and define the washout phenomenon [2,10]. In one

study, parameters such as relative contrast washout ratio between the arterial phase and delayed phase and attenuation ratio of the lesion to the background liver were studied and the attenuation ratio of the lesion to the background liver in the delayed phase was found to have excellent sensitivity and specificity for HCC detection and good correlation with subjective assessment [2]. In yet another study, an attenuation difference of greater than 10 HU between the arterial and delayed phase yielded optimal sensitivity and specificity for detecting HCC [10]. Certain studies have also quantitatively assessed the washout pattern on Magnetic Resonance Imaging (MRI), with a study evaluating the signal to noise ratio and liver to lesion contrast [11]. Overall the available literature is limited in this aspect with variable results. In present study, we analysed a large retrospective cohort of hypervascular liver tumours which were consecutively diagnosed over a period of four years in our hospital. We performed a qualitative assessment of the imaging characteristics of HCC and non HCC hypervascular liver tumours followed by quantitative assessment of the enhancement, washout kinetics and derived objective values that help in differentiating HCC from non HCC on CT. To the best of our knowledge this is the first such Indian cohort of hypervascular liver tumours being subjected to such qualitative and quantitative assessment.

MATERIALS AND METHODS

Institutional Ethics Committee approval was obtained and requirement for informed consent was waived after considering the retrospective nature of study. An extensive search of our Hospital Information System/Picture Archiving And Communication System (HIS/PACS-Vepro Medical Systems) for liver lesions on CT using keywords Hepatic, liver lesion, hepatic lesion, space occupying lesion, mass, HCC, Hepatocellular carcinoma and each of the individual common malignant and benign liver lesions revealed a total of 389 patients from January 2012 to February 2016 (four years duration). All Multidetector Computed Tomography (MDCT) examinations were performed on 64 slice MDCT (Somatom 64, Seimens healthcare) or 128 slice (Somatom Definition edge, Siemens healthcare) helical scanners. All studies were carried out in craniocaudal direction with patient supine with average 120 KV and 250-450 mA, values varying depending on patients build. Unenhanced images were obtained followed by administration of IV contrast (Iopromide 350-370 mg/mL), power injector was used for injection of contrast at a rate of 4 mL/sec. Automated bolus tracking was used. Images were obtained in arterial, venous and delayed phases, typically at 18-28 seconds, 55-65 seconds and 300 seconds after initiation of contrast administration.

Hypervascular tumours on arterial phase were studied; thus, all hypo or avascular lesions were excluded. Hypodense lesions with thin peripheral enhancement, the pattern which is most common in metastatic lesions, were also excluded. The other exclusion criteria were: i) HCCs without histopathology and not meeting the criteria mentioned below in confirmation of tumor subtype, ii) Diffusely infiltrative HCCs as enhancement pattern and washout characteristics are difficult to assess in them, iii) HCCs with changes related to treatments like thermal ablation or transarterial chemoembolisation, iv) Non HCCs without definitive histological diagnosis, v) Very small tumours less than one cm in size as placing ROI for measurements is difficult in them, vi) Benign lesions like hemangiomas, abscess and cysts were also excluded as they show fairly typical enhancement patterns and in most no histopathological confirmation is done. Histopathological confirmation was available for all non HCCs and HCC (35 cases). 53 HCCs, all in at risk population having underlying cirrhosis were diagnosed based on AASLD guidelines (2010) and LI-RADS (version 2014). First AASLD criteria was applied (a lesion of more than 2 cm showing arterial phase hyperenhancement and subsequent washout, in presence of cirrhosis and elevated AFP levels, we used AFP cutoff of >400 IU/mL to enhance specificity), tumours meeting these criteria are virtually diagnostic of HCC [13]. All of these 53 cases were LI-RADS 5 category (indicating 100% certainty of HCC), with 34 cases being LR-5, 17 cases LR-5V with macrovascular invasion and two cases being LR-5us (being 1-2 cm in size and being visible as discrete nodules on ultrasound) [14]. Two HCCs were histological variants, one a fibrolamellar HCC and another cholangiocellular variant. After application of exclusion and inclusion criteria we arrived at a study population of 120 patients (86 males and 34 females) mean age 58.5 years, range (3-78 years). There were 88 (73%) HCCs, 12 (10%) mass forming cholangiocarcinomas, 15 (12.5%) metastasis, 3 (2%) adenomas, 1 (0.08%) hepatoblastoma and 1 (0.08%) angiosarcoma [Table/Fig-1]. For purpose of comparability the tumours were divided in two broad groups of HCC and non HCC.



[Table/Fig-1]: Distribution of tumours.

A subjective or qualitative assessment was performed by two radiologists; having nine and five years of experience in abdominal imaging. After confirming the hypervascular nature of the tumour on the arterial phase assessment of subjective washout was done and presence or absence of washout on venous or delayed phases was noted. Presence of any delayed hyperenhancing central stroma was also noted. The examining radiologists were blinded to the results of histopathology and final diagnosis. Discrepancies if any were settled by consensus.

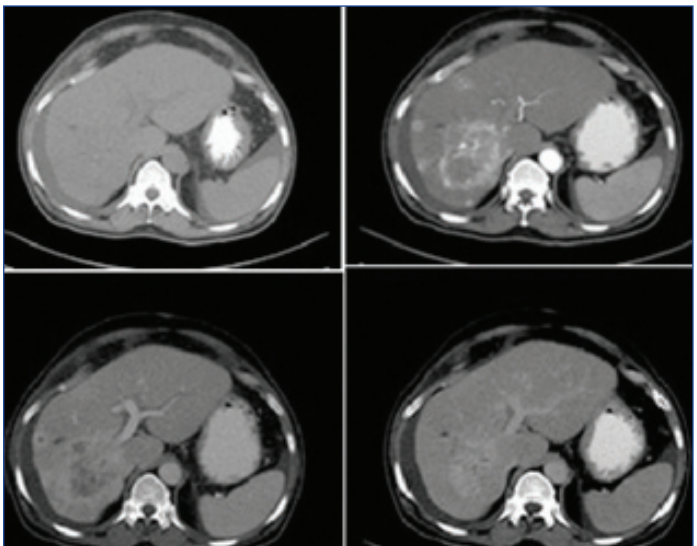
The quantitative analysis was done by one radiologist. The attenuation were measured in HU by drawing circular or oval ROI over the lesion. The ROIs were drawn to include maximally enhancing areas on arterial phase and ranged from 10 to 20 mm with similar ROI drawn on corresponding venous and delayed phase images. The necrotic areas of the tumour, major intratumoral feeding vessels or intratumoral arterioportal shunts were excluded [Table/Fig-2]. In case of large tumours with variable areas of enhancement, multiple ROIs were drawn in the enhancing regions of the tumour and averaged. Two ROIs were also obtained in the adjacent normal background liver in all the phases, taking care to avoid blood vessels. In case of multiple lesions, largest lesion was selected.

The following quantitative indices were calculated 1) Mean attenuation(MA) of lesions in different phases 2) Attenuation gain

[Table/Fig-2]: Hepatocellular carcinoma in caudate lobe with an eccentric necrotic component, ROI placement was done in the enhancing tumour component .

percentage on arterial phase (AGP): SOL a-BL a / BL a x100), Arterial phase attenuation change (AAC): SOL a –BL a (these indices assess the arterial enhancement of the lesions). 3) Attenuation loss percentage in venous and delayed phases (ALP-V, ALP-D): BL v/d-SOL v/d/ BL v/d x100; Percentage attenuation ratio in venous and delayed phases (PAR-V, PAR-D): 100x BL v/d/SOL v/d; Relative wash out ratio (RWR A-V, RWR A-D) from arterial to venous and delayed phases: 100x (SOL a-SOL v/d)/SOL a and from venous to delayed phases(RWR V-D): 100 x (SOLv-SOL d)/ SOL v.(these variables define the washout characteristics). (SOL a and BL a were attenuation of space occupying lesion and background liver attenuation on arterial phase respectively, SOL v/d and BL v/d were lesion and background liver attenuation on venous and delayed phases).

STATISTICAL ANALYSIS



Statistical analysis was performed using IBM SPSS Statistics for Windows, version 20.0 (IBM Corp., Armonk, N.Y., USA). Sensitivity and specificity for washout appearance were calculated. For quantitative variables comparative analysis between HCCs and non HCCs was done using Student's t-test. ANOVA analysis was used for comparison between HCC and individual categories in Non HCC (cholangiocarcinomas, metastasis and others). ROC curves were drawn for values that were significantly different to establish a cutoff value.

RESULTS

The demographic and qualitative characteristics of the HCC and non HCC are as in [Table/Fig-3]. On qualitative analysis all HCCs showed homogenous or patchy enhancement on arterial phase. There was excellent interobserver agreement between the two radiologists for hypervascularity (Kappa value of 0.91) and presence of washout (Kappa value of 0.86) and discrepancies if any, were settled by consensus. Washout was noted on venous phase in 62/88 (69.3%) patients while on delayed phase additional 19 patients showed washout (81/88,92%). Overall 92% HCCs demonstrated washout in either venous or delayed phase. There was lack of subjective washout as perceived by both radiologists in 7/88 (8%) tumours [Table/Fig-4]. Of these however, two tumours did demonstrate a difference in quantitative washout if absolute values of HU obtained from ROI between the lesion and background liver were considered (though the difference was less than 10 HU). In addition in 8 (9%) tumours the washout was perceived as subtle and required either extensive window setting adjustments (in five cases) or settlement by consensus (three cases). The confounding factors encountered affecting visual assessment were presence of 1) steatosis in the background liver with lesion appearing hyperdense relative to the surrounding fatty liver in two cases, 2) presence of enhancing peripheral pseudocapusle in five cases and a delayed enhancing central fibrous stroma (noted in one case of fibrolamellar HCC). The metastases were the commonest non HCC lesion. Most of the hypervascular metastases were from adenocarcinomas with known or unknown primary sites. A qualitative washout appearance similar to HCC was noted in three cases (20%). Amongst the carcinoid metastasis or neuroendocrine tumours in present study sparing one which washed out the other two were hyper or isodense to parenchyma. Both cases of sarcoma metastasis (n=2) had peripheral enhancement, while washout was seen in one, the other was seen filling in from periphery to the centre. Thus, most of metastatic lesions showed no washout in the venous or delayed phase except one case of transitional cell carcinoma, one of neuroendocrine tumour and one sarcoma. Most of the adenocarcinoma metastases were isodense to parenchyma on delayed phase. The metastasis from gastrointestinal stromal tumour had peripheral fill in pattern.

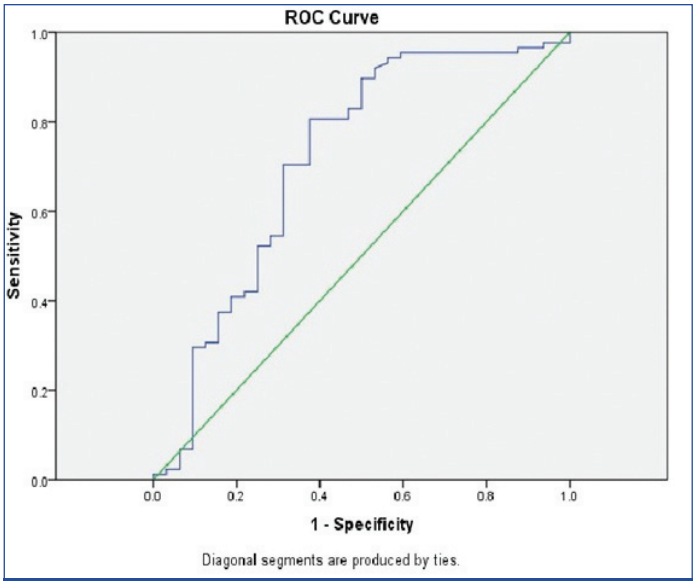
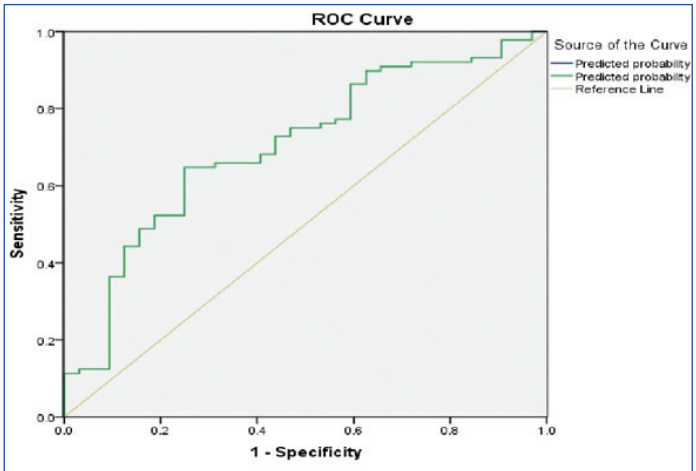
[Table/Fig-3]: Demographic and qualitative parameters of HCC and Non HCC. The difference is significant at p<0.05
HCC*- Hepatocellular carcinoma



[Table/Fig-4]: Histopathologically proven hepatocelluar carcinoma, multinodular in alcohol related cirrhosis, showing progressive enhancement pattern with lack of subjective or quantitative washout.

Amongst cholangiocarcinomas, none demonstrated washout on delayed phase, all the lesions appeared isodense, hyperdense or showed central enhancing stroma in the delayed phase. The true HCC mimics on qualitative analysis were the three cases of hepatic adenomas and one case of hepatoblastoma which had an enhancement and washout appearance similar to HCC. The only case of angiosarcoma showed hyperdense appearance on delayed phase. Thus, hepatic adenomas, few hypervascular non adenocarcinoma metastasis and hepatoblastoma showed washout appearance in venous or delayed phase; thus, mimicking HCC. The overall sensitivity of the qualitative washout appearance for predicting HCC was 92% while specificity was 78%.



The difference between the mean attenuation of the HCCs and non HCCs was significant in noncontrast (p-value 0.01), arterial (p-value 0.002) and delayed phases (p-value 0.013), while the difference was not significant in the venous phase (p-value 0.614). The quantitative indices are as listed in [Table/Fig-5]. There was no significant difference between the two groups in attenuation change in arterial phase (AAC), while AGP was significant (p-value 0.018). Of the washout parameters, in venous phase significant difference (p-value 0.002) was found in PAR-V in venous phases with no significant difference seen between the two groups in PAR-D. The washout parameters assessed were relative washout from arterial to venous or delayed phase (RWR A-V, A-D) and from venous to delayed phase (RWR-V-D). The relative washout from arterial to venous or delayed phases was (RWR A-V,A-D) was found to be significant (p-value 0.022, 0.004). Washout from venous to delayed phase (RWR-V-D) was also significant between the two groups (p-value 0.000). ALP-V that is attenuation loss percentage in venous phase was also significant (p-value 0.001). However, area under curve was significant for RWR V-D and PAR-V only (r-value >0.7) and analysis of ROC curves for PAR-V and RWR-V-D revealed good sensitivity and specificity for detection of HCC [Table/Fig-6,7].

	HCC (Mean)	Non HCC (Mean)	p-value
MA-NCCT	66.31	52.71	0.01
MA-Arterial	105.96	89.8	0.002
MA-Venous	89.34	91.73	0.614
MA-Delayed	51.75	63.09	0.013
AAC	13.5	2.46	0.070
AGP	27.9	7.17	0.018
PAR-V	116.29	101.89	0.002
PAR-D	117.33	116.09	0.810
RWR A-V	9.3	-6.6	0.022
RWR A-D	45.05	25.6	0.004
RWR V-D	43.27	31.38	<0.001
ALP-V	10.83	-1.16	0.001
ALP-D	12.01	9.73	0.487

[Table/Fig-5]: Details of quantitative variables assessed.
MA-NCCT*-Mean Attenuation Non Contrast CT
AAC*- Arterial phase attenuation change, AGP*- Attenuation gain percentage, PAR-V*- Percentage attenuation ratio-venous phase, PAR-D*- Percentage attenuation ratio-delayed phase, RWR A-V*- Relative washout ratios arterial-ratio, RWR A-D*- Relative washout ratios arterial-delayed, RWR V-D*- Relative washout ratios venous-phase, PLP-V*- Attenuation loss percentage-venous phase, ALP-D*- Attenuation loss percentage-delayed phase

[Table/Fig-6]: Receiver operating curve (ROC) for RWR-V-D, area under curve >0.7

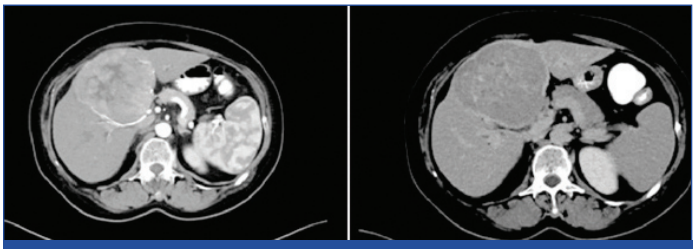
[Table/Fig-7]: Receiver operating curve (ROC) for PAR-V, area under curve >0.7

On individual comparison of HCC with metastasis, cholangiocarcinoma and others category, significant difference was seen between RWR V-D of HCC (mean 43.27) when compared to cholangiocarcinomas (mean 31.2, p value 0.035) and metastasis (mean 33.63, p value 0.026).

DISCUSSION

Studies show that combination of arterial hypervascularity and washout appearance of HCC on MDCT offers a specificity approaching 100% for HCC >20 mm in at risk populations. According to the AASLD guidelines (2010) a lesion of more than 10 mm showing arterial phase hyperenhancement and subsequent washout, in presence of cirrhosis can be considered as HCC and treated as such. Similar guidelines have been proposed by European Association for the Study of the Liver (EASL) in 2012 [13-15]. More recently LIRADS (2014) has been developed for categorising liver lesions in at risk population; this classification aims to facilitate clear communication between different personnel involved in care of these patients. The lesions falling in LR-5 category are nearly certain to be HCCs and consists of hypervascular lesions of more than 2 cm with one or more combinations of washout, capsule, threshold growth. In addition macrovascular mainly portal vein invasion constitutes LR-5V category [14].

A comprehensive quantitative analysis may help in providing further parameters that assists differentiation between HCC and non HCC. A quantitative assessment may also reduce interobserver variability and lay foundation for development of diagnostic algorithms and computed aided detection parameters. To the best of our knowledge, this is also the first study of this kind in India with no previous Indian cohort of hypervascular liver tumours having being subjected to this kind of qualitative and quantitative assessment.



HCCs showed uniform or nonuniform enhancement with most showing washout appearance. The overall sensitivity of the qualitative washout appearance for predicting HCC was 92% while specificity was 78%. The venous phase washout was seen in 69.3% patients while in delayed phase this number increased to 92%. About 8% of HCC did not washout at all while another 9% had a subtle washout. Latter could be resolved subjectively itself and washout even though subtle could be resolved qualitatively with a consensus agreement of two experienced radiologists. Thus, a qualitative washout assessment in a tertiary level setup with high volumes and experienced radiological staff does hold an excellent sensitivity and a reasonable specificity for HCC detection. The specificity may approach 100% if additionally presence of imaging features of cirrhosis is taken into account since none of the non HCCs had underlying cirrhosis. The overall sensitivity of the qualitative washout appearance for predicting HCC was 92% while specificity was 78%.

On quantitative evaluation there was significant difference in the attenuation between the two groups on noncontrast, arterial and delayed phases. Of the arterial parameters the AAC was found to be significantly different between the HCCs and non HCCs. However, when comparing the HCCs with individual subgroups of non HCCs the significance could not be elicited. The AGP was found to be significantly different between the two groups however, it merely represents arterial hypervascularity and doesn't quantitate washout. The PAR as suggested by Liu Y et al., is a measurement of washout appearance of HCC, measured as a ratio of liver and lesion attenuation [2]. The values for PAR in venous phase showed significant difference between the HCC and non HCC while in delayed phase the difference was not statistically significant. The mean PAR-V of HCC was higher than Non HCC. The absence of difference of PAR in delayed phase is probably because there were lesions like adenoma and certain metastases that washed out significantly more than HCC from venous to delayed phase as compared to HCC resulting in almost similar values of PAR-D. A cutoff of PAR-V of 106 provided 70% sensitivity in diagnosing HCC. Relative Washout Ratio (RWR) from arterial to delayed and venous phase was significantly different between the two groups but seems irrelevant as many of the values were negative, since maximum enhancement was obtained in venous phase in many tumours. Considering the fact that attenuation of the lesion was maximum in

venous phase, the calculated RWR from venous to delayed phase (RWR-V-D) showed that the HCC washout significantly more than non HCC and this temporal parameter of washout from venous to delayed phase seems more relevant than ascertaining washout from arterial to venous or arterial to delayed phase. As discussed earlier the washout phenomena is an appearance based on a lot of factors and RWR from venous to delayed phase seems to be one of the parameters that may differentiate the HCC and non HCC negating the effect of liver parenchymal attenuation. It is likely that gradient of loss of attenuation of lesion from venous to delayed phase is much more significant. The mean values of RWR-V-D of HCC (43.27) and non HCC (31.38) were significantly different and a cutoff of 41.79 offered a sensitivity of 75%.

When comparing individual groups there was a significant difference between the mean RWR-V-D values of HCC (mean 43.27) versus hypervascular IMCC (mean 31.2) and metastasis (mean 33.63). Loyer EM et al., compared the kinetics of HCC versus IMCC and found that HCC loose enhancement from venous to delayed phase while IMCC gain enhancement from the corresponding phases, however they included all cases of cholangiocarcinomas and not just the hypervascular variants [16]. Liu Y et al., used PAR ratio as a simple tool to measure the washout appearance [2]. In present study it is apparent that there are some arterial phase enhancing mimics showing the washout appearance complicating the oversimplified guidelines. We also had a much larger study population. In present study PAR-V was significant offering good sensitivity and specificity. This is in contradistinction to the study by Liu Y et al., which found PAR-D to be significant [2]. RWR-V-D was also significantly different between two groups and this gradient may actually help in cases that are not so straight forward.

In present study we found some true HCC mimics; however, which have similar qualitative appearance and quantitative indices like HCC, something which has not been highlighted in the other studies. These mimics were hepatocellular adenomas, hepatoblastoma and certain hypervascular metastasis [Table/Fig-8]. Hypervascular liver metastases from neuroendocrine tumours mimicking hepatocellular carcinoma in enhancement and washout pattern has been described in literature [16,17]. These mimics should be considered as differentials for HCC arising in noncirrhotic liver. The value of quantitative indices also appears to be doubtful for these mimics and appeared to be similar in both subgroups. Although, proving this statistically was difficult in present study due to the small sample size of the mimics. Thus, while a qualitative assessment combined with some useful quantitative parameters, can provide a noninvasive image based diagnosis in majority of cases in the settings of cirrhosis, the same may not hold true for HCC in noncirrhotic livers. A thorough clinicoradiological assessment can however, point to correct diagnosis with hepatocellular adenoma having distinct age group and predispositions, hepatoblastoma usually arising in pediatric age groups and metastatic lesions usually being accompanied by their primary known tumours, though biopsy may be needed for confirmation. Nevertheless a thorough qualitative assessment combined with assessment of certain useful quantitative indices mentioned above, can permit confident noninvasive image based diagnosis for a majority of HCCs in most radiological setup.

[Table/Fig-8]: Neuroendocrine tumour metastatic to liver, showing arterial phase enhancement and delayed phase washout, a pattern indistinguishable from HCC.

LIMITATION

There were some limitations of present study, firstly the lack of histopathology for all HCCs and the use of AASLD guidelines and LIRADS classification with AFP levels for identifying the same (partly because obtaining a biopsy is now almost unethical in patients with cirrhosis meeting the classic imaging diagnostic criteria), but we were stringent in including patients with image based diagnosis, only cirrhotic patients with AFP of more than 400 IU/mL with washout were included. The incidence of cholangiocarcinomas which is known to be the most common mimic would be very low in this group and is unlikely to alter the results. The other limitations included, HCCs less than 1 cm which were not included in our data set. Thus, their behavior was not assessed, heterogeneity within the non HCC group and the sample size of the non HCC group was small compared to HCC. Retrospective nature of analysis also limits the evaluation.

CONCLUSION

While there are number of guidelines which include the more popular likes of AASLD and LI-RADS for diagnosis of HCCs and categorising liver lesions; yet, most of these continue to be subjective in nature with lack of quantification of hypervascularity or washout. A quantitative analysis defining the washout is useful additional determinant adding objectivity to image based diagnosis. Quantitative variables like PAR-V (threshold value 106), RWR-V-D (threshold of 41.79) complement the qualitative analysis, for diagnosis of HCC and have future implications like incorporation into guidelines and development of diagnostic algorithms for computed aided detection software packages.

Case Report

An unusual cause of breathlessness and profuse micronodules

ABSTRACT

We describe a 21-year-old male with a history of smoking and subacute onset of breathlessness with normal cardiorespiratory examination. The presence of "track marks" and digital infarcts prompted evaluation for infective endocarditis and confrontational history taking revealed anorexia, weight loss over 3 months along with intravenous drug abuse of reconstituted tablets of tapentadol. Echocardiography was normal and blood cultures were sterile; computed tomography showed bilateral, diffuse, small centrilobular nodules with "tree-in-bud" appearance. In this clinicopathologic conference, we discuss the clinical and radiological differential diagnosis of centrilobular nodules, lung biopsy findings, and management options for patients with such a presentation.

KEY WORDS: Excipient lung disease, intravascular talcosis, pulmonary foreign body angiogranulomatosis, talc granulomatosis

PRESENTATION OF THE CASE

A 21-year-old college student presented with breathlessness and left-sided chest pain for a week. Breathlessness was insidious in onset and persisted on walking at own speed at level. Chest pain was left-sided, intermittent, pricking and non-exertional. There was no history of fever, rhinitis, headache, hemoptysis, cough, or joint pains. He did not raise pets but admitted to smoking 7–8 cigarettes/day and consuming whisky (192 g of alcohol weekly). He denied any recent worsening of educational performance. He did not report any significant prior medical illness or pertinent illness in family or occupational dust exposure. He was initially seen in cardiology and evaluation showed normal cardiac and respiratory examination without any pallor, clubbing, or organomegaly. Body mass index was 18.6 kg/m^2. The examination also showed extensive track marks over both arms with evidence of multiple peripheral digital infarcts [Figure 1], raising suspicion for infective endocarditis (IE). On confronting, he disclosed daily intravenous self-injections of three–four powdered and reconstituted 50 mg tablets of Tapentadol (Tydol, Sun Pharma) in sterile distilled water two–three times a day over the last 2 years. He also admitted to using inhaled cannabis twice weekly over the last 2 years. There was associated anorexia and unquantified weight loss over the last 3 months. Three sets of blood cultures were sterile. Electrocardiography showed T-wave inversions in leads V3–V6 and II, III, and aVF. Transthoracic echocardiography (TTE) showed normal valves without any evidence of vegetations or pulmonary hypertension and normal left ventricular function. Serum creatinine

Figure 1: Composite image of the clinical photographs (left) of the right forearm showing "track marks," indicating healed superficial septic thrombophlebitis and (right) both hands showing multiple bilateral distal digital pulp infarcts. Similar findings were also seen in both plantar surfaces (not shown)

was 0.6 mg/dL; urine microscopy was normal without any albuminuria. Hemoglobin was 14.2 g/dL with normal leukocyte and platelet counts. He remained afebrile. Transesophageal echocardiography (TEE) was planned; in the meanwhile, review of his chest radiographs showed diffusely scattered fine nodules bilaterally [Figure 2, left]. Spirometry showed mild restriction with reduced diffusion capacity for carbon monoxide (forced expiratory volumes at 1 s 2.25 L [65%]%, forced vital capacity 2.87 L [71%], DLco 62%). There was desaturation to 92% while walking 6 minutes, with preserved walk distance (545 meters, 89% predicted). Human immunodeficiency virus (HIV), anti-nuclear antibodies, hepatitis B, and hepatitis C antibodies were negative by enzyme-linked immunosorbent assay. Immunoglobulin E levels were 9 IU/mL (normal <100 IU/mL). High-resolution computed tomography (HRCT) of the thorax showed bilateral profuse evenly distributed micronodules with "tree-in-bud" [Figure 2, right]. There was no sputum production on induction with 3% saline. A procedure was planned for diagnosis.

DIFFERENTIAL DIAGNOSIS

Important features of this case

This HIV-negative young adult with significant smoking history, cannabis use, and intravenous drug abuse with reconstituted tablets over 2 years has breathlessness, anorexia, and weight loss with radiological findings of micronodules. There is evidence of distal embolic infarcts, but initial evaluation for endocarditis was negative. The reduced DLco, restriction on spirometry and unexpectedly low walk distance in a young individual with desaturation on walking implies extensive parenchymal and/or pulmonary vascular disease. The differential diagnosis of profuse bilateral micronodules is extensive [Table 1] but can be narrowed by careful history and analysis of HRCT findings in conjunction

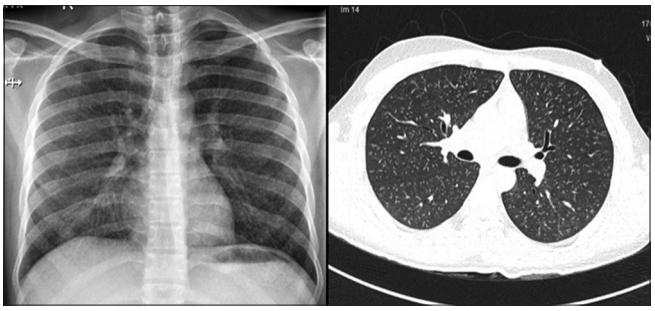

Figure 2: Composite image of the chest radiograph (left) showing small nodular opacities and high-resolution computed tomography of the thorax (right) showed bilateral profuse evenly distributed micronodules with tree-in-budding; pulmonary artery was normal in size, and there were no associated lymphadenopathy. Expiratory computed tomography did not show any air trapping (not shown)

distribution of the micronodules spatially within the lung and also the secondary pulmonary lobule. These nodules were uniform in size and were distributed evenly in a cephalocaudal direction, without any preferential lobar involvement. None of the nodules abut the pleural surface or the fissures [Figure 3]; there is clear evidence of extensive bilateral branching nodules in centrilobular distribution. There is no evidence of bronchiectasis; while no contrast was administered, in conjunction with echocardiography, there is no dilated pulmonary artery or lymphadenopathy. These findings limit the radiological differentials to causes of micronodules in a centrilobular distribution and extensive uniform "tree-in-bud" appearance. "Tree-in-bud" indicates the presence of dilated centrilobular bronchioles with lumen impacted by mucus, fluid, or pus and associated with peribronchiolar inflammation. "Tree-in-bud" indicates small airway disease and is associated with airway infection in the large majority but can also be rarely caused by arteriolar disease.[2] Its presence makes three common causes of centrilobular nodules unlikely: hypersensitivity pneumonitis, follicular bronchiolitis, and respiratory bronchiolitis.

Endobronchial tuberculosis

Mycobacterium tuberculosis is endemic in India, with more than 2.2 million new cases each year. Delayed recognition

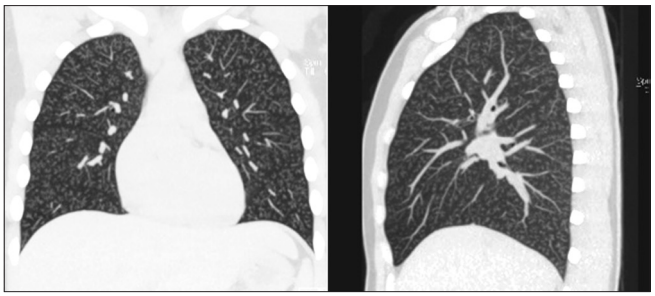

Figure 3: Coronal and sagittal reconstruction of the maximum intensity projection formatting of the high-resolution computed tomography images of the thorax showing diffuse, extensive, bilateral centrilobular nodules with branching and without any lobar predominance

and extensive disease are related to associated substance abuse, poverty, and malnutrition, all of which were present in this patient. Extensive endobronchial spread of tuberculosis can cause extensive tree-in-bud opacities although asymmetry is usually seen.[3] Tuberculosis is also the most common cause of micronodules with a random pattern (miliary). Even though the "pretest probability" of tuberculosis is high in this patient, the marked symmetry and the absence of any cavitation or consolidation is odd; digital infarcts are unusual but could be caused by an associated immune complex phenomenon that can occur with tuberculosis. *Mycobacterium avium*-intracellulare infection can also cause centrilobular nodules with "tree-in-bud," bronchiectasis, and consolidation. While it can be seen in immunocompetent patients, the classic phenotype is a middle-aged woman with slender build and without any constitutional symptoms.

Bronchopneumonia and viral bronchiolitis

Infectious bronchiolitis due to viruses, *Mycoplasma*, and chlamydia is a common cause of profuse and symmetric centrilobular nodules with "tree-in-bud;"[3] however, the prolonged illness and associated embolic phenomenon are unusual.

Allergic bronchopulmonary aspergillosis

Centrilobular nodules with "tree-in-bud" or miliary nodules can be caused by allergic bronchopulmonary aspergillosis but the absence of asthma, central bronchiectasis, and normal IgE levels rule out this diagnosis.[2,4]

Diffuse panbronchiolitis

Diffuse panbronchiolitis (DPB) is a rare disease of unknown cause presenting in males between the second and fifth decade with productive cough, diffuse bilateral centrilobular nodules with "tree-in-bud" and sinusitis. While reported in Indians,[5] it is extremely rare in our population but can explain all the clinical and radiological features.[6] Cold agglutinins are frequent in DPB and pulp infarcts may be due to an associated connective tissue disease. The absence of productive sputum, obstruction on spirometry, sinusitis, and air trapping on expiratory CT are unusual in DPB and necessitate further evaluation with surgical lung biopsy to establish the diagnosis.[6]

Excipient lung disease

Centrilobular nodules are usually caused by bronchiolar disease but can rarely be caused by arteriolar disease. Arteriolar causes include pulmonary edema and hemorrhage, excipient lung disease (ELD), granulomatosis with polyangiitis (GPA), plexogenic arteriopathy (PH), veno-occlusive disease (VOD), pulmonary capillary hemangiomatosis (PCH), and metastatic calcification.[2] There was no evidence of heart failure, renal failure or anemia and hemoptysis to suggest alveolar hemorrhage. The absence of pulmonary hypertension makes centrilobular nodules due to PH, VOD, and PCH very unlikely. Nodules due to GPA are larger, fewer, and associated with cavitation. Excipients are insoluble inert particulate filler materials that bind and protect the active drug during production as well as shape and lubricate tablets for easy swallowing. Excipients include talc (hydrated magnesium silicate), microcrystalline cellulose, crospovidone, and starch. Typically, excipients constitute 5% of a tablet's mass. On intravenous injection, excipient particles lodge in pulmonary arterioles and trigger an angiogranulomatous reaction; progressive disease is associated with dyspnea and pulmonary hypertension.[7] However, the presence of finger pulp infarcts, "tree-in-bud" appearance and absence of pulmonary hypertension are unusual in ELD.

CLINICAL DIAGNOSIS

In summary, the differential diagnosis of extensive centrilobular nodules with "tree-in-bud" without bronchiectasis or pulmonary hypertension in this young adult with smoking, cannabis use, and intravenous drug abuse of reconstituted tablets can be narrowed down to extensive endobronchial tuberculosis, diffuse panbronchiolitis, and ELD.

Dr. RM. PL. Ramanthan: With these clinicoradiological possibilities in mind, this patient underwent fundus examination and bronchoscopy with bronchoalveolar lavage (BAL) and transbronchial lung biopsy, with a plan for surgical biopsy if evaluation was inconclusive. Can we now have the findings?

Dr. K. Divya: Dilated fundus examination confirmed refractile particles scattered along both the retinal arteries and retinal veins [Figure 4], confirming systemic embolization of small (<5 μm) talc particles, consistent with intravenous talcosis. Inhalational talc exposure does not cause such marked retinal deposition as the inhaled particles are larger and are restricted by bronchioles and pulmonary circulation.[8,9]

Dr. Nidhya Ganesan: BAL was negative for acid-fast bacilli and for *M. tuberculosis* by Xpert MTB/RIF; occasional needle-shaped crystals were seen on cytology. The transbronchial lung biopsy specimen confirmed perivascular granulomatous reaction to talc particles [Figure 5, left] that appear as birefringent

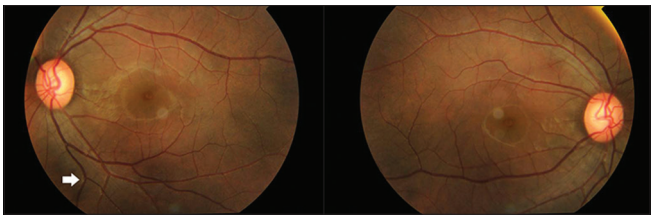

Figure 4: Fundus photograph of both eyes showing refractile particles scattered along both the retinal arteries and retinal veins, confirming the diagnosis of intravenous talcosis

needle-shaped crystals within the granulomas under polarized light [Figure 5, right]. Review of the composition of Tydol confirmed the presence of talc as excipient. Microcrystalline cellulose appears rod like while starch has a maltese cross pattern and crospovidone is nonbirefringent on polarization.[7]

Dr. Srinivas Rajagopala: A diagnosis of ELD (talc granulomatosis) was made. Psychiatry services were involved, and the patient underwent counseling, arrangement for family supervision, and daily-observed methadone replacement. He has successfully discontinued intravenous drug abuse and remains stable at 3 months of follow-up. Serial spirometry, DLco, and radiographs have been advised at 6 monthly intervals. Three unusual findings need an explantation; 1) The presence of "tree-in-bud" in a process that is hematogenous in origin 2)The absence of pulmonary hypertension in ELD and 3)The cause of the bilateral digital infarcts observed.

Dr. B. Devanand: Diseases involving pulmonary arterioles can cause centrilobular nodules as arterioles run in the peribronchovascular interstitium adjacent to bronchioles. Talcosis associated with intravenous abuse is most commonly associated with diffuse fine centrilobular nodules, ground-glass abnormalities or a combination of nodules and lower-lobe emphysema (Ritalin lung with methylphenidate).[9,10] The "tree-in-bud" pattern is unusual for arteriolar disease; it can be caused by intra-arteriolar accumulation of talc with associated adjacent perivascular granulomatous reaction giving the appearance of branching centrilobular nodules and has been described in a few cases of ELD earlier.[11]

Dr. Srinivas Rajagopala: What is the course of ELD? Can the disease progress despite cessation of abuse?

Dr. Kancherla Roopa: Lung fibrosis and pulmonary hypertension are related to the extent of vascular obstruction and granulomatous inflammation and are usually irreversible with talc, cellulose, and crospovidone as these cannot be mobilized; starch can be removed by metabolism and pulmonary hypertension can be reversible to a large degree. Disease progression can occur despite cessation due to ongoing granulomatous foreign-body reaction to the deposited, unmobilizable talc. The initial series of patients described all had progressive symptoms leading to death over 9 months to 5 years.[10,12] The index

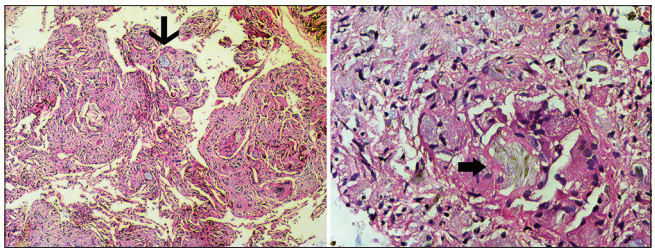

Figure 5: Photomicrographs of the transbronchial lung tissue biopsy specimen (left) demonstrating perivascular foreign body granulomatous reaction to the talc particles (thin arrow, H and E, ×100). Under polarized light, birefringent 20–95 μm needle-shaped crystals were seen in the granuloma, consistent with talc (block arrow, H and E, ×400)

patient has a large load of perivascular disease and is at risk for pulmonary hypertension and disease progression despite cessation of further abuse.

Dr. Srinivas Rajagopala: How common is systemic embolization of talc given that the lung acts as an effective filter?

Dr. K. Divya: The talc that is trapped in the pulmonary arterioles is typically around 10 μm, but smaller particles can escape to the systemic circulation and be detected in the retina, spleen, and virtually every organ on autopsy.[12] Finding excipient crystals in fundoscopy is a rapid noninvasive method to confirm intravenous talcosis.

Dr. Srinivas Rajagopala: Given the presence of digital infarcts, is TEE needed to exclude IE in this patient?

Dr. G. Rajendiran: The first consideration in this patient with possible unsafe needle practices, no murmurs, weight loss, breathlessness, and digital embolic manifestations was subacute native valve IE. TTE has low sensitivity compared to TEE (46% vs. 93%) although both are highly specific (96%).[13] Embolic manifestations are seen in about half of patients with IE.[14] He was not administered any antibiotics, three sets of blood cultures were sterile, and TTE showed all valves clearly without any vegetations. TEE is restricted in our practice to high probability for IE or in whom TTE is rendered less sensitive due to obesity, lung hyperinflation, or prosthetic valves. The index patient met only 2 minor Modified Duke's criteria and was considered low risk for IE after the initial evaluation and TEE deferred.[15] Furthermore, a clear alternative explanation for the observed distal infarcts in the form of talc deposition in the distal microcirculation with thrombosis is available and corroborated by fundoscopy. While this physical finding has not been described in ELD previously, it is consistent with the distal digital embolization and subsequent microthrombosis caused by talc.

Dr. Srinivas Rajagopala: What are the options for those with progressive breathlessness despite cessation of intravenous drug abuse?

Dr. RM. PL. Ramanthan: There are previous small series of lung allografts after a careful selection process in ELD with excellent outcomes.[16] Cadaveric bilateral sequential lung transplantation is a reality in our country today, and he can be listed for the same at our center if he meets criteria and remains free of substance abuse for at least 6 months with adequate psychiatry counseling.

SUMMARY

Clinical examination findings continue to have relevance in this era of investigation-driven medicine. Excipient lung disease can result from intravenous injection of reconstituted tablets and can present with ground glass opacities, small nodules, and emphysema. Pulmonary arteriolar diseases must be considered in the differential diagnosis of centrilobular nodules on CT.

Acknowledgments

The authors would like to thank Jagadeshwari, Research coordinator, and Nissy, Nurse, PSG Institute of Pulmonology, for their help in completing the paperwork for Ethics approval and collating the images for the manuscript.

Declaration of patient consent

The authors certify that they have obtained all appropriate patient consent forms. In the form, the patient has given his consent for his images and other clinical information to be reported in the journal. The patient understands that names, identifying marks, and initials will not be published and due efforts will be made to conceal identity, but anonymity cannot be guaranteed.

Congenital Biotinidase Deficiency-Clinching the Diagnosis with Classic Imaging Features

Dr.Maheswaran Viyannan, Dr.SuganyaPalanisamy,
Dr.DevanandBalalakshmoji,
Dept of Radiology and Imaging, PSG Institute of Medical Sciences and Research, Coimbatore.

Abstract: *Congenital biotinidase deficiency (CBD) is a rare inborn error of metabolism, resulting in biotin deficiency. The recognition of clinical, laboratory and magnetic resonance imaging findings can help us to arrive at a correct diagnosis at the earliest which can enable institution of appropriate early treatment and prevention of late complications. We present the typical MRI findings in a 3 ½ month old baby who presented with multiple episodes of seizures which finally turned out to be profound biotinidase deficiency.*

Key Words*: Congenital biotinidase deficiency, recurrent seizures, skin manifestations, bilateral symmetrical diffusion restriction, cerebral atrophy.*

Date of Submission:24-10-2019 Date of Acceptance:09-11-2019

I. Introduction

Congenital biotinidase deficiency (CBD) is a rare autosomal recessive congenital neuro- metabolic disorder,[1] which leads to profound deficiency of biotin which is an essential cofactor for many enzymes[2] Biotin deficiency can lead to neurological, cutaneous and visual problems.-4 Making a diagnosis based on clinical manifestations alone is difficult. Brain imaging especially Magnetic Resonance Imaging (MRI) with advanced MR techniques like diffusion weighted imaging and MR spectroscopy (MRS) has typical features which can clinch the diagnosis. As MRI plays a key role in making the diagnosis at an early stage of the disease it should be considered in all patients who present with clinical features suggestive of metabolic disorders.

II. Case Report

A 3 ½ months old baby girl presented with complaints of recent onset of multiple episodes of seizures, lethargy, hypotonia, skin peeling and alopecia. The antenatal and birth history were unremarkable. The baby was born of a non-consanguineous marriage. Baby was immunized up to the age. The baby was developmentally normaltill 3 months of age and attained social smile at 2 months. Head control has not yet been attained. The baby started to develop recurrent episodes of seizure for 15 days and regression of previously attained social smile. At presentation the child weighted 5.1kg. Head circumference measured about 40cm.In view of multiple episodes of seizures and lethargy, baby was admitted in neonatal intensive care ward and started on empirical antibiotic therapy. Routine blood investigations revealed markedly elevated lactate (11.6mmol/L), reduced bicarbonate (2.7mmol/L) and pH of 6.9. Further blood investigations showed elevated ammonia (200microgram/dl.) and urine ketones(3+). Blood culture and cerebrospinal fluid (CSF) culture were negative. In view of multiple episodes of seizures, skin manifestations, alopecia, severe metabolic acidosis and hyperammonemia, the diagnostic possibility of inborn errors of metabolism was suspected and referred to department of radiology for further evaluation with MRI of the brain.

Figure 1: Clinical photograph of the child showing severe alopecia and skin peeling.

MRI of the brainrevealed prominent cortical sulci and fissures, mildly dilated ventricles– suggesting loss of brain volume. In addition there wereconfluent areas of T2/ fluid attenuated inversion recovery (FLAIR) sequence hyperintensities with T1 hypointensities involving bilateral fronto-parietal white matter, bilateral cerebellar white matter, and cerebellar vermis. There were also bilateral symmetrical areas of diffusion restriction seen in corona radiata, posterior limb of internal capsule, cerebellar white matter, cerebellar vermis, midbrain and left medial temporal gyri. In addition to the above findings, subdural hygroma noted along bilateral frontal convexities (more on the left side). No evidence of mass lesion / hemorrhage seen within brain parenchyma. MRS showed elevated lactate and glycine. Based on the above MRI findings, the diagnostic possibility of inborn errors of metabolism such as CBD, Maple syrup urine disease (MSD)andLeigh's syndrome (LS)were suggested.

With the combination of clinical and radiological findings, biotinidase deficiency was considered as most probablediagnosisand baby was started on oral biotin.Subsequently the diagnosis was confirmed with tandem mass spectroscopy which revealed profound biotinidase deficiency. The baby responded well to oral biotin with reduction of lactate and ammonia and rise in bicarbonate and pH levels.

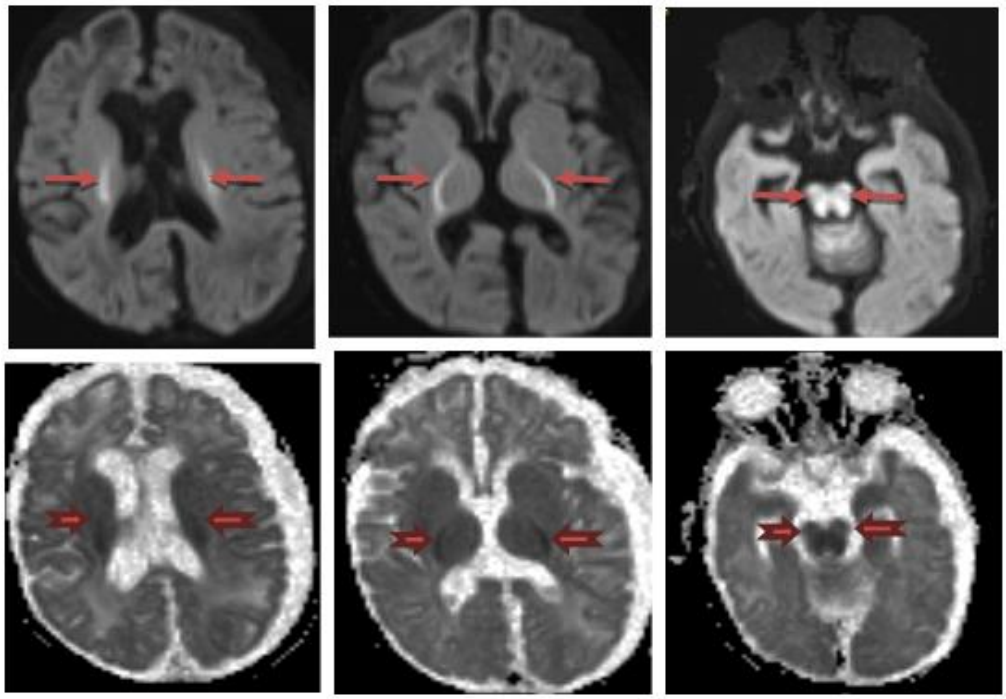

Figure 2: Diffusion weighted images (top row) and Apparent Diffusion Co-efficient (ADC) maps (bottom row) showing bilaterally symmetrical areas of diffusion restriction in the corona radiata, posterior limbs of internal capsule and midbrain which appear hyperintense in DWI (horizontal regular arrows in top row) and hypointense (horizontal notched arrows in bottom row) in ADC.

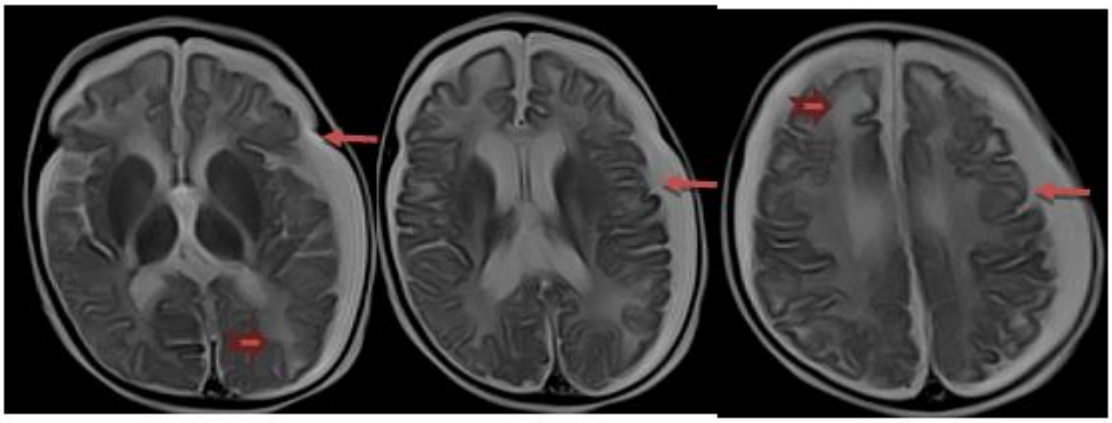

Figure 3: T2Weighted images showing bilateral prominent subdural hygroma (horizontal regular arrows) and abnormal hyperintense areas in the frontal and parieto-occipital white matter (Notched arrow)

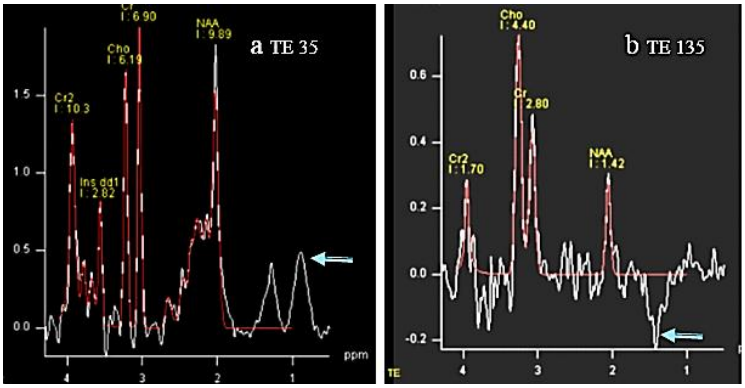

Figure 4: Magnetic resonance imaging H1 spectroscopy images (a, b) acquired with short time to echo (TE 35ms) and intermediate time to echo (TE 135ms). With short TE there is doublet peak at 1.3ppm (Horizontal arrow in a) and reversal of doublet in intermediate TE (horizontal arrow in b), consistent with lactate peak.

III. Discussion

CBD a neurocutaneous disorder,is a rare inborn error of metabolism with autosomal recessiveinheritancein which the body is unable to breakdown the conjugated form of biotin (vitaminB7)and clinical biotin deficiency[4]. This condition manifests due to mutation in biotinidase(BTD) gene at chromosome 3q25. The estimated prevalence of profound biotinidase deficiency (<10% of normal level) is approximately 1: 137000 newborns. The partial biotinidasedeficiency(<30%of normal) is estimated at 1:60,000 newborns[1]. The symptoms manifest in early to mid-infancy (mean age of onset – 3.5 months) [5].

Biotinidase deficiency causes biotin deficiency through multiple mechanisms such as, prevention of release of biotin bound to protein in food particles thus preventing absorption of biotin from intestine, impaired recycle of biotin from carboxylases and histones. The biotin serves as a co-factor for many enzymes such as pyruvate carboxylase, acetyl co-A carboxylase, propionyl Co-A carboxylase, beta methylcrotonyl-coA carboxylase and hence the enzyme biotinidase plays a role in fatty acid synthesis, amino acid catabolism and gluconeogenesis. The substrates accumulated in case of biotinidase deficiency are 3-hydroxy isovaleric acid, 3-methyl crotonylglycine, methylcitrate and 3-hydroxy propionate[6].When biotin is deficient,the activity of pyruvatecarboxylase in CNS falls, leading to localized lactic acidosis. The alopecia and dermatitis in these patients are possibly due to depletion of fatty acids as a result of deficient acetyl –CoA carboxylase.

Clinically, the babies present with multiple episodes of seizures, lethargy, hypotonia, ataxia, developmental delays, coma, alopecia, skin rash (mucocutaneous candidiasis) [2]. Hearing loss and decreased visual acuity are the late complications and are seen less frequently. Biochemically, there will be severe metabolic acidosis, ketosis, hyperammonemia, lactic acidosis and abnormal organic acids in urine. Ketosis and skin manifestations are the atypical features.

Radiologically, MRI will reveal, features of delayed myelination likeabnormalT2/FLAIR hyperintensities with T1 hypointensities in bilateral fronto-parietal white matter, bilateral cerebellar white matter, and cerebellar vermis. There can be bilateral symmetrical areas of diffusion restriction involving corona radiata, posterior limb of internal capsule, cerebellar white matter, cerebellar vermis, anterior midbrain, medial

temporal gyri, hippocampi and parahippocampal gyrus[1].The changes of restricted diffusion will be seen more in the myelinated white matter fibers. MR spectroscopy will show elevated lactateandglycine and decreased N-Acetylaspartate and choline. Some studies have shown involvement of the corpus callosum as well, which was not seen in our study[4].

There are few other conditions in which the MRI findings can closely mimic CBD, which should be considered in the differential diagnoses. They are 1.Maple syrup urine disease[7] (MSUD)–here the onset of clinical signs and symptoms is relatively early, during first week of life with poor feeding, vomiting, dystonia and seizures. Skin manifestations will be absent. Biochemically – ketoacidosis and characteristic maple syrup odor in urine. In MRI, diffusion restriction is seen in deep cerebellar white matter, dorsal brain stem, cerebralpeduncles, and posterior limb of internal capsule, basal ganglia and thalami. Basal ganglia and thalami are typically spared in CBD. 2.Leigh'ssyndrome (LS) – mitochondrial disorder which presents later, towards the end of first year with hypotonia, psychomotor deterioration, ataxia, ptosis and swallowing difficulties without any skin manifestations[8]. In MRI grey matter is more frequently involved, diffusion restriction can be less pronounced and seen only in acute phase in corpus striatum, sub thalamic nucleus, deep cerebellar nuclei, pons, medulla and periaqueductal grey matter. In MRS there will be large lactate peakand small NAA peak.

IV. Conclusion

When a baby presents in early infancy with multiple episodes of seizures, skin manifestations, elevated lactate, metabolic acidosis, ketosis and hyperammonemia with typical MRI findings of bilateral symmetrical areas of diffusion restriction and brain atrophy, the likely diagnosis ofCBD has to be considered which will help to institute proper and timely treatment and thereby avoiding complications and long term sequeale of permanent neuronal damage. Since the structural changes are reversible, it is of paramount importance to make correct and prompt diagnosis of CBD.

Abstract:

Background: Variceal bleed the major cause of mortality in cirrhosis. Upper gastrointestinal (GI) endoscopy remains the main stay of diagnosis and treatment in variceal bleed. Splenic elastography using Acoustic Radiation Force Impulse (ARFI) technique can be used to non-invasively predict presence and severity of esophageal varices.

Material and methods: It is a hospital based prospective case control study, done in 100 patients with chronic liver parenchymal disease, who had undergone upper GI endoscopy. Fifty consecutive patients with esophageal varies and 50 consecutive patients without esophageal varices were included in the study and subjected to splenic ARFI. Data was analyzed with SPSS version 20.0 software using chi-square test or Fischer exact test, independent sample-t test. The receiver operating characteristics (ROC) curve was plotted and the area under the curve was used to determine the cut off points for statistically significant variables.

Results: Spleen ARFI showed significant correlation between cirrhotics with esophageal varices and without varices groups. The cut off of ≥ 3.16 m/s (AUROC: 0.906) precisely detects varices with sensitivity of 94% and specificity of 92%. Spleen ARFI also correlates with severity of varices. Cut off of ≥ 3.29 m/s (AUROC: 0.874) can confidentially differentiate low grade from high grade varices in cirrhotics with sensitivity of 85% and specificity of 100%.

Conclusions: Amongst the noninvasive parameters analyzed in this study, spleenic ARFI exclusively showed highest sensitivity and specificity in the detection of varices and differentiation of high grade varices from low grade varices.

Key words: Splenic ARFI, cirrhosis, Endoscopy, Esophageal varices.

Introduction:

Diverse insults on the liver lead to a common endpoint as cirrhosis. Cirrhosis is pathologically characterized by extensive fibrosis, regenerative nodules and distortion of hepatic parenchymal architecture [1]. Alcoholism and viral hepatitis have been the most common etiologies leading to cirrhosis, however nonalcoholic fatty liver disease is emerging as an important underlying pathology.

Complications of cirrhosis can be categorized as portal hypertension related and portal hypertension unrelated complications. Most common portal hypertension related complications is development of esophageal varices and variceal bleeding [2]. Till date, invasive upper gastrointestinal endoscopy (UGI scopy) remains the mainstay

www.ijbamr.com P ISSN: 2250-284X , E ISSN : 2250-2858

for the detection and grading of esophageal varices [3]. In addition to diagnostic advantage, UGI scopy plays a major role in treatment such as band ligation and sclerotherapy. Despite its diagnostic and therapeutic utility, UGI scopy is an invasive procedure, has its inherent complications such as bleeding, perforation, infection and cardio-respiratory complications related to sedation [4].

With current advances in the field of Ultrasonography, estimation of elasticity of the tissue has been made possible with Elastography. It is analogous to manual palpation and in fact offers better information, based on the principle that pathology changes the stiffness of the tissue. Shear Wave Elastography (SWE) is a technique of elastography that uses "shear wave" generated within tissue secondary to the acoustic push, the so called Acoustic Radiation Force Impulse (ARFI). In this technique as no external compression is required and a push impulse can be directed anywhere, it is possible to attain a fine elastogram of entire organ. Additionally, quantification of elasticity of particular region of interest based on shear wave velocity (SWV) is possible [5].

Elasticity of the spleen will be decreased in cirrhosis due to portal venous congestion and hyperplasia of splenic tissue; hence the splenic stiffness will be increased. Portal venous congestion results in esophageal varices. Screening UGI scopy is recommended in all cirrhotic patients in accordance with recent guidelines as primary prophylaxis against variceal hemorrhage[6]. Implementing these guidelines is confronted with cost, complications and invasiveness of UGI scopy. Hence, it necessitates accurate and noninvasive methods for detecting and grading the severity of esophageal varices.

Aim:

To evaluate splenic ARFI as a noninvasive tool for detection of esophageal varices and grading of varices as to high and low grades in chronic liver parenchymal disease.

Materials and methods:

It is a prospective case control study done on 100 patients over a period of 14 months, who were referred to the department of radiology with a diagnosis of chronic liver parenchymal disease. Subsequently all these patients underwent UGI scopy and were divided into two groups. Consecutive 50 patients without esophageal varices comprised the first group and 50 patients with esophageal varices comprised second group. Study was undertaken after obtaining necessary clearance from the institutional human ethics committee. Patients who are of less than 18 years of age and who did not undergo UGI scopy were excluded from the study. All the patients were subjected to splenic ARFI and UGI scopy.

Splenic ARFI protocol:

Splenic ARFI was performed with Siemens Acuson S2000^{TM} / Siemens Acuson S3000 ^{TM} ultrasound systems with ARFI enabled 6C1 / 4C1 curvilinear transducers. Patient was made to lie in right lateral decubitus position and assessment was done by intercostal approach. In order to cover uniformly the spleen, we adopted the stratified random sampling method used in the previous studies [7] (Figure 1). Spleen will be subdivided into cranial external(1), cranial central(2), cranial internal(1), intermediate external(1), intermediate central(1), intermediate internal(1), caudal external(1), caudal central(1) and caudal internal(1) segments. Numbers in the parenthesis represents the number of ARFI values obtained in each segment. In breath hold position, region of interest measuring 10mm in depth and 5mm in width was placed in parenchyma devoid of visible blood vessels and >1 cm below the level of spleen capsule and ARFI evaluation was done (Figure 2). Total of 10 successful measurements were obtained for each patient. Mean ARFI values were automatically calculated and expressed

www.ijbamr.com P ISSN: 2250-284X , E ISSN : 2250-2858

in meters per second (m/s).

The data obtained was coded and entered in Microsoft Excel Spreadsheet. Data was analyzed using SPSS version 20.0 statistical software. Categorical variables were expressed as percentages and the comparative analysis was done using chisquare test or Fischer exact test. Continuous variables were expressed as mean ±standard deviation (SD) and the comparative analysis was done by independentsample 't' test. The receiver operating characteristics (ROC) curve was plotted and the area under the curve was determined to the cut off points for statistically significant variables. A probability value (p value) of less than or equal to 0.05 at 95% confidence interval was considered as statistically significant.

Various radilogical parameters like liver size, portal vein diamater, portal vein flow velocity, spleen size, liver ARFI and splenic ARFI were analysed for their value as predictors of presence or absence of esophageal varices, if present, to differentiate high grade varices from low grade varices using various statistical methods as mentioned above.

Discussion:

Recent guidelines endorse that endoscopic screening should be done for all cirrhotic patients at the time of diagnosis to recognize those at high risk of bleeding and possibly to benefit from primary prophylaxis [6]. Implementation of these guidelines imposes huge burden on UGI scopy units and frequent testing over time can decrease the compliance of patient. By noninvasive prediction of the presence of EVs, one can recommend the appropriate category of patients to undergo invasive UGI scopy, thereby reducing unnecessary endoscopic examinations and burden on endoscopy units.

Previous studies have correlated various radiological and laboratory parameters either alone or in combination with the presence or absence of EVs in cirrhotics. Although, the efficiency of parameters or combination of parameters reported in each study differ amongst them, due to the heterogeneous nature of the studies. Good predictive value of several non-endoscopic variables for the presence or absence of EVs have been documented

www.ijbamr.com P ISSN: 2250-284X , E ISSN : 2250-2858

by many previous studies, but the data is limited from our part of the country. This study was performed to assess the effectiveness of various clinical, laboratory and radiological parameters, in reliably detecting the existence of EVs and high grade EVs in cirrhotic patients.

In the present study, there is no significant association of demographic parameters between the two study groups. Previous studies by Zaman et al [8] and Cherian et al [9], showed that Child Pugh class B or C cirrhotic patients, as compared to class A cirrhotics, have high propensity towards the detection of EVs on UGI scopy. In contrary, our study inferred no significant association between Child Pugh class and the presence of EVs (p = 0.799). In addition, we assessed MELD scores and found significant affiliation with presence of EVs, in congruence to the results of previous studies by De Mattos et al [10] , Tafarel et al [11] and Chandail VS et al [12].

Our study showed no significant variation in either portal vein diameter or portal vein flow velocity between cirrhotic patients with EVs and without EVs. Our study in contradiction to previous studies inferred that there is no significant difference in liver stiffness measured by elastography between cirrhotics with EVs and cirrhotics without EVs (p= 0.458).

In agreement with previous studies, our study also showed significant difference in the values of spleen stiffness measured by ARFI between cirrhotics with EVs and without EVs (p= 0.000). We acquired the optimal cutoff of ≥ 3.16m/s (AUROC: 0.906) with sensitivity of 94% and specificity of 92%, thereby validating spleen ARFI as a non-invasive radiological marker for the presence of EVs in cirrhotics.

In the present study, we furthermore evaluated the utility of the above discussed noninvasive clinical, laboratory and radiological parameters in the detection of high grade EVs in cirrhotics. Of all the noninvasive parameters analyzed, spleen ARFI exclusively showed significant difference between the two subgroups (p= 0.001). We derived the optimal cutoff of ≥ 3.29m/s (AUROC: 0.874) with sensitivity of 85% and specificity of 100%, which is in very close approximation with spleen ARFI cutoff of ≥ 3.30m/s obtained by Takuma et al[13]. Thereby substantiating spleen ARFI as a non-invasive radiological marker for the presence of high grade EVs in cirrhotics. In other words, the presence of high grade EVs can be reliably ruled out with the spleen ARFI cutoff of < 3.29m/s in patients with chronic liver parenchymal disease. Our study was limited by only few patients with grade IV EVs being included in this study. It is due to the lower prevalence of grade IV EVs, as in part by the practice of generous prophylactic and therapeutic measures which delays or eliminates progression of low grade EVs to high grade EVs. Inter observer variability is not assessed in this study. Future studies on this context should focus on multicenter design with evaluation of equipment of various manufacturers and assessment of inter observer variability.

Conclusions:

Amongst the noninvasive parameters analyzed in this study, spleenic ARFI exclusively showed highest sensitivity and specificity in the detection of varices and differentiation of high grade varices from low grade varices.

ABSTRACT:

Background: Cervical spondylosis is a common degenerative disease of spine generally seen in old age, frequently causing compression of spinal cord and /or nerve roots by protruding disc or osteophytes. Magnetic Resonance Imaging (MRI) is the modality of choice for evaluation of patients with features of cervical spondylotic myelopathy. In addition to routine MRI sequences, advanced MR techniques like diffusion tensor imaging (DTI) can be used to obtain specific information about the spinal cord.

Materials and methods: It is a prospective observational study conducted in 30 patients who presented with clinical and neurological features of cervical spondylotic myelopathy, who had undergone MRI.

Result: All the patients had undergone routine MRI along with diffusion tensor imaging. The Apparent Diffusion Coefficient (ADC) and Fractional Anisotropy (FA) values of the spinal cord were measured at the level of normal spinal canal dimension and at the level where there is narrowing of the spinal canal. The ADC values were found to be high and the FA values were low at the level of the spinal canal stenosis in comparison with values measured at the level of normal spinal canal dimension, which were statistically significant.

Conclusion: DTI parameters showed significant correlation with the clinical parameters, suggesting that DTI can be used to detect microscopic changes related to compressive myelopathy, before changes are apparent in the routine MR sequences. This can enable us to intervene early to avoid irreversible damage to the spinal cord.

Key words: Cervical spondylotic myelopathy, Diffusion tensor imaging, Fractional anisotropy.

Introduction

Cervical spondylosis is a common degenerative disease of spine generally seen in old age, frequently causing compression of spinal cord and /or nerve roots by various pathological entities like protruding disc, osteophytes and thickening of ligamentous structures around the spinal cord.[1] Spondylotic myelopathy refers to compression of the spinal cord by the above mentioned structures leading to impairment of spinal cord function.[2] Cervical spondylotic myelopathy (CSM) is usually seen after the 5th decade. Patients with CSM usually present with symptoms of numbness and weakness in limbs, pain over shoulder and neck, incoordination. Magnetic Resonance Imaging (MRI) of cervical spine is non-invasive and accurate imaging tool in assessing the structural changes of spinal cord due to its high contrast and soft tissue resolution[3]. It helps to ascertain the site and the

severity of degenerative compressive myelopathy. It is also useful to exclude any other pathology, like neoplasm which can cause compressive myelopathy and mimic degenerative disc disease.

Classical MRI finding seen in compressive myelopathy is focal T2 hyperintensity in spinal cord at the level of a compressive lesion. This signal change is suggestive of either spinal cord oedema in acute cases, or gliosis and myelomalacia in chronic cases[4,5]. Oedema is associated with swelling of the spinal cord and chronic changes on the other hand show thinning of the spinal cord. Other imaging modalities like Computed Tomography (CT) and radiography play a complementary role in the evaluation of CSM. Due to its inherent high spatial resolution CT is better than MRI in the assessment of cortical bone, osteophytes and other calcified ligamentous structures. These structures can also cause spinal canal compromise. Plain radiography is still being used as an initial tool for evaluating degenerative disc changes[6]. The ultimate aim of doing imaging studies is to identify the spinal cord abnormalities early and take remedial measures to prevent further damage[7].

Aims:

1. To compare Fractional Anisotropy (FA) and Apparent Diffusion Coefficient (ADC) values of the spinal cord obtained at the level with above and below the level of spinal canal stenosis.
2. To compare the Diffusion Tensor Imaging (DTI) parameters with Nurick score and neurological examination findings.
3. To detect the early microscopic level structural abnormalities of spinal cord using DTI before overt, irreversible changes manifest in routine MR sequences.

Materials and methods:

It is a prospective observational study performed in 30 patients who were referred by the department of neurology. These patients presented with clinical symptoms and neurological findings suggestive of cervical myelopathy. The study period was from January 2018 to March 2019 at the department of Radiology and imaging sciences PSG Institute of Medical Sciences & Research. Prior to commencement of the study, clearance has been obtained from Institutional Human Ethical Committee and informed written consent has been taken from the participants. Patients with clinical and neurological features of CSM were included in the study. Patients with following abnormalities were excluded from the study: 1.focal or diffuse signal abnormality in the spinal cord. 2. History of cervical spine injury / surgery. 3. Focal lesions in the brain which may be the underlying pathology causing the neurological abnormality.

Prior to undergoing MRI all these patients were assessed symptom wise for the severity of CSM using Nurick score and neurological examination was performed to assess the power of lower and upper limbs. In Nurick score patients were categorized from grade 0 to 3, based on clinical history alone, where grade 0 represented mild form of disease with only symptoms suggestive of nerve root involvement (radiculopathy), grade 3 represents more severe neurological deficit where the patients are wheel chair bound with no independent mobility (myelopathy). On clinical examination muscle power of the limbs was assessed using standard grade 1 to grade 5.

All the patients underwent MRI in Siemens 1.5 Tesla 16 channel machine.

MRI protocol:

1. Routine non contrast T1 and T2 weighted images to look for overt signal changes in T2 Weighted Images.
2. DTI acquisition using EPI yielding the following set of images:

www.ijbamr.com P ISSN: 2250-284X , E ISSN : 2250-2858

1. Diffusion weighted imaging, 2.Trace weighted, 3.FA and ADC mapping 4.Tensor imaging.

DTI parameters:

Diffusion directions measured – 20.

The b factors – 0, 100 and 1000

TR/ TE - 3600 /94ms

Field of view - 230mm

Slice thickness - 5mm.

Images were analysed using Siemens Syngo via work station. Initially presence of any focal or diffuse spinal cord lesions was excluded. After that dimension of the spinal canal was measured at all the vertebral level. Subsequently DTI analysis was performed by drawing region of interest at the level of maximum spinal canal stenosis, one vertebral level above the spinal canal stenosis and one level below (Figure 1a). DTI Parameters assessed were FA and ADC, the values of which were displayed as a table in the system (Figure 1b) along with images of visual maps of ADC (Figure 2a) and FA (Figure 2b).

Statistical analysis:

The data has been analysed using SPSS 23.0 version. To describe the data descriptive statistics frequency analysis, percentage analysis were used for categorical variables and the mean & standard deviation (SD) were used for continuous variables. To find the significant difference in the multivariate analysis for repeated measures the repeated measures of ANOVA was used with Bonferroni correction to control the type I error on multiple comparison. To assess the relationship between the variables Pearson's Correlation was used. In all the above statistical tools the probability value .05 is considered as statistically significant.

Results:

A total of 30 patients were enrolled in our study of which 20 were men and 10 were women (Figure 3). Nurick Score distribution is given in the table 1.

All the patients had muscle power grade between III and V. (Figure 4). No patient in our study had muscle power less than 3.

Diffusion tensor parameters (ADC and FA) were measured at 3 levels of the spinal cord (Figure 1a). One measurement at the level of the spinal canal stenosis and 2 measurements (above and below the level of stenosis) at the level of normal canal dimension. The values of ADC and FA measured at different levels of the spinal cord are given in table 2.

Pairwise comparison of ADC and FA was performed and results are given in table 3 and table 4. Patients were found to have high ADC and low FA values at the level of stenosis when compared with ADC and FA values at the level of no stenosis. The differences were found to be statistically highly significant with a p value of 0.0005 (ANOVA test was used). There was negative correlation between the mean FA and ADC at the level of stenosis with r value of -0.424 and p value of 0.019. There was negative correlation between the mean FA and ADC at the level of no stenosis with r value of -0.0545 and p value of 0.002. There is negative correlation between Nurick score (clinical grading) and muscle power (neurological examination) r value of -0.07 and P value of 0.001.

www.ijbamr.com P ISSN: 2250-284X , E ISSN : 2250-2858

Correlation of FA and ADC with muscle power:

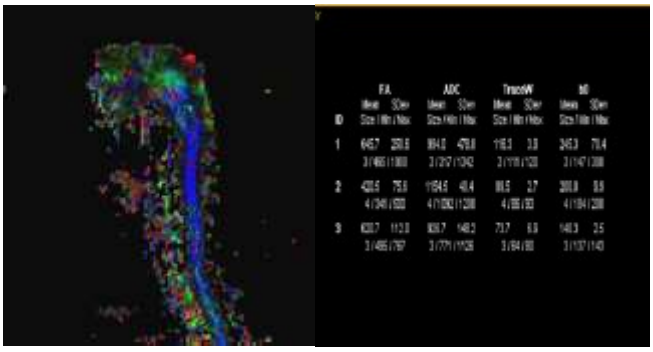
At the level of stenosis:

There was a positive correlation between muscle power and mean FA value with r value of 0.2 and p value 0.1. There is a negative correlation between muscle power and mean ADC value at the level of stenosis with r value of -0.1 and p value 0.1 and p value of 0.3.

At the level of no stenosis:

There is a positive correlation between muscle power grade and mean FA value at the non- stenosis level with r value of 0.18 and p value 0.32 and p value of 0.4. There is a negative correlation between muscle power grade and mean ADC value at the non-stenosis level upper with r value of -0.25 and p value 0.17.

Correlation of FA and ADC with Nurick score:



At the level of stenosis:

FA and Nurick score has negative correlation with r value of -0.4 and p value of .0005. ADC and Nurick score has a positive correlation with r value of -0.1 and p value of – 0.2

At the level of no stenosis:

FA and Nurick score had positive correlation with r value of 0.1 and p value of –0.4. ADC and Nurick score had negative correlation r value of -0.05 and p value of– 0.7

ROC analysis of FA in predicting microscopic level structural cord abnormality in the spinal cord at the level of the spinal canal stenosis. (Figure 5) was done. Subsequently test result variables (table 5) and sensitivity and specificity (table 6) were calculated. Likewise ROC analysis of ADC in predicting microscopic level structural cord abnormality was done (Figure 6). Test result variables (table 7) and sensitivity and specificity (table 8) were also calculated for ADC. Both FA and ADC showed good sensitivity and specificity in predicting the early microscopic level changes in the spinal cord caused by degenerative disease, ADC was slightly more specific than FA.

Discussion:

MRI has revolutionized the evaluation of pathology related to spinal cord. Exceptionally high contrast resolution and soft tissue resolution place MRI way above other imaging modalities in the evaluation of spinal cord.[2] Recent advances in respect to high field strength and fast and robust sequences have greatly contributed to the superior performance of MRI[8]. Very small yet important structures like the nerve roots and the thin ligaments need to be assessed in almost all patients which can harbour the pathology. However significant degree of anatomical and structures abnormalities need to be present before they are visible in routine MRI sequences, primarily in the spinal cord[6]. Hence the need for imaging technique which is similar to a biomarker to pick up early microscopic level changes in the neural structures, specially the spinal cord. Role of DTI in the evaluation of the brain pathologies has been proved and it is being used routinely, however its usage in the evaluation of spinal cord is still evolving.

The application of DTI in the evaluation of spinal cord is hindered by various factors. Spinal cord is a very narrow structure with a high elasticity and situated in anatomically complex location, which are the factors

www.ijbamr.com P ISSN: 2250-284X , E ISSN : 2250-2858

making evaluation difficult. Other factors like CSF pulsation, motion artefacts and breathing related artefacts make usage of DTI difficult as a routine sequence. Newer techniques like reduced field of view with oblique spin echo and OVS (outer volume suppression) have been used to overcome the limitations and better images can be obtained. All these improved techniques provide high resolution images not only in the cervical cord but also the entire spinal cord.

Budzik et al[9] studied the feasibility of DTI and fiber tracking in CSM. FA values showed correlation with the patients' clinical scores. High signal intensity of the spinal cord on T2WI did not correlated either with the DTI parameters or with the clinical symptoms, suggesting that FA is better in depicting the early structural abnormality of the spinal cord when compared with T2W imaging[10, 11]. But they did not study the relationship of DTI scalars with cervical canal width. In our study all the patients had spinal canal stenosis, in that about 73% of the patients had relative narrowing and 27% has absolute narrowing.

In our study degenerative changes like disc bulge, protrusion, osteophytes and ligament thickening led to spinal canal narrowing. These pathological changes caused disruption of the white matter tracts and other secondary changes in cervical cord. Secondary changes like cord edema and macrophage proliferation lead to increased diffusivity of water molecules with in the spinal cord parenchyma, especially in the white matter which can alter the FA and ADC values[12]. These changes were apparent much before macroscopic changes appear in routine T1 and T2W images.**UzeyirAhmadli et al**[13] investigated the utility of DTI sequence in patients with CSM symptoms for early detection of microscopic changes in the spinal cord at the level of narrowed spinal canal without any T2 signal alterations. FA values with in the cord were reduced and ADC increased at site of canal stenosis when compared with non-stenotic segments above the level of canal stenosis. However no significant difference was noted in FA and ADC values between stenotic segment and non-stenotic segment distal to the level of stenosis.

In our study there was statistically significant reduction in the FA values and increase in the ADC values at the site of stenosis when compared to the non-stenotic levels (upper and lower). There was no statistically significant reduction in FA value noted at the non-stenotic levels (upper and lower). The reduction in FA value at the stenotic level is presumably due to reduced neuronal fibers with increase in the extracellular space or due to extracellular edema which can result in increased diffusivity of water molecules and consequently facilitated diffusion.

Jones et al[14] reported a significant correlation between FA and modified Japanese orthopedic association score and Nurick score, and reported that patients who had a higher FA at the compressed level of spinal cord tended to have a better recovery of functionality after surgery when compared to patients undergoing surgery who had a lower FA value pre operatively. In our study there was significant correlation between the patient’s symptoms and the DTI parameters. We graded clinical symptoms using only Nurick score, modified Japanese orthopedic association score was not used.

FA and Nurick score had a negative correlation with r value of -0.4 and p value –0.0005, which implies that the FA values tend to be less when the Nurick score is on the higher side. ADC and Nurick score had a positive correlation with r value of-0.1 and p value of – 0.2, which is equal to higher ADC means higher Nurick score.There was also a significant correlation between the DTI parameters and muscle power. There was positive correlation between muscle power and mean FA value at the level of stenosis with r value of 0.2 and p

www.ijbamr.com P ISSN: 2250-284X , E ISSN : 2250-2858

value of 0.1. There is a negative correlation between muscle power and mean ADC value at the level of stenosis with r value of -0.1 and p value of 0.3. ROC was calculated between the stenotic and non stenotic level. The mean was calculated between the upper and lower non-stenotic level and it was compared with the stenotic level. FA showed a sensitivity of 86.7% and specificity was 86.7% when the cut was kept at 0.57 (Table 6). ADC showed a sensitivity of 86.7% and specificity was 90.0%, when the cut off is kept at 1.1. (Table 8).

Conclusion:

- Our study showed significant correlation between the patients' clinical symptoms and DTI parameters.
- DTI has the potential to detect microscopic structural changes in the spinal cord, before the T2 signal changes appear on conventional MRI.
- DTI can be used as a tool for detecting early changes in cervical spondylotic myelopathy, which would prognosticate the clinical and surgical outcome[14, 15].
- DTI technique should be routinely used on patients with clinical symptoms of cervical spondylotic myelopathy.

Limitations:

- The sample size of the study population was relatively small
- The long-term follow-up of the patients were not done
- It was impossible to determine the percentage of patients with early cervical spondylotic myelopathy who would have advanced to T2 hyperintensity changes in spinal cord, when left untreated.
- Cost and the availability of MRI.

Further studies have to be done on large group with long term follow up of those patients to determine the potential utility of quantitative diffusion tensor imaging.

Conflicts of interest:

There are no conflicts of interest to declare.

Evaluation of retrobulbar circulation in type 2 diabetic patients using color Doppler imaging

K Divya, Vikrant Kanagaraju[1], B Devanand[1], C Jeevamala, A Raghuram, D Sundar

Purpose: To investigate the retrobulbar circulatory parameters in type 2 diabetes mellitus patients with color Doppler imaging (CDI) and compare the results with nondiabetic controls. **Methods:** This prospective study included 50 type 2 diabetic patients and 50 age-matched controls. Seven field stereo fundus photography was used to diagnose and classify diabetic retinopathy (DR). Diabetic patients were further divided into two: Group 1, consisted of patients with no DR, mild and moderate non-proliferative DR (n = 36); Group 2, severe nonproliferative and proliferative DR (n = 14). CDI was performed using Philips iU22 xMATRIX ultrasound. The peak systolic velocity (PSV), end-diastolic velocity (EDV), resistivity index (RI) and pulsatile index (PI) of ophthalmic (OA), posterior ciliary artery (PCA), and central retinal artery (CRA) along with central retinal vein (CRV) were recorded. **Results:** RI in the ophthalmic artery was significantly higher in both DR groups than the control group (P = 0.000). Diabetic Group 1 had decreased blood flow velocity (PSV and EDV) in PCA compared to controls (P = 0.046 and P = 0.010, respectively). Group 2 DR had significantly reduced EDV and increased RI in CRA compared to Group 1 (P = 0.015). Binary logistic regression analysis revealed glycosylated hemoglobin and RI of OA to be independent risk factors of DR. **Conclusion:** Significant changes in resistivity index and flow velocities were observed in the retrobulbar vessels, especially in ophthalmic artery in diabetics compared to controls. CDI with results of increased resistance or decreased flow could be useful to predict individuals at higher risk for developing severe DR.

Ocular manifestations of diabetes are numerous and among them, diabetic retinopathy (DR) is a major clinical issue for ophthalmologists. DR is the most frequent cause of preventable blindness in working-age adults (20–74 years) and is therefore considered as a major public health issue.[1] Though treatable in appropriate stages, the prevention of retinal complications of diabetes and consequent visual impairment is vital to reduce the burden of DR. There is a felt need for better diagnostic modalities and surrogate markers in the evaluation and management of DR.

In spite of decades of research, the mechanisms behind the onset and progression of DR still remain unclear. From a hemodynamic point of view, evidence has shown that there is an early reduction in blood flow to retina before the onset of DR followed by a gradual increase as the retinopathy progresses.[2] Color Doppler imaging (CDI) is an established, safe, and noninvasive ultrasonic method useful for qualitatively and quantitatively assessing the blood flow velocities and indirect blood flow.[3] CDI has been suggested to be valuable in the diagnosis and management of several ocular diseases with altered hemodynamics such as glaucoma, retinal vascular diseases, ischemic optic neuropathy, and ocular ischemic syndrome.[4] An analysis of retrobulbar hemodynamics in diabetes using CDI can provide insight into the pathogenesis and prospective treatment for DR as well as predict those at higher risk of developing vision threatening DR. Several authors have evaluated the circulatory changes in diabetics using CDI and reported conflicting results. While few studies have reported a reduction in the retrobulbar blood flow velocities,[5-7] others have noted an increase[8] or no change.[9] Studies on the resistive index (RI) of orbital vessels which is a measure of peripheral vascular resistance have also shown significant discrepancies.[10,11] Factors such as demographic variables, duration of diabetes, methods of DR assessment, positions of CDI, and sample sizes account for the observed discrepancies. Moreover, most studies have not excluded patients with hypertension and those on medications affecting systemic blood flow which can influence the results. Studies on orbital hemodynamic alterations among type 2 diabetics from India are relatively few. The diabetic population in India is close to hitting the alarming mark of 69.9 million by 2025 and 80 million by 2030, denoting an expected increase of 266%. Hence, India is deemed as the world's capital of diabetes.[12] With increasing prevalence of diabetes and DR, it is important to know the hemodynamic alterations among diabetics from the Indian population.

The objective of this study was to evaluate the flow velocities and vascular resistance of orbital blood vessels using CDI in a pure cohort of type 2 diabetic patients from India and compare the results with healthy controls.

Methods

This prospective hospital-based study was carried out at a tertiary care institution from south India between March 2017 and April 2019. The study included consecutive patients of type 2 DM (as per definition of the American Diabetes Association) attending the ophthalmology outpatient clinic for the screening of retinopathy. Exclusion criteria were history of any ocular disease that might affect ocular blood flow such as glaucoma, nondiabetic retinal vascular occlusion, ocular inflammation, high myopia, previous ocular surgery, or panretinal photocoagulation. Patients with systemic hypertension, dyslipidemia, nephropathy, and cardiovascular diseases were excluded from the study. Pregnant and breastfeeding women were not included. Patients taking medications known to affect systemic hemodynamics such as Angiotensin-converting enzyme inhibitors, calcium channel blockers, and anti-migraine drugs were also excluded.

50 age-matched healthy subjects were enrolled as a control group. The control subjects were recruited from individuals attending the department of ophthalmology for a routine eye examination. They were not on any medication and did not have ocular or systemic disease. The study was conducted according to the principles of the Declaration of Helsinki and the study protocol was approved by the institutional ethics committee. Informed consent was obtained from all participants.

Information regarding age, gender, body mass index, duration of diabetes, antidiabetic medications, and blood pressure were obtained from all participants. Serum glycosylated hemoglobin (HbA1c) was determined from fasting venous blood sample.

All study participants underwent a comprehensive ophthalmic examination including dilated fundus with slit-lamp biomicroscope using a 90 diopter lens and indirect ophthalmoscopy. A 30° stereoscopic fundus photograph of 7 standard early treatment diabetic retinopathy study (ETDRS) fields was taken from both eyes of diabetic patients using a digital fundus camera (TRC-50 DX Mydriatic retinal camera; Topcon Medical Systems, Oakland, NJ).

The presence, as well as the severity of diabetic retinopathy, was determined by grading of color fundus photographs following the international clinical disease severity scale for diabetic retinopathy which is based on the findings of WESDR (Wisconsin Epidemiological Study of Diabetic Retinopathy) and ETDRS.[13] The diabetic patients were assigned to one of the following groups namely no retinopathy, mild nonproliferative diabetic retinopathy (NPDR), moderate NPDR, severe NPDR, and proliferative diabetic retinopathy (PDR). The

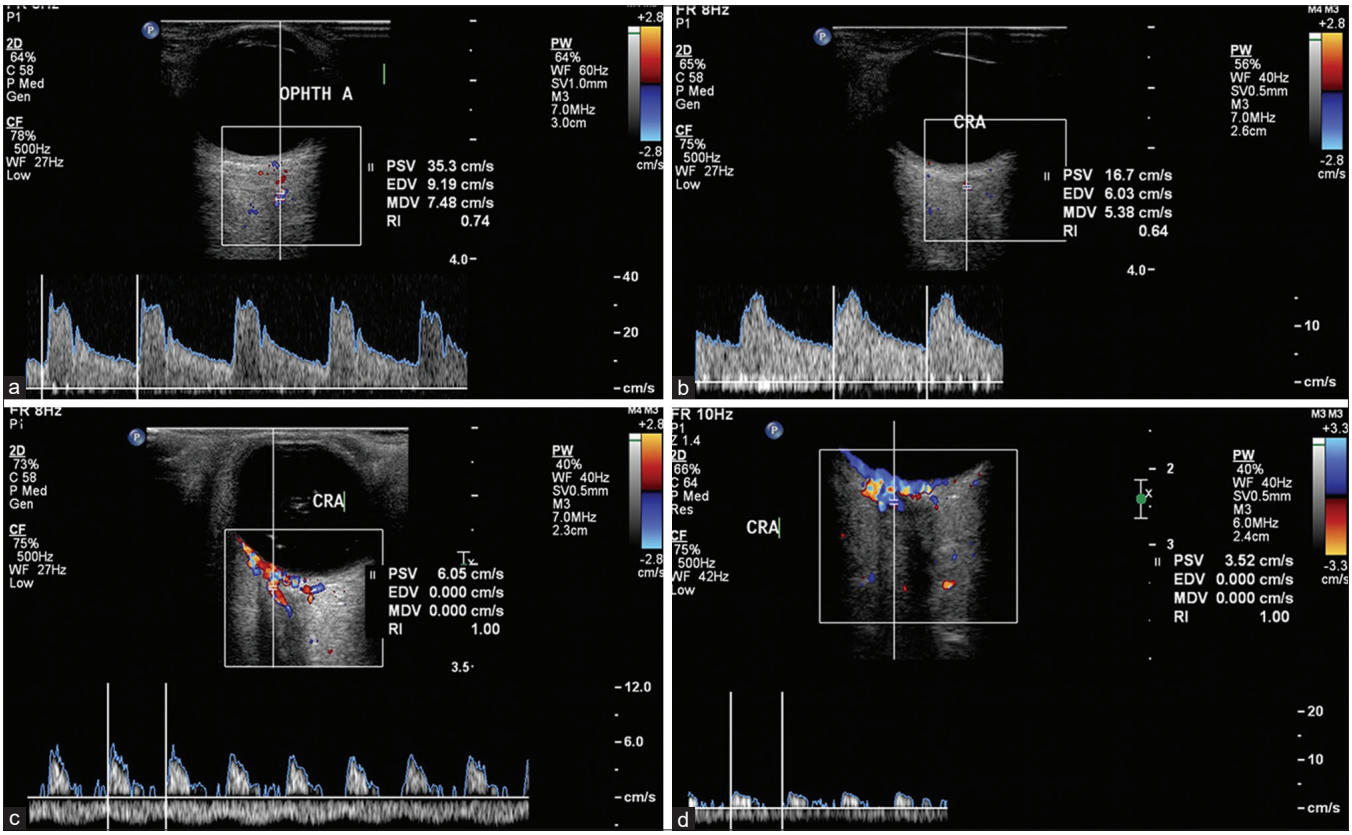

Figure 1: (a) Color Doppler image (CDI) showing normal color flow and spectral waveform in ophthalmic artery with preserved M wave pattern; (b) CDI showing normal color flow and spectral waveform in central retinal artery; (c) CDI showing low-velocity monophasic flow in central retinal artery in a patient with moderate NPDR; (d) CDI showing monophasic spectral waveform with absent diastolic flow in central retinal artery in a patient with severe NPDR

[Downloaded free from http://www.ijo.in on Thursday, June 4, 2020, IP: 192.168.70.71]

eye with worse retinopathy was included in the study. If both eyes had equal retinopathy, the right eye was assigned to the study.

Color Doppler sonography of the eye was performed for cases and controls by a masked expert Radiologist using a color Doppler unit and a 12 to 5 MHZ linear-array transducer (Philips iU22 xMATRIX ultrasound system). The patients were examined in the supine position and care was taken to avoid any undue pressure on the eye. Examiner's hand was rested on the orbital margin and sterile coupling gel was applied over closed eyelids. The Doppler signal was registered online after the cursor was positioned on the region of interest. To reduce errors in measurement of velocities, angle correction was applied to the pulsed Doppler recordings.

The peak systolic velocity (PSV) and end-diastolic velocity (EDV) readings were obtained from the ophthalmic artery (OA), central retinal artery (CRA), and the posterior ciliary artery (PCA). Since the velocity wave in a central retinal vein (CRV) is not in direct relation to the cardiac cycle its hemodynamic parameters were expressed as maximum (V max) and minimum (V min) blood velocity. Signals from the ophthalmic artery were obtained from the medial aspect of the eyeball, superior to the optic nerve. The central retinal artery and vein were located within the optic nerve, around 10 mm behind the eyeball. [Fig. 1] Signals from the temporal branch of the short posterior ciliary artery were located lateral to the optic nerve.

With the help of PSV and EDV, we calculated the vascular resistance expressed by the resistivity index and pulsatile index using Pourcelot's formula.

Resistive index (RI) = (PSV-EDV)/PSV; Pulsatile index (PI) = (PSV-EDV)/Vmean

Statistical analysis

For statistical analysis diabetic patients were further divided into two groups; Group 1 included patients with no retinopathy, mild NPDR, and moderate NPDR while Group 2 consisted of patients with severe NPDR and PDR.

Statistical analysis was performed using statistical package for social sciences (SPSS, SPSS Inc, Chicago, IL, USA) version 24. Data were expressed as mean ± standard deviation. The normality of data distribution was tested by the Kolmogorov-Smirnov test. One-way analysis of variance (ANOVA) with a *post hoc* Bonferroni was used for the analysis of normally distributed continuous data. Kruskal-Wallis analysis was used for analyzing non-normally distributed data. A comparison between hemodynamic parameters was calculated by ANOVA followed by Tukey-Kramer *post hoc* comparison. Pearson's coefficient was used to study the correlation between variables.

Table 1: Demographic and clinical characteristics of controls and diabetic subjects

Characteristic	Controls (*n*=50)	Group 1 (*n*=36)	Group 2 (*n*=14)	*P*

Binary logistic regression analysis was performed to determine independent risk factors for retinopathy. All tests for statistical significance were two-tailed and performed assuming a type I error probability of <0.05.

Results

Demographic and clinical parameters

The study included 52 males and 48 females. The age of patients ranged from 41 to 76 years. The duration of diabetes ranged from 6 months to 20 years. Among the diabetic patients, 29 were on oral hypoglycemic agents, 9 were on insulin, and 12 were on combination therapy. Group 1 (n = 36) consisted of 16 patients with no DR, 13 with mild NPDR, and 7 with moderate NPDR. Group 2 (n = 14) consisted of 6 patients with severe NPDR and 8 with PDR. There were no statistically significant differences in the age, body mass index and blood pressure between controls and diabetic groups. Glycosylated hemoglobin (HbA1c) levels were found to be significantly higher in Group 2 diabetic patients (P = 0.014). No significant difference was noted in the duration of diabetes among diabetic groups. The demographic and clinical characteristics of controls and diabetic subjects are presented in Table 1.

Hemodynamic parameters

Table 2 shows the hemodynamic parameters of retrobulbar blood vessels among controls and patient groups.

Ophthalmic artery

Significant differences were noted in the RI and PI values of the ophthalmic artery between controls and diabetic patients with various DR grades. OA flow velocities did not vary between groups.

Table 3: Pearson correlation coefficients between the duration of diabetes, HbA1c, and hemodynamic parameters

Variable	Duration of diabetes	HbA1c
OA PSV	0.021 (0.885)	-0.120 (0.407)
OA EDV	-0.141 (0.328)	-0.055 (0.706)
OA RI	0.314* (0.026)	0.097 (0.504)
OA PI	0.299* (0.035)	0.078 (0.588)
CRA PSV	-0.135 (0.349)	-0.269 (0.059)
CRA EDV	-0.464* (0.001)	-0.299*(0.035)
CRA RI	0.375* (0.007)	-0.046 (0.753)
CRA PI	0.487* (0.000)	0.131 (0.370)
PCA PSV	-0.052 (0.722)	0.170 (0.239)
PCA EDV	-0.234 (0.102)	0.196 (0.172)
PCA RI	0.332* (0.019)	-0.075 (0.606)
PCA PI	0.321*(0.023)	-0.085 (0.556)
CRV V max	0.134 (0.354)	0.128 (0.375)
CRV V min	-0.143 (0.322)	-0.058 (0.687)
CRV RI	0.390* (0.005)	0.172 (0.233)
CRV PI	0.415*(0.003)	0.210 (0.144)

Corresponding P values are shown in brackets. HbA1c=Glycosylated hemoglobin; OA=Ophthalmic artery; CRA=Central retinal artery; PCA=Posterior ciliary artery; CRV=Central retinal vein; PSV=Peak systolic velocity; EDV=End diastolic velocity; V max=maximum blood velocity; V min=minimum blood velocity; RI=Resistivity index; PI=Pulsatility index; *P<0.05

Central retinal artery and vein

The hemodynamic parameters of CRA were significantly different between controls, DR Group 1, and Group 2 whereas no such difference was seen in the CRV. *Post hoc* comparison revealed a significantly reduced PSV and EDV of CRA (P = 0.005 and 0.000, respectively) along with increased PI (P = 0.003) in DR group 2 compared to controls. Patients with group 2 DR also demonstrated a significant decrease of EDV and increased RI of CRA compared to group 1 (P = 0.015). PSV, EDV, and RI of CRA did not differ significantly between controls and DR group 1.

Posterior ciliary artery

The EDV and PI of PCA were found to vary significantly between controls and diabetic groups. Significant reduction in PSV and EDV of PCA was noted in DR group 1 compared to controls (P = 0.046 and P = 0.010, respectively after *post hoc* comparison).

Relation between duration of diabetes, HbA1c, and hemodynamic parameters

Duration of diabetes correlated positively with the resistive and pulsatile indices of all retrobulbar vessels studied namely ophthalmic artery, CRA, PCA, and CRV. HbA1c levels, as well as the duration of diabetes, were found to correlate negatively with EDV of CRA. No correlation was found between duration of diabetes and HbA1c levels (R = 0.183, P = 0.203). Table 3 shows the relationship between duration of diabetes, HbA1c levels, and hemodynamic parameters.

Binary logistic regression analysis revealed that HbA1c levels and RI of OA were independent risk factors of retinopathy.

Discussion

The main observations of our study are as follows: (1) RI in the ophthalmic artery was significantly higher in both DR groups than the control group and was an independent risk factor of retinopathy, (2) Patients with Group 1 DR had decreased blood flow velocity (PSV and EDV) in the posterior ciliary artery compared to control group, (3) Patients with Group 2 DR had significantly reduced EDV and increased RI in the CRA compared to Group 1, (4) Compared to the control group, patients with Group 2 DR had slower flow velocities and increased PI in CRA but RI values did not vary significantly.

Our finding of decreased EDV in the posterior ciliary artery in patients with Group 1 DR supports the hypothesis that choroidal blood flow is affected in the early stages of DR. Laser Doppler flowmetry has shown decreased choroidal blood flow in the foveal region in early DR.[14] Choroidal vascularity index (CVI) analysis by swept-source optical coherence tomography (OCT) has also shown reduced CVI in patients with mild/moderate NPDR.[15] Cao *et al.* have reported a 4 times more choriocapillary loss in diabetic eyes compared to non-diabetic eyes in histopathologic studies.[16] Ferrara *et al.* have demonstrated the loss of intermediate and large blood vessels in the Sattler's layer and Haller's layers in diabetic eyes in choroidal OCT.[17] Our observation of decreased EDV in the PCA suggests increased peripheral vascular resistance of the choroidal circulation in early DR and is in concordance with these studies. Dimitrova *et al.* reported decreased EDV and increased RI in PCA in patients

[Downloaded free from http://www.ijo.in on Thursday, June 4, 2020, IP: 192.168.70.71]

with background DR compared to controls in CDI of diabetic patients performed in sitting posture.[6] The authors have suggested that erect posture during CDI measurement is essential to appreciate significant alterations in posterior ciliary circulation. Supine posture has been suggested to increase EDV and decrease the RI.[18] As autoregulation and autonomic nervous responses are altered in diabetics, the correlation of change in circulatory parameters between normal individuals and diabetics associated with postural variation may not be expected to be equal. However, CDI was performed in supine posture in our patients. Our observations could be attributed to the shorter duration of diabetes in our patients than theirs.

RI in OA was higher in both DR groups compared with controls in our study. These findings are similar to those of previous studies.[5,19] Basturk *et al.* evaluated the association between the resistivity index of orbital arteries and DR in 91 types 2 diabetics with microalbuminuria using CDI. The authors have demonstrated increased RI values of all orbital arteries in patients with DR compared to those without DR and controls. RI value of ≥ 0.72 in OA indicated the presence of DR with 78.4% sensitivity and 70% specificity.[10] Our finding of increased RI in the OA in both DR groups can be attributed to the statistically nonsignificant reduction in EDV observed in diabetic subjects because of downstream vascular changes in the retina and choroid. We did not observe significant differences in CRA parameters between controls and DR Group 1. Hence, we believe that the OA hemodynamic parameters in our study probably represent alterations in choroidal blood flow. It has been suggested that of the total ocular blood supply from OA, less than 10% flows to the retina while the remainder is directed to choroid via the ciliary circulation due to the high metabolic demand of photoreceptors.[20] Moreover, the diastolic blood flow of PCA is higher than CRA since these vascular channels of choroid have low resistance.[21]

Khatri *et al.* assessed the correlation between RI of OA and topographic alterations of retinal pigment epithelium (RPE) on spectral-domain optical coherence tomography (SD-OCT).[22] In their study involving 75 patients with type 2 diabetes and 24 controls, a significant increase in OA RI was noted with the severity of DR ($F = 14.23$, $P < 0.001$). A positive correlation was noted between RI of OA and grades of RPE alterations on SD-OCT suggesting that decreased blood flow contributes to RPE dysfunction. Studies demonstrating early retinal damage in experimental diabetes have reported morphological changes in RPE and animal studies have also shown reduced choroidal blood flow in young diabetic animals suggesting that blood flow deficit could be an early pathological change in DR.[23,24] Although it is difficult to propose a causal association it can be postulated that changes in choroidal circulation (as reflected by increased RI of OA) lead to downregulation of antiangiogenic PEDF (pigment epithelial-derived factor) and upregulation of VEGF (vascular endothelial growth factor) thereby contributing to progression of DR. Differential expression and secretion of these growth factors derived from the retinal pigment epithelium have been suggested to lead to nonproliferative and proliferative DR.[25]

Patients with Group 2 DR had significantly reduced EDV in the CRA compared to Group 1 DR as well as healthy controls. Our observations are in line with previous studies.[5,6,8] These can be attributed to the increased peripheral vascular resistivity with the progression of DR. Pathological findings in DR such as capillary basement membrane thickening, retinal capillary leukostasis, loss of retinal capillaries, and altered blood rheology support this circulatory feature.[2,26,27]

Another observation of our study was that DR Group 2 had significantly reduced flow velocity in the CRA but an increase in RI was not statistically significant compared to the control group. This can be due to the concomitant decrease of both PSV and EDV in patients with Group 2 DR. Neudorfer *et al.* evaluated the long-term changes in the retrobulbar circulation of 138 eyes of diabetic subjects at a 10-year follow-up.[28] Patients were divided into four groups, namely, nondiabetic controls, diabetics without DR, nonproliferative DR, and proliferative DR. RI values of CRA and PCA had increased in the two no retinopathy groups and in the nonproliferative DR group, with a surprising nonsignificant decrease in the proliferative DR group. The authors have concluded that an increase of resistance in the retrobulbar blood vessels due to DR can decrease over time and may even be reversed. It has been suggested that the decrease in resistance reflects the beginning of an increase in retinal blood flow with the progression of DR due to the short-circuiting of the obstructed retinal capillary network.[28] This is supported by histopathologic studies, which have shown areas of capillary closure being traversed by preferential dilated anastomotic channels.[29]

Our finding of a positive correlation between duration of diabetes and RI of all retrobulbar vessels was similar to the observations of Karami *et al.*[30] We found negative correlation between EDV of CRA and duration of diabetes as well as HbA1c levels ($R = -0.464$, $P = 0.001$; $R = -0.299$, $P = 0.035$, respectively). Poor glycemic control (as reflected by increased HbA1c) and longer duration of diabetes can be associated with increased peripheral vascular resistance and thus reduced EDV in CRA. Our findings of HbA1c and RI of OA as independent risk factors of DR are similar to that of Basturk *et al.*[10]

Table 4 shows the various published studies on ocular circulation in diabetic patients using CDI.

Our study has several strengths. None of the diabetic patients had associated vascular diseases. Hypertension as well as antihypertensive medications significantly alter the resistive indices of blood vessels and therefore confound the results. We intentionally excluded these patients to study the influence of diabetes alone on ocular hemodynamics. A single masked, experienced radiologist performed all the Doppler examinations gently with the least pressure on the globe thus eliminating interobserver variability. The presence and severity of DR were graded based on seven field stereo fundus photography for accuracy.

To our knowledge, this study is the first of its kind in a pure cohort of diabetics from India.

There are a few limitations to our study. The sample size was small which accounts for the limited subgroup analysis. CDI provides information on blood flow velocity only and absolute volumetric blood flow cannot be quantified since it is not possible to study the diameter of retrobulbar vessels with CDI accurately. In spite of this limitation, blood velocity is probably a good indicator of blood flow within a given vessel.[31,32] Moreover, measurement of retinal blood flow is difficult and no accurate method to quantitatively assess perfusion is currently used clinically.

Conclusion

In conclusion, significant changes in the blood flow velocities and RI were observed in the retrobulbar vessels, especially in an ophthalmic artery in diabetics compared to controls. RI could be potentially useful for early diagnosis and follow-up of DR. CDI with results of increased resistance or decreased flow can be of help to identify diabetic individuals at higher risk for developing severe DR. This is especially useful in patients with opaque media where conventional methods are of little use.

Utility of ultrasound elastography in evaluation of thyroid nodules and correlation with cytology

Vikrant Kanagaraju, S. Sukithra, N. Jayaprakash, B. Devanand

Department of Radiology, PSG Institute of Medical Sciences and Research, Coimbatore, Tamil Nadu, India

Abstract

Background: Ultrasound elastography (USE) has emerged as a potentially useful tool in the evaluation of thyroid nodules. The aim of this study was to assess the efficacy of elastography in differentiating benign from malignant thyroid nodules with fine-needle aspiration cytology (FNAC) analysis as reference standard.

Materials and Methods: This was a cross-sectional prospective study carried out at a tertiary care center in South India between May 2014 and March 2015. Consecutive patients with solid nodule in the thyroid gland on conventional ultrasound (US) underwent USE, followed by US-guided FNAC of the thyroid nodule. The findings of B-mode images and USE were correlated with cytology. Statistical analysis was performed using SPSS version 24. Descriptive statistics were presented as mean ± standard deviation. The diagnostic sensitivity, specificity, positive predictive value, and negative predictive value of USE were calculated.

Results: A total of sixty patients with sixty solid thyroid nodules were enrolled in the study. The mean age of the patients was 48.27 ± 16.10 years. About 83.3% were females. The frequency of benign nodules on cytopathologic analysis was 60% (n = 36). Seventy-five percent of the malignant lesions had irregular or poorly defined borders with lobulated margins on US. The sensitivity, specificity, positive predictive value, and negative predictive value of USE were 91.7%, 77.77%, 73.33%, and 93.3%, respectively, with FNAC as reference standard. Higher elastography scores were found to be significantly associated with malignant cytology (P = 0.0001).

Conclusion: Elastography, with its fairly high diagnostic accuracy and correlation with malignant cytology, can be an effective noninvasive adjunctive tool in distinguishing benign from malignant thyroid nodules.

Keywords: Elastography, thyroid nodules, ultrasound

INTRODUCTION

The prevalence of thyroid nodules which are clinically palpable is about 2%–6% in the general population.[1] Although majority of these nodules are benign, up to 7% can be malignant.[2,3]

On palpation, a hard or firm nature is associated with an increased risk of malignancy. However, palpation is a highly subjective method and its value is limited in patients with multinodular goiter or deep-seated nodules. Ultrasonography (USG) is the most commonly used imaging modality to diagnose thyroid nodules. The utility of

USG in differentiating benign from malignant lesions has been established by several studies.[4-6] However, no USG feature has been shown to have both high sensitivity and high specificity in detecting malignancy in thyroid nodules.[7] Elastography is a newly developed noninvasive dynamic imaging technique analogous to manual palpation. This technique uses ultrasound (US) to estimate tissue stiffness by measuring the degree of distortion under application of an external force.[8] Several studies have used US elastography (USE) for evaluation of thyroid disorders.[9-11]

Fine-needle aspiration cytology (FNAC) is an efficient tool in distinguishing benign nodules that can be managed conservatively from those with suspicious or malignant features that warrant further intervention. Limited data exist on the utility of elastography in differentiating benign from malignant lesions of the thyroid and its correlation with FNAC, especially from India. The aim of this study was to assess the efficacy of elastography in differentiating benign from malignant thyroid nodules with FNAC analysis as reference standard.

MATERIALS AND METHODS

This prospective study was carried out at a tertiary care center in South India between May 2014 and March 2015. Consecutive patients of either gender who were found to have thyroid swelling/goiter on clinical examination and referred for USG were considered. Only those with solid thyroid nodules at least 8 mm in size on conventional US were included in the study. Cystic lesions with no solid component, multinodular goiters with coalescent nodules, and nodules with eggshell calcification were excluded from the study. A large nodule involving more than 75% of thyroid lobe volume was also excluded because of inadequate normal thyroid tissue to be used as reference. The institutional review board approved the study protocol, and the protocol complied with the tenets of the Declaration of Helsinki. Informed consent was obtained from all participants.

With a patient in supine position and neck fully extended, B-mode US of the thyroid gland was performed with SIEMENS ACUSON S2000 machine using high-frequency probes 9 L4 and 14 L5. US features studied included echogenicity, regularity of borders, presence of halo, vascular pattern, and calcification. Thyroid imaging reporting and data system (TIRADS) scoring was used to categorize the lesions[12] [Table 1].

USE was performed with SIEMENS ACUSON S2000 at the same time as the B-mode examination. The probe was placed over the region such that the lesion is in the center of the image, holding the scan plane perpendicular to the skin surface. At least 5 mm of normal adjacent tissue was included to assess the lesion stiffness in relation to the average elasticity of surrounding tissue. Patients were asked to hold their breath and avoid swallowing during examination in order to minimize the motion of the thyroid gland. The elasticity images were obtained by appropriate compression, followed by decompression of the transducer. The images were displayed on split-screen mode with US grayscale images on the left and USE images on the right. Multiple frames were acquired, and the best-fit B mode-USE image pairs were selected for examination [Figures 1 and 2]. The targeted lesion was scored as 1–4, using strain elastographic scores proposed by Asteria *et al*.[9] [Table 2].

US-guided FNAC of the thyroid nodule was done using a 22G needle, and the lesion was aspirated at least twice with the freehand technique. The aspirated contents were expelled onto glass slides and immediately fixed with 95% ethyl alcohol. The slides were stained with modified Papanicolaou staining and examined under light microscopy. The cytological results were classified

Table 1: Thyroid image reporting and data system scoring of thyroid nodules

Category	Description
TIRADS 1	Normal thyroid gland
TIRADS 2	Benign conditions
TIRADS 3	Probably benign nodules (<5% malignant)
TIRADS 4	Suspicious nodules (5%-80% malignancy rate)
TIRADS 5	Probably malignant nodules (malignancy rate >80%)
TIRADS 6	Biopsy-proven malignant nodules

TIRADS – Thyroid image reporting and data system

Table 2: Asteria's criteria of scoring of thyroid nodules on elastography

Elasticity Score	Description
Score of 1	Elasticity in the entire examined area
Score of 2	Elasticity in a large part of the examined area
Score of 3	Stiffness in a large part of the examined area
Score of 4	Nodule without elasticity

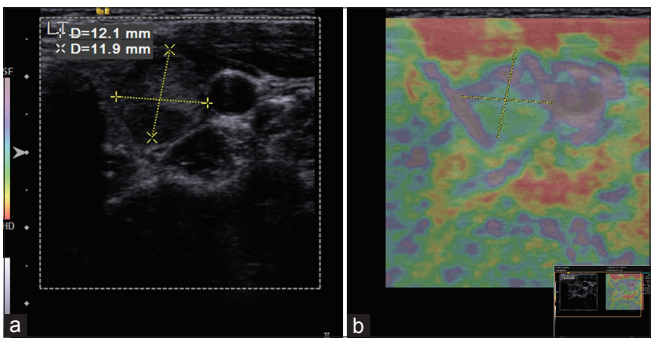

Figure 1: Thyroid nodule images obtained on conventional ultrasound (a) and ultrasound elastography with elasticity score 2 (b)

as benign, indeterminate/suspicious (follicular lesions), and malignant according to standard pathological criteria.

Statistical analysis

Statistical analysis was performed using the Statistical Package for the Social Sciences (SPSS, SPSS Inc., Chicago. IL, USA) version 24. Descriptive statistics were presented as mean ± standard deviation. Qualitative variables were presented in the form of frequency and percentages and compared using the Chi-square test. The diagnostic sensitivity, specificity, positive predictive value, and negative predictive value were calculated. Statistical significance was set at $P < 0.05$.

For statistical purposes, USE score of 2 was strongly predictive of a benign lesion and therefore considered sample negative for malignancy. Scores of 3 and 4 describing stiffness in a large part of the examined area and nodule without elasticity, respectively, were considered as positive for malignancy in our study. With regard to cytology, two groups were considered for evaluation: benign and malignant. Patients with fine-needle aspiration (FNA) reports of indeterminate/suspicious (follicular lesions) were also included in the malignant group for statistical purposes.

RESULTS

A total of sixty patients with sixty solid thyroid nodules were enrolled in the study. The age of the patients ranged from 19 to 85 years (mean: 48.27 ± 16.10 years). About 83.3% (n = 50) were female and 16.7% (n = 10) were male. The frequency of benign nodules on cytopathologic analysis was 60% (n = 36), whereas 40% (n = 24) were nonbenign (follicular lesions and malignant tumors). Of the 24 nonbenign thyroid nodules, 20 had been reported as papillary carcinoma, 2 as medullary carcinoma, and 2 as follicular neoplasm. Table 3 shows the presenting clinical features and cytologic diagnoses of patients with thyroid nodules.

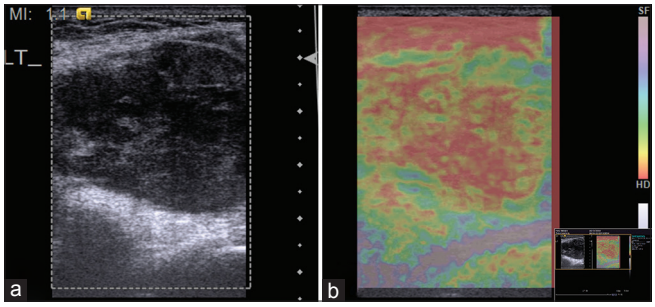

Figure 2: Heterogeneous nodule on conventional ultrasound (a) and ultrasound elastography with elasticity score 4 (b)

Seventy-five percent of the malignant lesions had irregular or poorly defined borders with lobulated margins on US and 68% had microcalcification. Seventy-seven percent of the benign nodules were hyperechoic. On TIRADS scoring, score of 2 was found in 24 cases, all benign lesions; score 3 in 14 cases, 8 benign and 6 malignant; score 4 in 12 cases, 4 benign and 8 malignant; and score 5 in 10 cases, all malignant lesions. Table 4 shows the correlation of USE scores and FNAC diagnoses of patients.

The sensitivity, specificity, positive predictive value, and negative predictive value of US elastography were 91.7%, 77.77%, 73.33%, and 93.3%, respectively, with FNAC as a reference standard [Table 5]. Higher elastography scores were found to be significantly associated with malignant cytology ($P = 0.0001$).

DISCUSSION

Thyroid nodules are common in the general population, and the reported prevalence varies depending on the identification method. Apart from serum markers and FNAC, USG plays an important role in the detection and evaluation of thyroid nodules. Being noninvasive conventional US provides information regarding the nodule dimensions, structure as well as parenchymal changes and is widely used to determine which nodules should be biopsied. Microcalcifications, hypoechogenicity,

Negative	2 (false negative)	28 (true negative)	30
Total	24	36	60

FNA – Fine-needle aspiration; USE – Ultrasound elastography

irregular or microlobulated margins, taller than wide shape, and increased intranodular vascularity have been reported as independent risk factors for malignancy.[13,14] Although these features are characterized by high specificity, their positive predictive value is lowered by their relatively low sensitivity.[15]

USE is based on the principle that the softer parts of tissues deform easier than the harder parts, under compression, thereby allowing an objective determination of tissue consistency. Malignancy is often associated with changes in the mechanical properties of a tissue, and USE has been used to differentiate benign from malignant lesions in the breast, liver, and prostate.[16-18] The two general criteria for evaluating the efficacy of USE are elasticity scores and strain ratio. Although elastography has been suggested to be of great use as an adjunctive tool in the diagnosis of thyroid cancer, studies have reported conflicting evidence on its additional value in predicting thyroid malignancy.[19-21]

This study was planned to assess the efficacy of elastography in differentiating benign from malignant thyroid nodules with FNAC analysis as a reference standard. The mean age of presentation for benign nodules was 44.31 ± 14.28 years, whereas that for malignant lesions was 54.21 ± 17.13 years ($P = 0.018$) A majority of our cases diagnosed with thyroid nodules were females (83.3%). Thyroid nodules are reported to be four times more common in women than men, and their frequency increases with age and low iodine intake.[22] The female preponderance has been explained by the hormonal influences of estrogen and progesterone, as increasing nodule size and new nodule development have been demonstrated to be related to pregnancy and multiparity.[23]

Of the sixty nodules studied, 60% were benign ($n = 36$) and 40% ($n = 24$) were nonbenign. Of the 36 benign nodules, 26 were colloid nodules and 10 were adenomatoid nodules. The 24 nonbenign lesions included 20 papillary carcinomas, 2 medullary carcinomas, and 2 follicular neoplasms. The most common clinical presentation was painless mass in the neck which was encountered in almost 47% of the patients. Majority of the patients who presented with significant weight loss, dysphagia, and hoarseness of voice were found to have malignant lesions. Dysphagia, dysphonia, reports of rapid growth, male gender, prior head-and-neck irradiation, and presentation at extremes of age have been reported as significant elements in the patient's history, which increase the likelihood of malignancy.[24]

Our study found that 75% of malignant lesions had irregular or poorly defined borders with lobulated margins, whereas 68% of malignant lesions had microcalcification. Seventy-seven percent of the benign nodules were hyperechoic, whereas 23% were hypoechoic. None of the hyperechoic nodules was malignant. Although none of these US features is sufficient to differentiate benign lesions from malignant ones, studies have shown that a combination of at least two of the features is better helpful in pointing out a subset of lesions at high risk for malignancy.[25,26]

With regard to TIRADS score, all the nodules with TIRADS score of 2 ($n = 24$) had benign FNA characteristics, whereas all the patients with TIRADS score of 5 ($n = 10$) were found to have malignant lesions on FNA. Among TIRADS 3 lesions ($n = 14$), 57% were benign, and among TIRADS 4 lesions ($n = 12$), 33% were found to be benign on FNA.

On US elastography, score of 2 was found in 30 nodules, 28 benign and 2 malignant; score 3 in 10 cases, 8 benign and 2 malignant; and score 4 in 20 cases, all malignant. The sensitivity, specificity, positive predictive value, and negative predictive value of US elastography were 91.7%, 77.77%, 73.33%, and 93.3%, respectively, with FNAC as a reference standard.

The elastography scores of 3–4 were achieved in 22 of the 24 malignant nodules in our study. Among the 20 nodules with cytologic diagnosis of papillary carcinoma, 18 were correctly scored as malignant by USE, thus achieving 90% diagnostic accuracy in terms of confirming the malignant etiology. Only two nodules were incorrectly given a USE score of 2. Both of the two nodules with medullary carcinoma thyroid had been scored as malignant on USE (score 4). We had eight false-positive nodules (score 3) which can be attributed to the fibrotic changes and calcification that lead to hardness of the nodule under study.

Our observations are in line with that of Mehrotra *et al.* who have reported the sensitivity and specificity of USE for thyroid malignancy to be 90% and 79.6%, respectively.[27] Of the 147 nodules examined by USE and US-guided FNAC, 122 were nonneoplastic, 5 were benign neoplasm, 10 had indeterminate cytologies, and 10 had malignant neoplasms. The observed positive and negative predictive values were 24.3% and 99.1%, respectively. In contrast, we found the positive predictive value of elastography to be 73.3% in our study. This can be explained by the high prevalence of malignant lesions among our study population.

The sensitivity and specificity of elastography based on elastography scores have been reported to vary from

86% to 97% and 66%–100% from various studies.[8,9,28] The observed wide differences are due to the fact that these studies involve different groups of populations, referral bias (patients referred for FNAC/surgery), varied inclusion and exclusion criteria, different machines as well as criteria for USE scoring. A recent comprehensive meta-analysis to investigate the diagnostic value of qualitative elastography in distinguishing benign from malignant thyroid nodules included 20 studies involving 3973 thyroid nodules.[29] Pooled results of elastography have shown a summary sensitivity of 85% (95% confidence interval [CI], 79%–90%) and specificity of 80% (95% CI, 73%–86%). The respective pooled negative predictive and positive predictive values were 97% (95% CI, 94%–98%) and 40% (95% CI, 34%–48%), respectively.

Despite the potential limitations of USE such as intra/interobserver variability and nodule characteristics such as calcification and follicular carcinoma (which appears soft), USE is considered to be reliable in the diagnosis of benign nodules in view of the high negative predictive values observed in most of the studies including ours.

FNAC is an essential diagnostic modality in the evaluation of thyroid nodules and features in all the guidelines in patient management.[30] Although the use of FNAC in the evaluation of thyroid nodules provides reliable results, it is invasive and the potential for complications such as postprocedural hematoma, increased patient morbidity, cost, and possibility of nondiagnostic specimen does exist. Unnecessary/repeat FNACs and FNA-induced changes can result in false-positive results on thyroid cytology and false-negative results or understaging of the tumor on thyroid pathology.[31,32]

Higher elastography scores were found to be significantly associated with malignant cytology ($P = 0.0001$) in our study. Merino *et al*. have also noted a statistically significant association between elasticity scores and cytological results, suggesting that malignant nodules could be excluded by elastography.[33]

Limitations of our study include small sample size and the fact that observations are from a single center.

CONCLUSION

With scanty literature comparing elastography with FNAC available from this part of the world, our study highlights that elastography has a fairly high diagnostic accuracy and correlation with malignant cytology. It can be an effective noninvasive adjunctive tool in distinguishing benign from malignant thyroid nodules and reduce the burden of unnecessary invasive procedures.

Role of Transrectal Ultrasound Elastography in the Diagnosis of Prostate Carcinoma

Vikrant Kanagaraju*, P. V. K. Ashlyin, N. Elango, B. Devanand

Department of Radiology, PSG Institute of Medical Sciences and Research, Coimbatore, Tamil Nadu, India

Abstract

Background: The purpose of this study was to evaluate the diagnostic value of transrectal real- time strain elastography (RTE) in identifying prostatic carcinoma (PCa). **Materials and Methods:** 60 patients suspected of having PCa based on abnormal digital rectal examination and raised prostate specific antigen levels underwent transrectal ultrasound (TRUS), color Doppler (CD) and RTE. Elastograms were scored on a five point scale based on distribution of strain in relation to hypoechoic area on TRUS. Twelve core systematic biopsy as well as targeted biopsy was performed from suspicious areas on TRUS and RTE. Diagnostic performance of sonoelastography was evaluated using histopathology as reference standard. **Results:** Histopathology revealed cancer in 28 out of 60 patients (47%) studied. Gleason score ranged from 6 to 9. The sensitivity, specificity, positive predictive value (PPV), and negative predictive value (NPV) of TRUS in detecting prostate cancer were 78.57%, 81.25%, 78.57%, and 81.25%, respectively. On CD evaluation 87.5% (n = 28) of benign lesions showed symmetric, radial flow compared to 14.3% (n = 4) of malignant lesions ($P < 0.0001$). The sensitivity and specificity of RTE was 89.29% and 56.25% with PPV and NPV being 58.13% and 82.35%, respectively. Higher elastography score was found to be significantly associated with malignant histopathology ($P = 0.004$). Cancer detection rate with RTE was greater for tumors with higher Gleason score. **Conclusion:** RTE was found to have better sensitivity than TRUS as well as combination of TRUS and CD. Although less specific, RTE can be an effective adjuvant tool to TRUS for guidance of biopsy and improve detection rate of PCa.

Keywords: Elastography, prostate cancer, ultrasonography

Introduction

Prostate carcinoma (PCa) is the second most frequently diagnosed cancer in males all over the world and is a major healthcare concern associated with significant morbidity and mortality. The burden of PCa is estimated to grow to 1.7 million new cases and 499000 new deaths by 2030 as a result of growth and aging of the global population.[1]

Digital rectal examination (DRE), screening for prostate specific antigen (PSA), and imaging techniques such as transrectal ultrasound (TRUS) and magnetic resonance imaging (MRI) are the methods commonly employed for detection of PCa. DRE is limited by its low sensitivity, subjective nature, and depends on the experience of the clinician. Although PSA testing has been widely used for screening of prostatic cancer, it is not disease specific and can be elevated in patients with prostatitis as well as benign prostatic hyperplasia.[2,3] In a patient with suspicion of prostatic cancer, current guidelines involve histopathologic examination of systematic biopsy cores to confirm or rule out cancer.[4] However, the conventional biopsy protocol misses significant cancer in a large proportion of patients.[5] Further many insignificant cancers that do not need immediate treatment are also detected leading to overdiagnosis and treatment.[6] Use of TRUS for detecting prostate cancer has limitations such as poor specificity of focal abnormalities, frequent multifocality of cancer within the prostate, and substantial percentage of isoechoic prostatic carcinoma (PCa).[7] Although MRI results are promising, it is expensive and not always available. In view of these limitations, improved noninvasive imaging modalities that

can provide better characterization of prostatic lesions and increase detection of prostatic cancer are needed.

Ultrasound elastography (USE) is a dynamic technique that uses ultrasound to estimate tissue stiffness by measuring the degree of distortion under application of an external force. As cancerous tissue has greater stiffness than a benign lesion USE has been used to differentiate malignant from benign lesions in breast, thyroid, liver, and cervix. Recent studies have demonstrated the utility of sonoelastography in detecting prostate cancer.[8-10]

Data on the usefulness of transrectal strain elastography (SE) in evaluation of prostatic cancer and its correlation with histopathology are relatively few, especially from India. The purpose of the present study was to evaluate the usefulness and diagnostic performance of transrectal SE in identifying prostatic cancer with histopathologic diagnosis obtained by needle biopsy of prostate as reference standard.

Materials and Methods

This prospective study was performed in a tertiary care center in South India between December 2014 and September 2016. 60 consecutive patients who were referred to the department of Radiology with suspicion of PCa based on abnormal DRE and elevated PSA levels (>4 ng/ml) were enrolled. The institutional review board approved the study protocol and the protocol was in compliance with tenets of the Declaration of Helsinki (IRB approval Number: 14/399). Informed consent was obtained from all participants. Exclusion criteria consisted of patients with bleeding disorders, inflammatory bowel disease and surgical absence of rectum or ileoanal pouch. All patients underwent TRUS (grey scale and Doppler) and SE as well as needle biopsy of prostate in the same session.

TRUS of prostate was done using an endocavitary transducer (Siemens Accuson S3000, Siemens Healthineers, Erlangen, Germany) with 9–4 MHz range and 174 degree field of vision, capable of user selectable multi hertz imaging. Xylocaine gel was applied over a probe cover applied onto the probe. All patients were examined in the left lateral decubitus position. Prostate was imaged in both axial and sagittal planes with assessment of volume, echogenicity, surface, calcification, vascularity, and the presence of nodules. Each nodule was assessed for size, margins, location in the gland, morphology, and echogenicity.

Glands with homogeneous echotexture or minimal heterogeneity on TRUS were labeled as benign while those with ill-defined echotexture abnormality, focal bulge or hypoechoic mass were categorized as malignant. For Color Doppler (CD) imaging, capsular/periurethral flow and symmetric radial flow from capsular branches were considered benign while asymmetric or increased flow with disorganized pattern was labeled malignant.[11]

Using the same probe transrectal real-time strain elastography (RTE) of prostate was done by a single experienced radiologist. The probe was placed over the region such that the lesion is in the center of the image. Elastograms were obtained by slight compression and decompression of the prostate. The appropriate frequency and pressure of the compression/decompression was optimized with the help of real time display of quality index. Elastograms obtained with quality index equal to or >60 were only included. At least a 5 mm thickness of normal adjacent tissue was included, to assess the lesion stiffness in relation with the average elasticity of the surrounding tissue. A standardized color coding system was used, where red indicated soft, more compliant areas and blue indicated stiff areas. Green color indicated average strain in the region of interest. The elastograms along with conventional B-mode images were displayed side by side on split screen mode. Multiple frames were acquired and the best fit B mode-elastography image pairs were selected for examination. The elasticity patterns were scored using a five point scale proposed by Kamoi *et al*.[10] [Table 1] The cut off for malignancy was set between scores of 2 and 3 [Figures 1-4].

Sampling of the prostate was performed either in the sagittal or in the axial plane. Biopsies were taken using an 18 G biopsy gun under strict aseptic precautions. Extended core biopsy protocol (12 cores) was used. Additional targeted biopsy was carried out on suspicious areas identified by B mode US and elastography. The grade (degree of aggressiveness) of prostate cancer was evaluated on the basis of the Gleason score. No major complications were encountered after the procedure.

The findings of TRUS, Doppler and RTE were interpreted by consensus by two experienced radiologists who were blinded to patients' clinical profile and biopsy results. The histopathologic results were considered as the reference standard, and utility of RTE was evaluated.

Statistical analysis

Data was entered in the Statistical Package for Social Sciences version 24 (SPSS Inc., Chicago, IL, USA). Descriptive statistics was presented as mean ± standard deviation. Qualitative variables were presented in the form of frequency and percentages. The diagnostic sensitivity, specificity, positive predictive value (PPV) and negative predictive value (NPV) were calculated with histopathologic analysis as reference standard. For analyzing the combined diagnostic performance of tests, the test was considered positive if either of them was

Table 1: Sonoelastography scoring system proposed by Kamoi *et al*.

Elastography score	Description
Score 1	Normal - homogeneous strain
Score 2	Probably normal - symmetric heterogeneous strain
Score 3	Indeterminate - asymmetric focal stiff lesion which is not related to any hypoechoic area
Score 4	Probably carcinoma (strain at the periphery of the hypoechoic lesion with sparing of the center
Score 5	Definitely carcinoma (no strain in the entire hypoechoic lesion or in the surrounding area)

suspicious for malignancy and negative if neither showed suspicious features. Pearson Chi-square test was used to study the association between categorical variables. $P < 0.05$ was considered as statistically significant.

Results

The age of the patients ranged from 53 to 88 years (Mean: 69.16 ± 9.40 years). Serum PSA levels ranged between 4.3 and 178.6 ng/ml (Mean 48.54 ± 56.69 ng/ml). No Significant difference in PSA levels were noted between patients with carcinoma and benign lesions of the prostate ($P = 0.083$). In 60 patients, 784 biopsy cores were harvested out of which 720 was according to the extended core biopsy protocol and 64 were targeted (36 and 28 targeted to areas found suspicious on B-mode US and RTE, respectively). Histopathology revealed cancerous focus in at least one biopsy core in 28/60 (47%) patients. Gleason score ranged from 6 to 9 (Mean: 7.42 ± 1.13). Among the 32 patients with benign histopathology results, 20 (62.5%) were found to have benign prostatic hyperplasia and 12 (37.5%) had prostatitis. The mean prostatic volume was 38.20 ± 18.25 cm^3 (range: 8–89 cm^3). The mean age of patients with benign and malignant lesions were 66.78 ± 9.56 years and 71.89 ± 8.59 years, respectively ($P = 0.035$).

Out of the 60 patients, 28 (47%) were suspected of having prostate cancer by TRUS. The sensitivity, specificity, PPV, and NPV of TRUS in detecting prostate cancer were 78.57%, 81.25%, 78.57%, and 81.25%, respectively, with histopathology as reference standard. On CD evaluation 87.5% ($n = 28$) of benign lesions showed symmetric, radial flow compared to 14.3% ($n = 4$) of malignant lesions ($P < 0.0001$).

Table 2 shows the correlation of elastography scores and histopathologic diagnoses of lesions. Out of the 32 patients

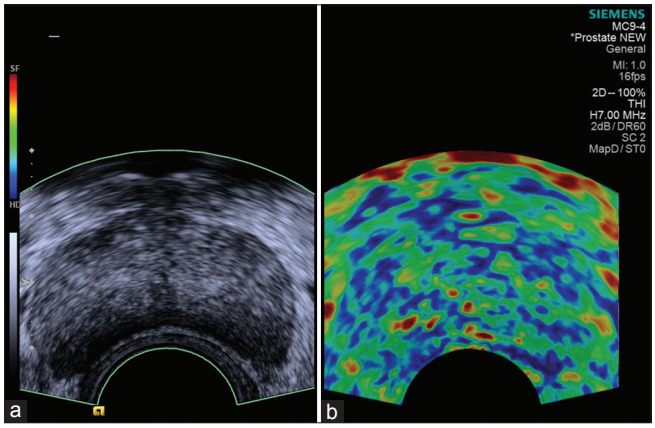

Figure 1: (a) Transrectal ultrasonography image showing mild enlargement of prostate. (b) Sonoelastography showing heterogeneous appearance with symmetrical mosaic pattern of green and blue (Score 2 – probably normal). Histopathology revealed hyperplasia of prostate with benign glandular pattern

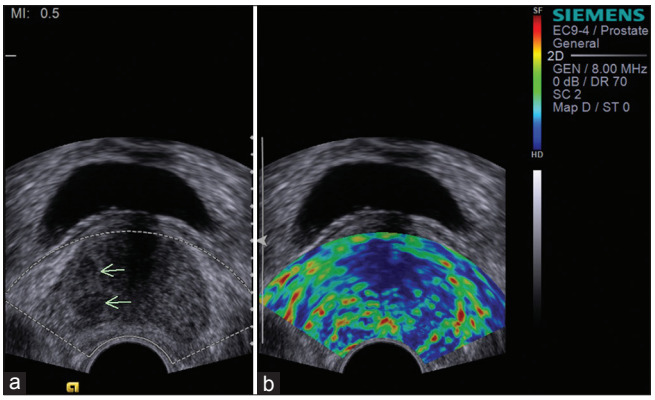

Figure 2: (a) Transrectal ultrasonography image showing hypoechoic lesion in the right peripheral zone (arrows) of prostate. (b) Sonoelastography showing focal asymmetric stiff lesion not related to hypoechoic area (score 3 – indeterminate). Histopathology was suggestive of adenocarcinoma prostate

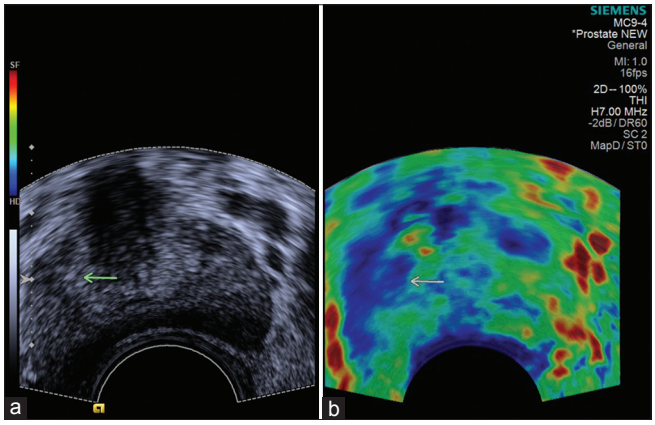

Figure 3: (a) Transrectal ultrasonography image showing hypoechoic lesion in the right peripheral zone (arrow) of prostate. (b) Sonoelastography showing stiffness in the center of the lesion and strain at the periphery; the peripheral part of lesion appears green and the central part appears blue (score 4 – probably carcinoma). Histopathology confirmed adenocarcinoma prostate

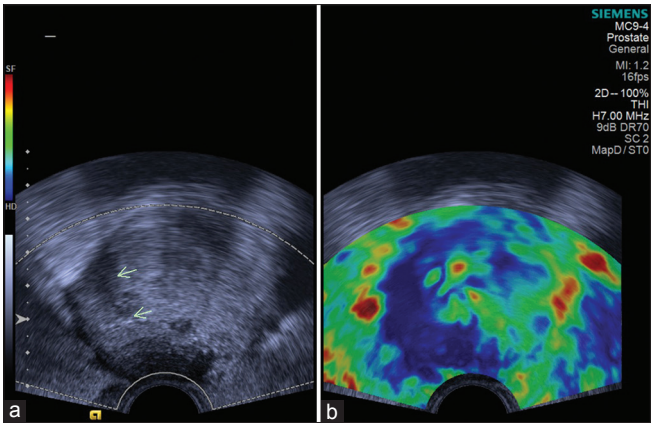

Figure 4: (a) Transrectal ultrasonography image showing hypoechoic lesion with irregular margin in the right peripheral zone (arrows) of prostate. (b) Sonoelastography showing stiffness in the entire hypoechoic lesion and in the surrounding area; the entire lesion appears blue (score 5 – definitely carcinoma). Histopathology confirmed adenocarcinoma prostate

with benign histopathology, 14 were judged as negative for malignancy at RTE. There were 3 false negative patients on elastography with score of 2. The sensitivity and specificity of RTE was 89.29% and 56.25% with positive and NPV of 58.13% and 82.35%, respectively. Higher elastography score was found to be significantly associated with malignant histopathology ($P = 0.004$).

Table 3 shows the relation between Gleason score and elastography scores. Approximately 84% of patients with a Gleason score ≤6 were detected by RTE whereas for scores 8–9, the detection rate was 100%.

The diagnostic performance of TRUS, combined modalities (TRUS and Doppler) and RTE are shown in Table 4.

Discussion

In this prospective study from South India, we evaluated the diagnostic performance of transrectal real-time elastography (RTE) in detection of prostatic cancer in patients with abnormal DRE and elevated PSA levels. RTE showed superior sensitivity of nearly 90% versus sensitivity of 79% by TRUS and 86% by a combination of TRUS and CD ultrasound.

Table 2: Correlation between elastography score and histopathologic diagnosis of lesions

Elastogram pattern	Benign ($n=32$)	Malignant ($n=28$)	Total ($n=60$)
1	0	0	0
2	14	3	17
3	18	4	22
4	0	9	9
5	0	12	12

Table 3: Relation between Gleason score and elastography scores

Gleason score	ES 1	ES 2	ES 3	ES 4	ES 5
≤6	0	1	0	2	3
7	0	2	2	6	2
8	0	0	0	1	1
9	0	0	2	0	6

ES: Elastography score

Table 4: Diagnostic performance of transrectal ultrasound, combined modalities (transrectal ultrasound and Doppler) and real-time strain elastography

Performance measure	TRUS	TRUS and doppler	RTE
Sensitivity (%)	78.57	85.71	89.29
Specificity (%)	81.25	75	56.25
Positive predictive value (%)	78.57	75	58.13
Negative predictive value (%)	81.25	85.71	82.35

TRUS: Transrectal ultrasound, RTE: Real-time strain elastography

Ever since the description of principles of elastography by Ophir *et al*., elasticity imaging has been applied to a wide variety of tissues such as breast, thyroid, liver, lymph nodes and prostate.[12]

The two US elastography techniques in clinical use are SE and shear wave elastography. Several studies have evaluated the utility of SE in diagnosing prostatic cancer and have shown varied results. While few have compared the diagnostic accuracy with needle biopsy of prostate,[13-15] others have used histopathologic examination of radical prostatectomy specimen as the reference standard.[8,9,16] The heterogeneous results can be attributed to the varied inclusion criteria, demographic characteristics of patients, serum PSA levels, location of tumors, reference standard, number of biopsy cores, systematic or targeted biopsies and Gleason score of the tumors examined.

The age of patients with malignancy of prostate was significantly higher compared to those with benign lesions in our study ($P = 0.035$). Age is considered to be an established risk factor for prostatic cancer and study of age-specific incidence curves have shown that risk of prostate cancer begins to rise sharply after 55 years of age and peaks at 70–74, declining slightly thereafter.[17]

In our study, TRUS revealed hypoechoic/focal lesions in 28 patients (47%). Out of these, 22 were confirmed as adenocarcinoma prostate while 6 turned out to be benign on histopathology. The results from our study in terms of specificity and PPV of TRUS in detecting prostatic cancer are similar to that of Ferrari *et al*. who had evaluated 84 patients suspected of prostatic cancer by TRUS, RTE and transperineal prostate biopsy.[18] B-mode US demonstrated 56% sensitivity, 80% specificity, 70% PPV and 67% NPV in diagnosing prostatic cancer. A hypoechoic lesion in the peripheral zone of prostate is suggested to be more likely malignant, the proposed cause being replacement of normal loose glandular tissue by a packed mass of tumor cells which results in fewer reflecting interfaces. Hyperplasia, prostatitis, fibrosis and cysts of prostate are other lesions that appear hypoechoic on TRUS.[19] Nearly 25%–40% of prostate cancers are isoechoic and missed by TRUS.[20]

CD and Power Doppler (PD) have been reported to be useful in detecting isoechoic tumors which may be missed by conventional ultrasound.[21,22] In 2 patients with prostatic cancer in our study, Doppler evaluation revealed asymmetric, increased flow while TRUS was not suspicious for malignancy. Few authors have shown that increased CD signal correlates positively with grading and staging of prostate cancer as well as risk of recurrence after treatment.[23,24]

On CD evaluation, 87.5% ($n = 28$) of benign lesions showed symmetric, radial flow compared to 14.3% ($n = 4$) of malignant lesions ($P < 0.0001$) in our study. A combination of TRUS and Doppler revealed superior diagnostic performance with sensitivity and NPV of nearly 86% compared to TRUS. However, benign lesions like prostatitis can also show

increased flow on CD and CD does not reveal microscopic vessels of prostatic cancer that do not possess enough flow to cause Doppler shift.[25,26] Despite these limitations, our findings indicate that CD imaging can be a useful adjunct to improve tumor detection by TRUS.

Prostatic cancer tends to be stiffer than benign lesions due to replacement of normal glandular tissue by neoplastic cells.[27] Stiffer tissues demonstrate less strain to deformation, and RTE helps in differentiation of benign and malignant tissues based on distribution of strain. Miyagawa *et al*. evaluated the usefulness of RTE in detecting prostatic cancer prior to systematic biopsy and have noted a diagnostic sensitivity of 72.6% for elastography and 89.5% for combination of TRUS and elastography.[14] Kamoi *et al*. used a five point subjective scale based on degree and distribution of strain in relation to hypoechoic area and found that RTE had 68% sensitivity and 81% specificity in detecting prostatic cancer. The combination of RTE with PD US further increased the sensitivity to 78%.[10]

Using the cutoff value of 3 (suggesting focal asymmetric lesion without strain unrelated to hypoechoic lesion) proposed by Kamoi *et al*., RTE was found to have sensitivity of 89.29% and specificity of 56.25% in our study. Of 43 patients with RTE findings suspicious for carcinoma, 25 were confirmed to be malignant on histopathology. Benign entities such as benign prostatic hyperplasia, adenomyomatosis, fibrosis and prostatitis can be associated with increased tissue stiffness and therefore may be difficult to distinguish from carcinoma prostate. This can be responsible for the relatively low specificity and PPV observed in our study. Because of the high frequency of false-positive results, RTE should be used in combination with TRUS to increase the detection rate.

In 5 of 28 patients with prostatic cancer (17.9%), B mode US was normal but RTE was suggestive of carcinoma. While systematic biopsy picked up malignancy in 3 patients, targeted biopsy based on RTE findings resulted in detection of cancer in 2 patients. The role of RTE targeted biopsy in detecting prostatic cancer has been reported by several authors. Pallwein *et al*. compared a 5-core RTE targeted biopsy with a 10-core systematic biopsy and concluded that cancer detection rate per patient was not significantly higher for targeted approach compared to systematic approach but an RTE targeted core was 2.9 fold more likely to be positive for cancer than a systematic core.[28] Salomon *et al*. analyzed the incremental detection rate of 4-core RTE targeted biopsy in addition to randomized 10-core in 1024 patients.[29] Additional use of RTE resulted in an incremental detection rate of 18.3%. 34 patients who harbored high-grade PCa (Gleason score ≥4) were diagnosed by RTE targeted biopsy only. A recent meta-analysis on the role of RTE targeted biopsy has shown that the detection rate of malignancy is enhanced when systematic biopsies are combined with RTE targeted biopsies.

Further RTE targeted biopsy can make a nearly equivalent diagnosis with fewer cores.[30]

In our study RTE detected 5 of 6 patients with prostatic cancer of Gleason score ≤6, 10 of 12 with score 7 and all with Gleason score 8 or 9. Our observations are similar to that of other authors who have noted that RTE detection rate of prostate cancer with higher Gleason score was greater than that of prostatic cancer with a lower Gleason score.[9,31] This might be explained by the greater cell density in high grade tumors resulting in stiffer tissue. In contrast, Tsutsumi *et al*. have noted a lower RTE detection rate for high grade tumors.[32]

Our study has few limitations. The sample size was small and no interobserver variability was studied since the RTE findings were interpreted by consensus. Another main limitation of RTE is that the degree of manual compression influences the elasticity image and may compromise diagnostic accuracy of RTE. However all examinations were performed by a single experienced radiologist and only images with optimal compression as displayed by the quality index were included in the study. Recent literature suggests that multiparametric MRI has greater sensitivity and specificity for detection of clinically significant prostate cancer.[33]

Although the incidence of prostatic cancer is low in Asian countries compared to the west, demographic and epidemiological transition in recent times have resulted in increase in the burden of various cancers including prostate in India. Prostate is reported to be the second leading site of cancer among males in several cities in India and cancer projection data estimate that the number of cases will become doubled by 2020.[34]

Conclusion

In this initial study from South India, RTE was found to have better sensitivity than TRUS as well as combination of TRUS and CD. With its greater sensitivity and NPV, RTE can be an effective adjuvant tool to guide biopsy and thereby increase the detection rate of prostatic cancer. Further prospective studies with larger sample size are needed before recommending RTE along with conventional TRUS for routine use in the evaluation of suspected prostatic malignancy in India.

Abstract

Background: The purpose of this study was to evaluate the usefulness of strain elastography and acoustic radiation force impulse (ARFI) imaging in the differentiation of benign and malignant cervical lymph nodes (LNs). **Materials and Methods:** In this prospective study, 50 enlarged cervical LNs (33 benign and 17 malignant) were examined by B-mode ultrasound (US), color Doppler, and strain elastography. Elastographic patterns (1–5) were categorized based on distribution of hard area within LN. The shear wave velocity (SWV) of LNs was evaluated by ARFI imaging. Diagnostic performance of sonoelastographic parameters was compared taking histopathology of LN as a reference standard. Optimal cutoff value of the mean SWV values for predicting malignancy was determined using receiver operating characteristic curve analysis. **Results:** Among US parameters, borders of LN had the highest diagnostic accuracy (80%), while echogenicity had the least (48%). Majority of benign LNs ($n = 31$) had elastography patterns 1 and 2, while majority of malignant LNs ($n = 16$) had patterns 3–5 ($P = 0.000$). The sensitivity, specificity, and accuracy of elastography were 94.1%, 93.9%, and 94%, respectively. The mean SWV of benign LNs (1.670 ± 0.367 m/s) differed significantly from malignant LNs (2.965 ± 0.826 m/s; $P = 0.000$). A cutoff value of 2.05 m/s predicted malignancy with 88.2% sensitivity and 84.8% specificity and gave an area under the curve of 0.949 (95% confidence interval: 0.70–1.20). **Conclusion:** Elastography has high diagnostic accuracy in differentiating benign and malignant cervical LNs and can be potentially useful in selecting the LN with high probability of malignancy, on which fine-needle aspiration cytology/biopsy can be performed.

Keywords: Acoustic radiation force impulse imaging, elastography, lymph nodes, ultrasound

Introduction

Cervical lymphadenopathy, a common condition encountered by physicians in clinical practice, could be caused by a variety of pathologic processes such as infections, vasculitis, and malignancies such as lymphoma and metastases. Metastatic cervical lymphadenopathy is a common problem in head and neck oncology. Depending on the primary site, up to 80% of patients with upper aerodigestive mucosal malignancy have been reported to have cervical nodal metastasis at presentation.[1] The differentiation of malignant from benign lymph nodes (LNs) is essential because it predicts the patient prognosis and helps in decision-making and planning of management.[2]

High-resolution ultrasound (US) is the extensively used imaging technique for evaluating the morphology and internal architecture of cervical LNs. Color Doppler sonography is used to assess the pattern of intranodal vessels, blood flow velocity, and vascular resistance.[3] Although Gray-scale sonography in combination with Doppler has been suggested to be useful in differentiating metastatic LNs from reactive ones based on various criteria, there is no single US criterion for diagnosing malignant LNs with satisfactory sensitivity and specificity.[4,5]

Real-time elastography (RTE) is a novel, noninvasive imaging modality that assesses tissue elasticity by comparing local tissue displacement from US signals before and after the application of a compressive force.[6] Stiff tissues show less deformation (strain) than soft tissues under the compression of a transducer. Since malignant tissues are stiffer than their benign counterparts at many

sites, several reports have documented the utility of US elastography in differentiating malignant from benign lesions in the breast, prostate, liver, thyroid, and cervix.[7-11] There are two types of elastography techniques, namely strain elastography and shear wave-based elastography. Recent studies have shown the usefulness of strain elastography in differential diagnosis of benign and malignant cervical LNs.[12-14] However, some authors have questioned its additional value over conventional US in predicting malignancy and decision-making in terms of selection of LNs for biopsy.[15-17] Shear wave elastography with acoustic radiation force impulse (ARFI) imaging is an emerging sonographic technique in the assessment of malignant cervical nodes.[18,19]

Data on the utility of elastography in the evaluation of cervical LNs are relatively few, especially from India. The purpose of the present study was to evaluate the utility and diagnostic performance of strain elastography compared to conventional B-mode US and color Doppler in the differentiation of benign and malignant cervical LNs. We also investigated the usefulness of ARFI imaging in differentiating benign and malignant LNs.

Materials and Methods

This prospective study was performed at a tertiary care center in South India between August 2016 and February 2018. Fifty LNs of 50 consecutive patients who were referred for ultrasonogram of enlarged cervical LNs were enrolled. The Institutional review board (IRB) approved the study protocol, and the protocol complied with the tenets of the Declaration of Helsinki (IRB Approval No. 16/334). Informed consent was obtained from all participants. Patients with suboptimal image quality and those with completely necrotic nodes without solid component were not included. Patients who had received specific treatment (chemotherapy/radiotherapy) were also excluded from the study.

High-resolution US imaging was performed in the supine position with a high-frequency linear probe 9 L4 (Siemens Accuson S3000, Siemens Healthineers, Erlangen, Germany) by a single expert radiologist, blinded to patient's clinical profile. In gray-scale US, the LNs were evaluated for short-axis diameter and short-to-long axis diameter ratio (S/L ratio) in the longitudinal plane, borders (regular or irregular), echogenicity (homogeneous/heterogeneous), and hilum (present or absent). Intranodal vascular pattern was evaluated using color Doppler imaging. Absent flow signals or blood flow limited to the hilum was categorized as benign. Nonhilar blood flow with spotted, peripheral, or mixed types of vascularization was categorized as malignant. RTE was performed for the targeted node using the same probe. Manual light compression and decompression of the target LN by the transducer were performed to achieve an optimal image. Patients were asked to hold their breath and avoid swallowing during the examination to minimize motion of LNs. The elastographic box contained the LN and adjacent sternocleidomastoid muscle for each patient. Elastograms obtained with quality factor score ≥60 were included in the study. Color map settings with red coded as hard area and blue coded as soft area were used. The images were displayed on split screen mode with US gray-scale images on the left and elastogram images on the right. The best-fit B-mode US elastogram image pairs were selected for analysis. The elasticity patterns were categorized on a 5-point scale described by Alam *et al*.[12] [Table 1]. LNs showing type 1 and 2 elastography patterns were considered benign, while those with types 3, 4, and 5 were categorized as malignant.

For ARFI imaging, the targeted LN on B-mode image was identified using a region of interest, characterized by a fixed box [Figures 1-5]. Three measurements of shear wave velocity (SWV) were performed, and the average was calculated. SWV was expressed in meter/second.

Table 1: Elastographic patterns of lymph nodes

Patterns	Description
1	Absent or very small hard area
2	Small, scattered hard areas, hard area <45% of LN
3	Hard area ≥45% of LN
4	Peripheral hard area and central soft area
5	Hard area occupying entire LN

LN: Lymph node

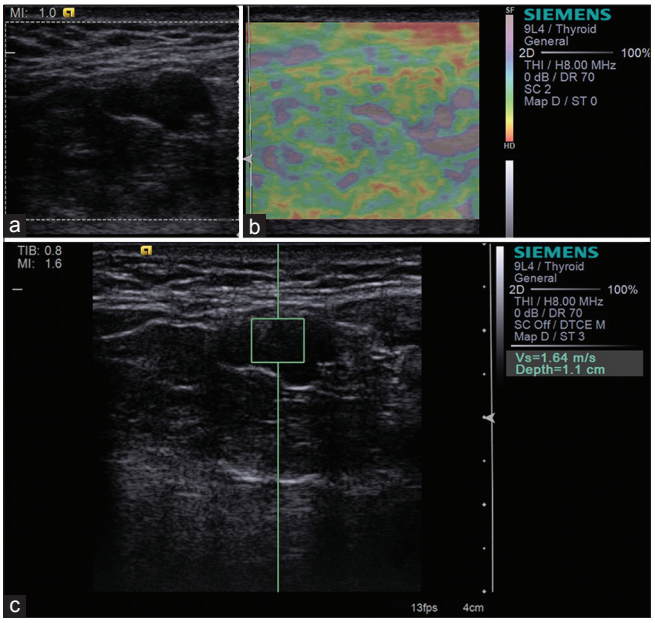

Figure 1: (a) B-mode ultrasound showing oval hypoechoic lymph node with irregular margins and absent hilum, (b) elastography image showing absent or very small hard area corresponding to pattern 1, and (c) acoustic radiation force impulse imaging shows a shear wave velocity of 1.64 m/s in the boxed area. Histopathology was suggestive of tuberculous lymphadenitis

[Downloaded free from http://www.jmuonline.org on Tuesday, December 17, 2019, IP: 10.232.74.23]

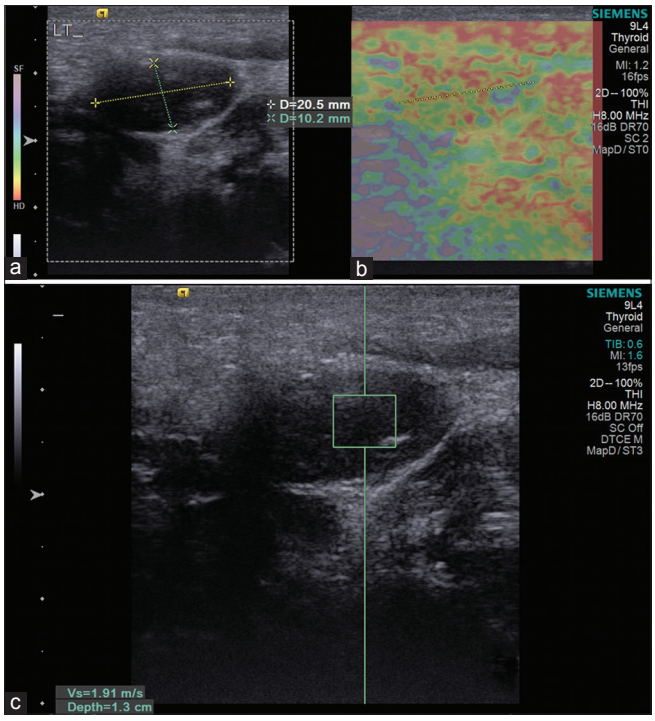

Figure 2: (a) B-mode ultrasound showing oval hypoechoic lymph node, (b) elastography image showing small, scattered hard areas corresponding to pattern 2, and (c) acoustic radiation force impulse imaging shows a shear wave velocity of 1.91 m/s in the boxed area. Histopathology was suggestive of reactive lymphadenitis

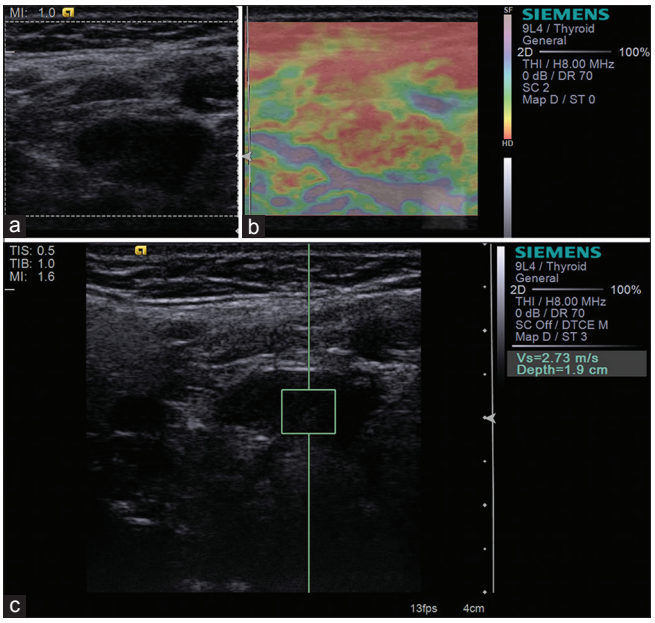

Figure 3: (a) B-mode ultrasound showing oval hypoechoic lymph node with loss of fatty hilum, (b) elastography image showing hard area ≥45% of lymph node corresponding to pattern 3, and (c) acoustic radiation force impulse imaging shows a shear wave velocity of 2.73 m/s in the boxed area. Histopathology revealed metastatic lymph node from carcinoma breast

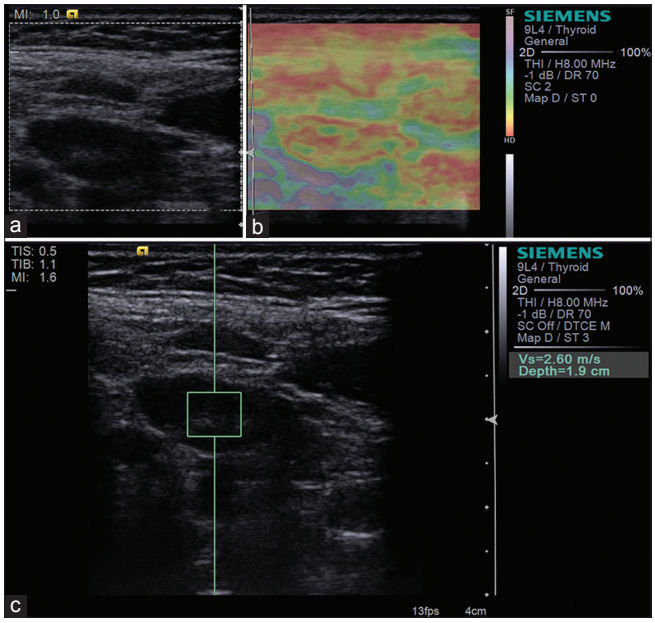

Figure 4: (a) B-mode ultrasound showing oval hypoechoic lymph node with loss of fatty hilum, (b) elastography image showing peripheral hard area and central soft area corresponding to pattern 4, and (c) acoustic radiation force impulse imaging shows a shear wave velocity of 2.60 m/s in the boxed area. Histopathology revealed metastatic lymph node from mucoepidermoid carcinoma parotid

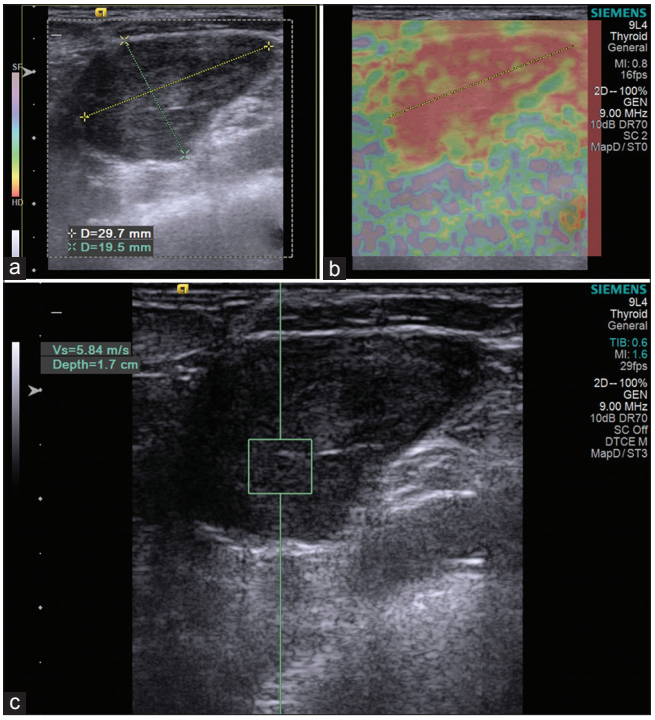

Figure 5: (a) B-mode ultrasound showing hypoechoic lymph node with irregular margins and absent hilum, (b) elastography image showing hard area occupying entire lymph node corresponding to pattern 5, and (c) acoustic radiation force impulse imaging shows a shear wave velocity of 5.84 m/s in the boxed area. Histopathology revealed metastatic lymph node from small cell carcinoma lung

Following elastography, all patients underwent surgical excision of the LN after cutaneous marking under US guidance. Histopathologic analysis of the LN was taken as the diagnostic standard of reference.

Statistical analysis

Statistical analysis was performed using the Statistical Package for Social Sciences version 24 (SPSS Inc., Chicago, IL, USA). Descriptive statistics was presented as mean ± standard deviation. Qualitative variables were presented in the form of frequency and percentages. Chi-square test was used to know the association between categorical variables. The diagnostic sensitivity, specificity, positive predictive value (PPV), negative predictive value (NPV), and accuracy were calculated with histopathologic analysis as reference standard. For analyzing the combined diagnostic performance of B-mode and Doppler, scores were assigned for five criteria: S/L ratio (ratio ≤0.5, score of 1: >0.5, 2), hilum (present, 1; absent, 2), borders (regular, 1; irregular, 2), echogenicity (homogenous, 1; heterogeneous, 2), and blood flow (hilar, 1; nonhilar, 2). The score for each LN was determined by adding the individual scores. A statistically supported cutoff line was set between scores 6 and 7. LNs with score <6 were categorized as benign, and 7–10 were categorized as malignant. Student *t*-test was performed to evaluate for significant difference in SWV values between benign and malignant LNs. A receiver operating characteristic (ROC) curve analysis was applied to obtain the optimal cutoff value for SWV to differentiate between benign and malignant LNs. Statistical significance was set at $P < 0.05$.

Results

The age of the patients ranged from 12 to 75 years (mean: 45.4 ± 16.9 years). About 52% (n = 26) were female and 48% (n = 24) were male. Of the 50 LNs examined, 33 (66%) were benign and 17 (34%) were malignant on histopathology. Of the 33 benign LNs, 27 had been reported as reactive and six as tuberculous lymphadenitis. Among the 17 malignant nodes, 15 were metastatic and two were due to lymphoma. Metastatic nodes were secondary to carcinoma lung, 4; parotid, 2; thyroid, 1; stomach, 1; breast, 1; poorly differentiated carcinoma from occult primary, 1; and head-and-neck squamous cell carcinoma, 5.

The US characteristics of the LNs and their diagnostic sensitivity, specificity, PPVs and NPV s, and accuracy are shown in Table 2. There were no significant differences between the benign and malignant LNs with respect to S/L ratio and echogenicity ($P = 0.273$ and $P = 0.623$, respectively). Hilum was found to be abnormal in all the 17 malignant LNs studied. Almost 81.8% of benign LNs (n = 27) had regular borders, whereas only 23.5% (n = 4) of malignant LNs had regular borders (P = 0.000). Among all B-mode parameters, borders of LN had the highest diagnostic accuracy (80%), while echogenicity was found to have the least accuracy (48%). On color Doppler evaluation, nearly 72% (n = 24) of benign nodes showed hilar flow compared to 35% (n = 6) of malignant nodes (P = 0.010).

Table 3 shows the correlation of elastographic pattern and histopathologic diagnosis of LNs. Majority of benign LNs (n = 31) had elastography patterns 1 and 2, while majority of malignant LNs (n = 16) had patterns 3–5. Higher elastographic pattern was significantly associated with malignant histopathology (P = 0.000).

The diagnostic performance of combined modalities (B-mode and color Doppler) and elastography is shown in Table 4.

The mean SWV of benign LNs was 1.670 ± 0.367 m/s. Metastatic LNs were significantly stiffer with mean SWV of 2.965 ± 0.826 m/s (P = 0.000). Figure 6 shows the ROC curve for SWVs measured using ARFI imaging in the differentiation of benign and malignant LNs. The best cutoff value for differentiating benign from malignant LNs was estimated to be 2.05 m/s with sensitivity of 88.2%, specificity of 84.8%, and area under the curve equal to 0.949 (95% confidence interval [CI]: 0.70–1.20).

Table 2: Ultrasound characteristics of lymph nodes and their diagnostic performance

US criteria	Benign LNs (n=33)	Malignant LNs (n=17)	Sensitivity (%)	Specificity (%)	PPV (%)	NPV (%)	Accuracy (%)
S/L ratio							
≤0.5	15 (45.4)	5 (29.4)	70.5	45.4	40	75	54
>0.5	18 (54.6)	12 (70.6)					
Hilum							
Present	22 (66.7)	0	100	66.6	60	100	78
Absent	11 (33.3)	17 (100)					
Borders							
Regular	27 (81.8)	4 (23.5)	68.4	87.1	76.4	81.8	80
Irregular	6 (18.2)	13 (76.5)					
Echogenicity							
Homogeneous	16 (48.5)	7 (41.2)	41.1	51.5	30.4	62.9	48
Heterogeneous	17 (51.5)	10 (58.8)					
Color Doppler							
Hilar	24 (72.8)	6 (35.3)	64.7	72.7	55	80	70
Nonhilar	9 (27.2)	11 (64.7)					

US: Ultrasound, LNs: Lymph nodes, S/L ratio: Ratio of short-axis diameter to long-axis diameter, PPV: Positive predictive value, NPV: Negative predictive value

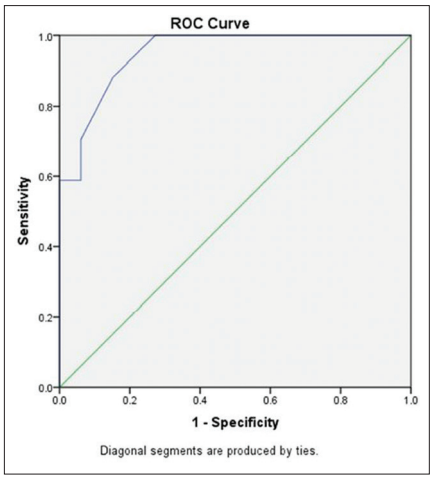

Figure 6: Receiver operating characteristic curve for shear wave velocities measured using acoustic radiation force impulse imaging in the differentiation of benign and malignant lymph nodes. The area under the curve was 0.949

Discussion

In this prospective study from India, we evaluated the performance of RTE in classification of benign and malignant cervical LNs. Our results indicate that RTE has a high specificity and diagnostic accuracy for identification of malignant LNs.

Although B-mode US is the most extensively used method for classification of cervical LNs because of its noninvasiveness and easy accessibility, specific criteria for distinguishing benign and malignant LNs are yet unclear. The association of signs often produces a highly suggestive appearance in most cases. In our study, the accuracy rate in distinguishing benign and malignant LNs was greatest for borders of LN (80%) and least for echogenicity (48%).

There were no significant differences between the benign and malignant LNs with respect to S/L ratio in our study. In contrast, several studies have noted S/L ratio >0.5 or a rounded shape to be associated with malignancy.[12,20] However, shape of LN can be misleading as nodes in nonmalignant conditions such as tuberculosis and Rosai–Dorfman disease have also been described as round.[21]

Our criterion of regular versus irregular borders revealed a diagnostic accuracy of 80%. Some other studies have categorized the LN borders as sharp and unsharp.[22,23] In a study by Khanna *et al*. from India, irregular margins were found in 7% of reactive LNs versus 55% of metastatic and 66% of tubercular nodes.[24] The absence of visible hilum due to replacement or effacement is considered as an important criterion for malignant LNs and has been reported by several authors.[12,13,25] In our study, all the 17 malignant LNs had no visible hilum, thus showing 100% sensitivity and NPV.

We observed a statistically significant difference in the vascular patterns between benign and malignant LNs ($P = 0.010$). Our observations can be comparable to that of Misra *et al*. and several other authors who have noted significant difference in vascularity between benign and malignant LNs.[13,26] In our study, the accuracy of vascularity of LN in predicting malignancy was 70%.

Table 3: Correlation of elastographic pattern and histopathologic diagnosis of lymph nodes

Elastogram pattern	Benign ($n=33$)	Malignant ($n=17$)	Total ($n=50$)
1	5	0	5
2	26	1	27
3	1	2	3
4	1	4	5
5	0	10	10

Table 4: Diagnostic performance of elastography and combined evaluation (B-mode and color Doppler)

Performance measure	Elastography	Combined B-mode and Doppler
Sensitivity (%)	94.1	94.1
Specificity (%)	93.9	81.2
PPV (%)	88.9	72.7
NPV (%)	96.9	96.4
Accuracy (%)	94	86

PPV: Positive predictive value, NPV: Negative predictive value

Even though combined B-mode US and Doppler could be potentially useful in differentiating reactive from malignant LNs, this modality may not have definite diagnostic value because of some overlapping sonographic appearances of benign and malignant nodes. Fine-needle aspiration cytology (FNAC) in the evaluation of cervical LNs has been reported to have a sensitivity of 82% and specificity of 97%.[27] However, FNAC is invasive and does not always provide a conclusive diagnostic result. Core needle biopsy from cervical LNs is also difficult owing to their relatively small size and potential injury to adjacent vascular structures.

RTE being noninvasive, has been suggested to be an adjunctive imaging tool to conventional US and could potentially reduce unnecessary biopsies.[28] Few prospective and retrospective studies concerning strain elastography of cervical LNs have been published in the literature.[29] While some have performed the measurement of elasticity scores (ES), some have measured both ES and strain ratio.

In our study, we used a 5-point scale described by Alam *et al*. to categorize the elasticity patterns. Accordingly, LNs showing types 1 and 2 elastography pattern were considered benign, while those with types 3, 4, and 5 were categorized as malignant. Nearly, 93.9% of benign LNs ($n = 31$) had a score of 1 or 2, while 94.1% of malignant LNs ($n = 16$) had a score of 3–5. The sensitivity, specificity, and accuracy of elastography were 94.1%, 93.9%, and 94%, respectively.

[Downloaded free from http://www.jmuonline.org on Tuesday, December 17, 2019, IP: 10.232.74.23]

Alam *et al*. evaluated 85 cervical LNs (53 metastatic and 32 reactive) using 5-point elasticity scale and documented 83% sensitivity, 100% specificity, and 89% accuracy in differentiating metastatic from reactive LNs.[12] Bhatia *et al*. evaluated 74 cervical LNs (37 malignant and 37 benign) using RTE.[17] Dynamic cine loops of elasticity imaging were qualitatively scored on a 4-point elasticity scale by three independent observers. Median ES for benign and malignant nodes was 2 and 3, respectively. A cutoff ES score of ≥2 achieved only 62.2% sensitivity, 83.8% specificity, and 73% accuracy for malignancy. Fair to good interobserver agreement was noted in their study.

Higher accuracy rates observed in our study can be attributed to the fact that there were very few cases of lymphoma ($n = 2$) and tuberculous adenitis ($n = 6$) in our study. Lymphomas have been reported to show low stiffness from an elastographic point of view because of the large size and homogeneous structure of LNs which can produce false-negative results for malignancy.[30] Granulomatous lymphadenitis associated with tuberculosis may demonstrate calcification, scarring, or necrosis and therefore show areas of greater stiffness (false positive).[14]

Ying *et al*. performed a meta-analysis to evaluate the performance of RTE for diagnosis of malignant LNs.[29] Nine studies including 835 LNs were analyzed. The pooled sensitivity and specificity for ES in diagnosing malignant LNs were 74% (95% CI: 66%–81%) and 90% (95% CI: 82%–94%), respectively.

In the present study, we were able to obtain greater specificity, PPV, and accuracy with RTE than conventional US and Doppler for detecting malignant LNs from diverse primary sites. Hence, RTE with its fairly high specificity and diagnostic accuracy can reduce unnecessary invasive procedures for diagnosis of malignant LNs. However, it cannot replace the conventional B-mode US and Doppler because it is dependent on the machine as well as operator's expertise since excessive compression can cause nonaxial displacement and change the tissue stiffness. This in turn can affect the accuracy of the software's correlation algorithms. Furthermore, elastography is not useful for calcified LNs and those with cystic degeneration.

Relatively, few clinical studies have evaluated ARFI in the assessment of malignant cervical LNs.

In our study, ARFI imaging revealed higher SWV for malignant LNs than benign ones. The cutoff value of 2.05 m/s had sensitivity of 88.2% and specificity of 84.8% in identifying malignant LNs. Our results are comparable to that of Fujiwara *et al*. who evaluated SWVs of 42 cervical LNs using ARFI.[31] Of the numerous cutoff values tested, a SWV cutoff value of 1.9 m/s best distinguished between reactive and malignant LNs. Their criterion of SWV >1.9 m/s had 95.0% sensitivity and 81.8% specificity. According to a recent meta-analysis of nine ARFI imaging studies that included 1084 LNs, the pooled sensitivity and specificity values for detecting malignancies were 87% (95% CI: 83%–91%) and 88% (95% CI: 82%–92%), respectively.[19]

Our study has few limitations. The sample size was small, and only enlarged LNs were included. Strain elastography using free hand compression is dependent on the compression technique, and excessive compression can alter tissue stiffness. A single expert radiologist performed all the elastograms, and no interobserver variability was studied. However, studies have reported fair to almost perfect interobserver agreement in strain elastography.[6]

Head-and-neck cancers account for nearly one-third of the cancer burden in India, and it is a well-known fact that status of cervical LN is the single most important prognostic factor in squamous cell carcinoma of the head and neck.[32] To the best of our knowledge, this is the first study from India to document the diagnostic performance of elastography in evaluation of cervical lymphadenopathy, and it has shown encouraging results.

Conclusion

Elastography has high diagnostic accuracy in differentiating benign and malignant cervical LNs and can be an effective noninvasive adjunctive tool in the evaluation of cervical lymphadenopathy. It is potentially useful in selecting the LN with high probability of malignancy, on which FNAC/biopsy can be performed, thereby reducing sampling errors. ARFI imaging can be a useful technique for differentiating benign from malignant cervical LNs.

Utility of Ultrasound Strain Elastography to Differentiate Benign from Malignant Lesions of the Breast

Vikrant Kanagaraju*, B. Dhivya, B. Devanand, V. Maheswaran

Department of Radiology, PSG Institute of Medical Sciences and Research, Coimbatore, Tamil Nadu, India

Abstract

Background: The purpose of this study was to determine the utility and diagnostic performance of strain elastography (SE) in differentiating benign from malignant lesions of the breast. **Materials and Methods:** In this prospective study, 50 palpable breast masses in 50 patients were examined by mammography, B-mode ultrasound (US) and SE. Lesions were categorized using Breast Imaging Reporting and Data System (BIRADS) scoring based on mammographic and sonographic features. Elasticity scores were assessed on a five-point scale based on the distribution of strain, and the lesion size on SE imaging and B-mode (elasticity imaging/B mode [EI/B] ratio) was compared. Findings were correlated with the BIRADS assessment and diagnostic performance of sonoelastography was evaluated taking histopathology as reference standard. **Results:** Histopathology revealed 29 (58%) malignant and 21 (42%) benign lesions. Infiltrative ductal carcinoma and fibroadenoma were the most common malignant and benign lesions, respectively. The sensitivity, specificity, positive predictive value, negative predictive value, and accuracy of SE was 100%, 76.1%, 85.2%, 100%, and 90%, respectively. Higher elasticity score was significantly associated with malignant histopathology ($P < 0.00001$). The mean EI/B ratio for malignant lesions was 1.36 ± 0.24 while that of benign lesions was 1.03 ± 0.30 ($P = 0.000$). **Conclusion:** Real-time SE of the breast, with its superior sensitivity and specificity, could provide improved characterization of benign and malignant breast masses compared with mammography and conventional US. Due to greater diagnostic accuracy, SE can be an effective adjunctive tool to B-mode US in predicting malignancy of breast, as well as in reducing the need for biopsies in benign breast lesions.

Keywords: Breast, elasticity imaging technique, sonoelastography

Introduction

Breast cancer is the most common malignancy in women all over the world and continues to remain a leading cause of cancer-related death in females. The incidence of breast cancer has been increasing steadily in both developing and developed countries.[1] Increased life expectancy, urbanization, changes in lifestyle, and delay in diagnosis contribute to the increasing incidence as well as mortality in the low- and middle-income countries. Early detection is critical to improve the breast cancer outcome and survival.

Current imaging techniques available for screening of breast cancer include mammography, ultrasonography, and magnetic resonance imaging (MRI). Although mammography is the current standard breast screening technique, its sensitivity is reduced in high-density breast tissue, in smaller tumors, and in young women.[2] Breast ultrasonography is widely used in the evaluation and categorization of breast lesions, owing to its high sensitivity. However, inability to image deeper lesions, limited ability to distinguish isoechoic lesions from surrounding fat, low specificity and increased biopsy rates resulting in patient discomfort and anxiety are some potential limitations of breast ultrasound (US).[3] Even though MRI is useful for screening of subjects with high breast cancer risk, its use for routine screening is limited because of high cost, time consumption and lack of widespread availability as well as need for experienced radiologists.

US elastography (USE) is a noninvasive imaging modality complimentary to US that detects tissue elasticity by the

application of an external stress. As malignant tissues are firmer than benign ones, the estimate of tissue stiffness by USE can aid in the differentiation between benign and malignant lesions. Recent studies have reported the utility of USE in the characterization of lesions in various tissues, such as thyroid, liver, prostate, lymph nodes, and breast.[4-8] It has been suggested that current elastography systems can evaluate histological information by depicting the distribution of tissue stiffness or strain which might have the potential to predict the therapeutic effect of treatment with anticancer agents.[9]

Published literature on the usefulness of strain elastography (SE) in the evaluation of breast lesions and its correlation with histopathology is limited, especially from India. The purpose of this study was to determine the utility and diagnostic performance of SE in differentiating benign from malignant lesions of the breast with histopathology as the reference standard.

Materials and Methods

This prospective study was conducted at a tertiary care center in South India from December 2014 to December 2017. The institutional review board approved the study protocol, and the protocol complied with the tenets of the Declaration of Helsinki. Informed consent was obtained from all participants. Fifty consecutive female patients aged 40 years and above referred to the department of radiology for the evaluation of palpable breast lump and sonography-guided biopsy were included in the study. Exclusion criteria consisted of those with cystic lesions of breast, history of prior biopsy, postsurgical status, prosthetic breast implants, and subcentimeter lesions. All patients underwent mammography, B-mode US, and SE followed by US-guided biopsy in the same session. All examinations and biopsy were performed by a single expert radiologist with over 10 years of experience in sonography.

Mammography was performed with SIEMENS MAMMOMAT 3000. Mediolateral oblique and craniocaudal views were taken in all patients, and in addition, coned-down or magnification views were used when necessary.

Ultrasonography of the breast was performed with SIEMENS ACUSON S3000 using high-frequency probe 18 L6. Sonographic features studied included size of the lesion, shape, margins, orientation, internal echogenicity, vascularity, calcification, and posterior acoustic shadowing. The lesions were categorized using the Breast Imaging Reporting and Data System (BIRADS) scoring based on mammographic and sonographic features as the following categories – category 2: benign; category 3: probably benign; category 4: suspicious for malignancy; and category 5: highly suggestive of malignancy.[10] BIRADS category 1 lesion was excluded from the study. Categories 2 and 3 were considered negative for malignancy and categories 4 and 5 were labeled as malignant.

SE of the breast was performed using the same probe in the supine position. The probe was placed over the region such that the lesion was at the center of the image. Holding the scan plane perpendicular to the skin surface, a slight compression–decompression movement was applied. The appropriate pressure and frequency of compression/decompression were optimized with the help of real-time display of quality index. Elastograms with quality index equal to or greater than 60 were included. The region of interest (ROI) included the lesion with subcutaneous layers and pectoralis muscle. It was ensured that the target tissue occupied no more than 25% of the total area of ROI. At least 5 mm thickness of normal adjacent tissue was included to assess the lesion stiffness in relation with average elasticity of surrounding tissue. Color map settings with blue coded as hard area and green coded as soft area were used. The images were displayed on a split screen mode with B-mode images on the left and elastographic images on the right. The best fit B-mode elastographic image pairs were selected for analysis. [Figures 1-4] The longest dimension of the lesion on elastographic image was compared with that of the corresponding B-mode image, and elasticity imaging/B mode ratio (EI/B ratio) was calculated.

The elasticity patterns were scored using the TSUKUBA scoring system [Table 1] described by Itoh *et al*.[11] The elasticity scores 1, 2, and 3 were considered benign, while scores 4 and 5 were labeled as malignant.

Biopsy of the lesion was performed under US guidance using an 18G tru-cut needle. Histopathology results were taken as the reference standard.

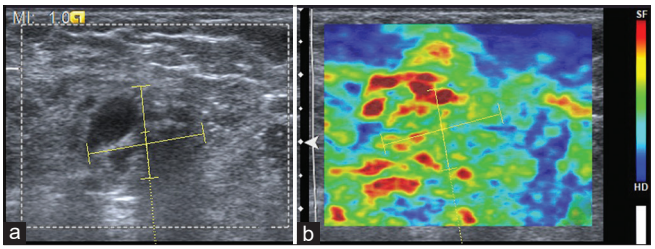

Figure 1: (a) B-mode ultrasound showing ill-defined hypoechoic lesion which was categorized as Breast Imaging Reporting and Data System category 4. (b) With strain elastography, entire hypoechoic lesion is deformable and evenly shaded green as surrounding breast tissue, corresponding to elasticity score 1. Histopathology was suggestive of nonspecific mastitis

Table 1: TSUKUBA elasticity score

Elasticity score	Description
1	Even strain in the entire lesion
2	Parts of the hypoechoic lesion does not show strain
3	Periphery of the hypoechoic lesion shows strain, no strain at the center
4	Entire lesion shows no strain
5	Entire lesion and surrounding area shows no strain

Statistical analysis

Statistical analysis was performed using Statistical Package for the Social Sciences (SPSS, SPSS Inc., Chicago, IL, USA) version 24. Descriptive statistics was presented as mean ± standard deviation. Qualitative variables were presented in the form of frequency and percentages. Chi-square test was used to know the association between categorical variables. The diagnostic sensitivity, specificity, positive predictive value (PPV), negative predictive value (NPV), and accuracy were calculated using 2 × 2 tables with histopathological analysis as the reference standard. Statistical significance was set at $P < 0.05$.

Results

Patients were aged between 40 and 72 years (mean: 48.96 ± 7.52 years). The mean age of the patients with benign and malignant lesions was 45.4 ± 5.47 and 51.5 ± 7.84 years, respectively ($P = 0.001$). On histopathological evaluation, 29 (58%) were found to be malignant and 21 (42%) were benign. Infiltrative ductal carcinoma and fibroadenoma were the most common malignant and benign lesions, respectively. Of the 29 malignant lesions, 17 (59%) were infiltrative ductal carcinoma, 11 (38%) were invasive lobular carcinoma and 1 (3%) was mucinous carcinoma. Among the 21 benign lesions, 7 (33%) were fibroadenoma, 4 (19%) were atypical ductal hyperplasia, 3 (15%) were breast abscess, 2 (9%) were sclerosing adenosis, and 2 (9%) were nonspecific mastitis. Granulomatous mastitis, complex cyst, and benign phyllodes tumor accounted for 1 (5%) each.

Mammography of 14 patients (28%) did not show any demonstrable lesion due to dense breast with predominantly fibroglandular tissue. 41% of the malignant lesions (12/29) had spiculated appearance on mammography, and microcalcification was encountered in 34% (10/29). 14% (4/29) showed architectural distortion.

Based on the BIRADS assessment, three were assigned BIRADS category 3, 18 were assigned category 4, and 29 were assigned category 5. The sensitivity, specificity, PPV, NPV, and accuracy of BIRADS assessment were 96.5%, 9.5%, 59.5%, 66.6%, and 60%, respectively, with histopathology as the reference standard.

Qualitative SE using elasticity scores had a sensitivity of 100% and specificity of 76.1% in detecting malignancy. The PPV and NPV were 85.2% and 100%, respectively, with diagnostic accuracy of 90%. Higher elasticity score was significantly associated with malignant histopathology ($P < 0.00001$). The mean EI/B ratio for malignant lesions was 1.36 ± 0.24 while that of benign lesions was 1.03 ± 0.30 ($P = 0.000$). Table 2 shows the correlation between histopathology, BIRADS assessment, and elasticity scoring among the lesions.

Discussion

In this prospective study, we evaluated the diagnostic performance of SE in predicting malignancy in lesions of breast. Qualitative SE with elasticity scoring was found to have a superior sensitivity, specificity, and diagnostic accuracy compared to conventional BIRADS assessment.

USE estimates the stiffness of tissues based on the degree of deformation of a tissue in response to an externally applied force. SE is a qualitative technique that uses either manual compression or an acoustic radiation force impulse push pulse to deform tissues.

Several authors have reported the additional value of SE to improve the specificity of conventional US in the differentiation

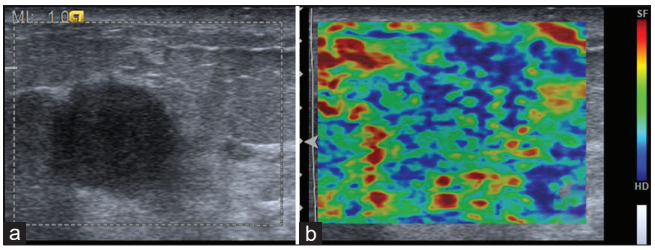

Figure 2: (a) B-mode ultrasound showing poorly marginated round hypoechoic lesion categorized as Breast Imaging Reporting and Data System category 3. (b) Strain elastographic image showing deformability of the peripheral portion of the lesion with stiff tissue in the center corresponding to elasticity score 3. Histopathology was suggestive of fibroadenoma

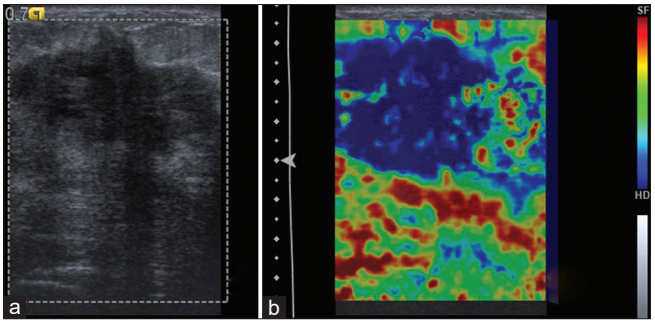

Figure 3: (a) B-mode ultrasound showing ill-defined hypoechoic lesion categorized as Breast Imaging Reporting and Data System 4. (b) With strain elastography, entire lesion is stiff, corresponding to elasticity score 4. Histopathology was suggestive of calcified fibroadenoma

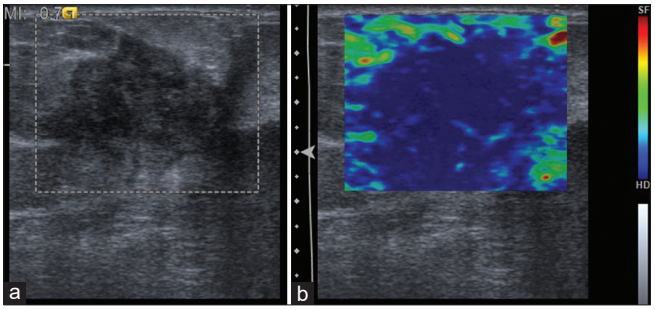

Figure 4: (a) B-mode ultrasound showing ill-defined hypoechoic lesion categorized as Breast Imaging Reporting and Data System 5. (b) With strain elastography, entire lesion and surrounding area are stiff, corresponding to elasticity score 5. Histopathology was suggestive of infiltrative ductal carcinoma

Table 2: Correlation between histopathology, Breast Imaging Reporting and Data System assessment and elasticity scoring among the lesions

Histopathology	BIRADS category	Elasticity score					Total (n=50)
		1	2	3	4	5	
Benign	3			2			2
	4	1	1	8	1	2	13
	5	1	1	2		2	6
Malignant	3					1	1
	4					5	5
	5					23	23

BIRADS: Breast Imaging Reporting and Data System

of benign and malignant breast masses and decrease the need for biopsies. While few have used EI/B ratio,[12] others have used five-point color scale and strain ratio[13,14] in the interpretation of SE images of the breast. However, the superior diagnostic performance of SE over B-mode US is controversial and factors such as operator experience, use of varied cutoffs, tumor size, and histologic subtype have been shown to influence the outcome.[15,16] Elasticity scoring had a sensitivity of 100% and specificity of 76.1%% in detecting malignancy among breast lesions in our study. The mean size of benign and malignant lesions was 17.06 ± 3.7 and 16.77 ± 3.1 mm, respectively. No significant difference in size was noted between benign and malignant lesions (P = 0.767). The superior diagnostic performance observed in our study can be attributed to the fact that most of the lesions (40/50) were smaller than 2 cm in size. Giuseppetti *et al*. have reported a better diagnostic performance of elastosonography in lesions smaller than 2 cm.[15] This is because a larger lesion has more chances of having hemorrhage or necrosis which might alter the tissue stiffness inside the lesion. Parajuly *et al*., based on their experience, have observed that lesions more than 5 cm should not be recruited in a study.[17]

Our results are comparable to that of Schaefer *et al*. and Atabey *et al*., who evaluated the performance of SE in breast lesions using a five-point scoring system.[18,19] With a cutoff between elasticity scores 3 and 4, elastography provided higher sensitivity and NPV. The authors have concluded that elastography can be an effective adjunct imaging modality in differential diagnosis of breast lesions, before the decision to biopsy a lesion in certain cases.[19]

In our study, 34 lesions were categorized as malignant on SE. Among these, 85% (29/34) were confirmed as malignancy on histopathology. Five benign lesions which had been categorized as malignant on SE were fibroadenoma (1), atypical ductal hyperplasia (3), and sclerosing adenosis (1) associated with calcification, which might have increased the stiffness of lesion. The false-positive rate was 23.8% in our study. In contrast, Zhi *et al*. have noted a false-positivity rate of 4.3% with SE in their study. Calcification and organized hemorrhage in benign lesions were responsible for false-positive diagnoses on SE.[3]

All the lesions with elasticity score less than or equal to 3 turned out to be negative for malignancy in our study. There were 13 benign lesions that presented as BIRADS category 4 necessitating biopsy. With a cutoff between 3 and 4 on SE, 10 of these 13 (76.9%) were true negatives on SE. Our observations are in line with recent literature, suggesting that SE can be useful in downgrading BIRADS category 4 lesions and reduce benign biopsy rates.[20]

Seven out of 18 BIRADS category 4 lesions and 25/29 BIRADS category 5 lesions had elasticity score 5. Among these, 87.8% turned out to be malignant, suggesting that elasticity scoring can be a useful predictor of malignancy. Satake *et al*. evaluated the ability of sonoelastography in predicting malignancy in breast masses classified as BIRADS category 4 or 5. Elasticity score was found to be a significant predictor of malignancy in BIRADS 4 masses (P = 0.002). However, elasticity score was not a significant predictor of malignancy in BIRADS category 5 lesions.[21]

A recent meta-analysis by Gong *et al*. on real-time elastography (RTE) in the differentiation of benign and malignant lesions of the breast that included 22 studies evaluating 4713 breast nodules reported an overall mean sensitivity and specificity of 0.834 and 0.842, respectively for elasticity scoring.[22] The authors have stated that RTE has high sensitivity and specificity in differentiating benign from malignant lesions and therefore can potentially reduce unnecessary breast biopsies. The mean EI/B ratio for malignant lesions was 1.36 ± 0.24 while that of benign lesions was 1.03 ± 0.30 (P = 0.000, P < 0.00001) in our study. Several studies have shown that tumors appear larger on elastography than on B-mode US.[23,24] A cutoff value of less than 1 for benign lesions and greater than or equal to 1 for malignant lesions has been shown to have high sensitivity and specificity for the characterization of lesions.[12] The variable dimension in elastography has been attributed to the desmoplastic reaction occurring in many cancers of the breast. Malignant lesions have been reported to appear significantly larger on strain imaging presumably because strain is uniquely sensitive to desmoplasia surrounding the lesion.[25]

Our study has few limitations. The sample size was limited and a single experienced radiologist performed all the examinations. SE is an operator-dependent technique and steady compression is needed for optimal images. However, in our study only images with optimal compression as displayed by the quality index were included. Intra- or inter-observer variability was not taken into account.

To the best of our knowledge, this is the first study on the utility of SE among the Indian population. The cancer projection data from India show that the number of breast cancer cases will become almost double by 2020.[26] Owing to the fact that the density of Indian breasts is different from that of the Western population[27] and density of breast parenchyma

can significantly influence the diagnostic performance of elastography, there is a need for more studies from this part of the world.

Conclusion

In this initial study from India, we conclude that real-time SE of the breast, with its superior sensitivity and specificity, could provide improved characterization of benign and malignant breast masses compared with mammography and conventional US. Due to greater diagnostic accuracy, SE can be an effective adjunctive tool to B-mode US in predicting malignancy of breast as well as decreasing unnecessary biopsies in clinical practice.

Analysis of different pathologies presenting as acute abdomen and performance of MDCT in making the diagnosis with clinical, intra-operative and histopathology correlation

Maheswaran Viyannan, Sucharitha Periyasamy and Balalakshmoji Devanand

DOI: http://dx.doi.org/10.33545/26644436.2020.v3.i1a.56

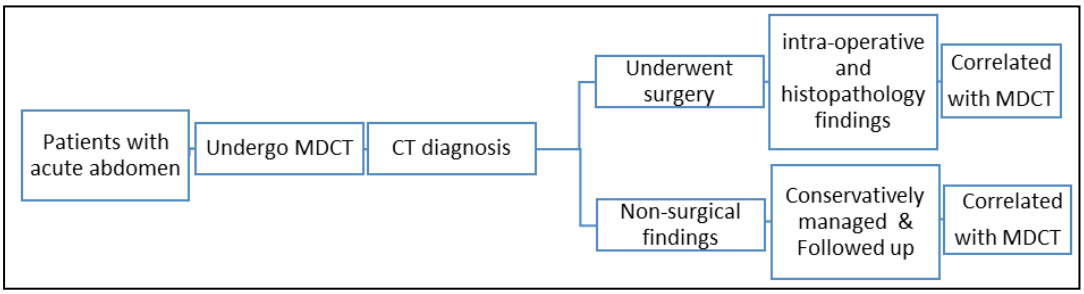
Abstract
Background: Acute abdomen is one of the most common emergencies presenting in the emergency room which requires immediate attention. Making an accurate diagnosis is of paramount importance in managing these patients, since most of these patients frequently require a surgical intervention. The divergence of patient population and the underlying pathology in acute abdomen calls for high quality imaging studies to make quick and precise diagnosis. Multi-detector computed tomography is an ideal tool in this regard.
Materials and Methods: It is a prospective study conducted on 73 patients who presented with acute abdomen and subsequently underwent multi-detector computed tomography to ascertain the underlying pathology. The radiological findings in computed tomography were correlated with clinical, intra-operative and histopathological findings whenever available.
Results: In our study the performance of multi-detector computed tomography, when compared with diagnosis made based on intra-operative findings, post-operative histopathology and clinical findings showed sensitivity of 97% and specificity of 75%. Overall Positive Predictive value of 98.5% and negative predictive value of 60% and accuracy of 96%.
Conclusion: Since most of the patients presenting with acute abdomen have non-specific and overlapping clinical findings, making an accurate clinical diagnosis is challenging. In this scenario MDCT comes as a handy tool with high accuracy and good sensitivity and specificity. The results obtained in our study are comparable with other studies conducted worldwide.

Keywords: Acute abdomen, MDCT performance, acute abdominal pain

Introduction
Acute abdomen is a clinical entity in which patients present with sudden onset of intense abdominal pain necessitating emergency medical/surgical management [1]. Majority of these patients present to the emergency department. The underlying pathology in acute abdomen could be anything ranging from acute inflammatory conditions involving the appendix, gallbladder, pancreas to non-specific pain usually associated with mesenteric adenitis, especially in children. In a given patient there are numerous differential diagnoses and making a single specific diagnosis is seldom seen and it is very difficult, given the overlap of presenting symptoms and clinical examination findings in various pathologies. Further evaluation with laboratory blood tests and radiological investigations is part of management of these patients.

Patients presenting with acute abdomen are in severe pain and very sick. Hence it is essential to make a prompt and accurate diagnosis in these patients [2]. Most of these patients are initially evaluated with abdominal radiograph and ultrasound. The role of these basic radiological investigations is limited by various factors. Major limiting factors are two dimensional nature of radiographs. In ultrasound limiting factors are inability of the patient to cooperate for the study due to severe pain, thick body habitus of the patient, excessive bowel gas and lack of adequately filled urinary bladder. However radiograph has fairly good specificity in diagnosing pneumoperitoneum. It gives useful information in only in less than 50% of patients [2].

Ultrasound has its own advantages. It is cheap, easily available, no need to administer contrast and it is free of ionizing radiation, hence better suited for children and pregnant women. Ultrasound is a valuable tool in the assessment of pathology related to gallbladder and acute ureteric colic, especially when the obstruction is at the vesico-ureteric junction, which is by far the most common site.



Though these basic radiological investigations do indeed provide valuable information, in a good number of patients computed tomography (CT) examination is essential. Multi-Detector CT (MDCT) is a widely accepted primary investigation of choice in these patients [3, 4, 5]. The scanning is fast, (acquisition time of 2-3 minutes), and yields specific diagnosis. In MDCT, multiple images can be acquired in a single tube rotation. The whole abdomen and pelvis can be scanned within a single breath hold at a slice thickness of less than a millimeter (0.3-1mm). These sub millimeter sections can be used to obtain good quality reconstructed images like multi-planar reconstructions (MPR) maximum intensity projection (MIP) and 3dimentional (3D) reconstruction**.** MDCT is a great tool for comprehensive evaluation of entire abdomen. There is excellent visualization of the solid organs, hallow viscera, vasculature, peritoneum and retroperitoneal structures along with lung bases.

Our study aims at analyzing the incidence and frequency of various pathologies presenting as acute abdomen in a tertiary care hospital and the accuracy of 128 slice MDCT in making a correct diagnosis by correlating the CT diagnosis with intra-operative and post-operative histopathology diagnosis, whenever available and clinical diagnosis if the patient does not undergo surgery. Intra-operative and post-operative histopathology are considered as gold standard.

Materials and Methods

It is a prospective study performed on 73 subjects who presented with acute pain abdomen, who were referred to radiology department for MDCT abdomen. The duration of this study was from May 2015 to June 2016. Prior to the commencement of the study, necessary clearance was obtained from the institutional ethics committee and written informed consent was taken from the participating patients. Inclusion criteria: Patients who are presenting with clinical symptoms of acute abdomen and undergoing MDCT. Exclusion criteria: Patients who have contraindication to iodinated contrast media either due to contrast allergy or due to impaired renal function. Patients lost to follow up.

CT protocol: MDCT was performed with Siemens SOMATOM definition edge 128 slice scanner. Oral iodinated contrast was not given in patients who are kept nil by mouth in view of immediate surgical exploration, who cannot tolerate oral liquids (pancreatitis), suspected high degree of bowel obstruction, and suspected vascular pathology where the study is done in abdominal angiogram protocol (oral contrast interferes with vascular reconstructions). All the other patients were administered oral and rectal contrast as per routine protocol. All patients underwent a non-contrast study followed by contrast study. Approximately 80-90ml (1-2ml/kg body weight) iodinated non-ionic contrast was given intravenously using a pressure injector at 4ml/sec rate. Images were obtained at arterial (20-25sec), venous (50-60seconds) and delayed phases (>120 sec) using bolus tracking and automatic triggering of acquisition. Raw data was acquired with slice thickness of 0.625mm with a pitch of 0.8-1.5. The images were reconstructed in 5mm thickness for viewing purpose and in 1mm thickness for doing various reconstructions [6].

Study design

Results

In this study 73 patients with acute abdomen underwent MDCT. The findings of MDCT were correlated with the intraoperative findings and histopathological findings in patients who had undergone surgery. In conservatively managed patients the MDCT findings were correlated with clinical course. Table 1 shows the age distribution in the study population.

Table 1: Age group wise distribution of acute abdomen in the study population

Age (years)	Frequency	Percentage
0 to 10	4	5
11 to 20	6	8
21 to 30	8	11
31 to 40	16	22
41 to 50	12	16
51 to 60	9	12
61 to 70	11	15
71 to 80	6	8
91 to 100	1	1
Total	73	100

The sex distribution of the study population is shown in figure 1.

Specificity	75.00%
Positive Predictive Value	98.53%
Negative Predictive Value	60.00%

Discussion

The current generation of the MDCT scanners with cutting edge technology have become the main stay of evaluation of patients with acute abdomen. The technology enables acquisition of isotropic images with exquisite spatial resolution and significantly reduced radiation exposure. The multi-row multi-detector spiral scanning technology has reduced scanning time significantly, leading to improved output and reduced movement related artefacts. The large volumetric data obtained in the axial plane allows reformations into any required plane with same resolution [7]. The advances in reformation techniques have made the process automatic which saves time. Further increase in the computing speed has facilitated faster radiological interpretation in critically ill patients. The shear speed and accuracy of CT in acute abdomen has made the role of plain radiography nearly obsolete.

In our study group of 73 patients 53 were males and 20 were females, ranging from 5 to 93 years. We analyzed various pathologies presenting as acute abdomen. Most common pathology found in our study was acute appendicitis, seen in 22% followed by bowel obstruction in 18%, acute pancreatitis 15% and bowel perforation 14%. Among which appendicitis is the most common cause and is consistent with most of the studies carried out internationally [8].

However we did not encounter any definitive gynecologic pathology, which may be due to the fact that patients with gynecological pathology were primarily evaluated by ultrasound which itself can yield a specific diagnosis.

In our study 16 patients had CT findings suggestive of acute appendicitis and related conditions (Figure 7). CT diagnosis in one out of these16 cases was non-concordant with intraoperative surgical findings. Intra-operatively it was found to be ileo-cecal tuberculosis which was confirmed by histopathological examination. The actual CT findings in this case were masked by clumping of bowel loops in the right iliac fossa, which made visualization of appendix difficult. This was erroneously diagnosed as inflammatory appendicular mass.

The sensitivity and Positive Predictable Value in acute appendicitis were 100% and 93.75% respectively. Intra operative findings very well correlated with CT findings except for one case. This is consistent with study conducted by Rao PM *et al.* [9] which shows 91% to 100% sensitivity for CT in the diagnosis of appendicitis. In another study done by Mawiah H. Alshebromi *et al.* [10] CT showed high sensitivity of 100% and poor specificity of mere 16%.

Fig 7: Axial and coronal MPR images showing a typical case of appendicitis with thickened and enhancing appendix (arrow in a). Coronal MPR (arrow in b) in same patient

In our study 13 out of 73 cases were diagnosed to have bowel obstruction. The various etiologies of bowel obstruction are stricture, adhesion, hernia and mesenteric band [11]. The sensitivity and positive predictable value were 100%. Our results are comparable with Mallo *et al.* [12] in which sensitivity of MDCT in diagnosis of bowel obstruction was 81% to 100% and specificity 68% to 100%. A study conducted by Suri S *et al.* [13] shows that CT is highly sensitive in determining level and cause of obstruction. This is made possible by the exquisite coronal and sagittal reformatted MPR images [14] which are very useful in identifying the transitional zone (Figure 8a). MPR images in any oblique or orthogonal plane are good in identifying intussusception and the underlying pathology as well (Figure 8b)

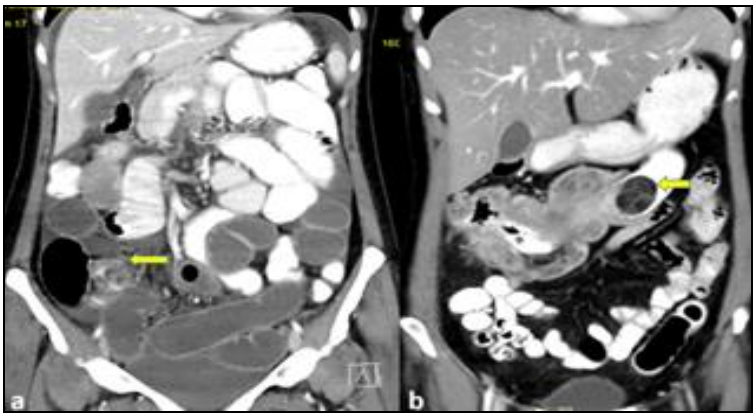

Fig 8: Case of acute bowel obstruction. Coronal MPR shows the transitional zone, in this case it was adhesion causing obstruction (a); Colo-colic intussusception and the underlying pathology, lipoma are shown well in coronal MPR (b).

We encountered 11 cases of pancreatitis out of 73 cases. In all the cases MDCT correctly identified the pathology. In all of the cases diagnosis was confirmed by abnormal levels of elevated pancreatic enzymes. The sensitivity of MDCT in acute pancreatitis was 100%. Comparable results were shown by B. Gianni *et al.* [15]. This is a disease entity where CT clearly scores over ultrasound, because visualization of pancreas itself, in most of the cases of pancreatitis is interfered by bowel gas. Estimation of pancreatic necrosis is impossible with ultrasound, which is the key factor in management and prognostication. CT also is better in identifying and quantifying the peripancreatic collections, pseudo cysts and identifying air in emphysematous pancreatitis (Figure 9).

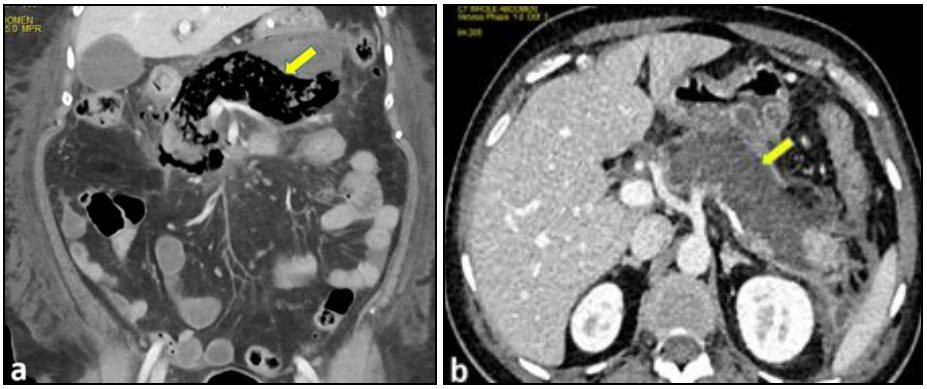

Fig 9: Coronal MPR showing extensive air replacing the entire pancreas, suggestive of emphysematous pancreatitis (arrow in a). Axial post contrast image shows extensive necrosis of the pancreatic parenchyma (arrow in b)

In our study 8 out of 10 cases of confirmed perforation were correctly diagnosed by MDCT. Two missed cases presented very late in the course of the disease, nearly after a week. Because of this delay in presentation these cases lacked the typical imaging features. Hence the perforation had already been sealed off and the pneumoperitoneum had been absorbed, the diagnosis was missed. In hallow viscus perforation the site of perforation can be exactly identified with MDCT. The early and occult perforations and sealed off perforations can be made out with MDCT, due to its ability to detect even smallest amount of free air. The sensitivity and accuracy for bowel perforation in our study was 80%, which was comparable to the study done by Sung Hwan Kim *et al.* and other investigators [16, 17, 18] who gave an accuracy of 82% to 90% for predicting site of perforation by CT.

In our study 5 out of 73 cases had urolithiasis, all the 5 cases were correctly identified by MDCT with sensitivity of 100%. The above findings are comparable with study performed by Isabelle Boulay *et al.* and others [19, 20, 21]. Leschka Sebastian *et al.* [5] state that thin slices and good multi-planar reconstructions helps in identifying even sub-millimeter calculi (Figure 10). This is complemented by the fact that nearly 100% of the renal calculi are radio-opaque.

Fig 10: Coronal MPR image showing the dilated calyces, and ureter in its entirety with an obstructing calculus in the mid ureter (arrow).

In our study 4 out of 73 cases had CT findings suggestive of cholecystitis with sensitivity of 100% which is comparable to other international studies. However the limitation of CT in gall bladder pathology is its failure to detect radio-lucent calculi, which could be the underlying predisposing factor for cholecystitis. Ultrasound and Magnetic Resonance Imaging (MRI) have better sensitivity in identifying Cholelithiasis. MDCT clearly performs better than ultrasound in detecting the complications like emphysematous cholecystitis and gangrenous cholecystitis. MDCT is the most sensitive modality in identifying complications related to cholecystitis as stated by L. Turturici *et al.* [22]

In 3 out of the 73 patients no significant abnormalities were detected by MDCT. And this was the case even in diagnostic laparoscopy. These patients were considered to have non-specific abdominal pain. The pathology in these patients presumed to be due to transient pain caused by intestinal colic or pain caused by a passing ureteric calculus, which would have completely passed out from the urinary bladder also, hence not seen in CT.

In our study the overall accuracy, sensitivity, specificity and positive and negative predictable values of MDCT were 96%, 97%, 75% and 98% and 60% respectively which were comparable to the study results of Monica Mangini *et al.* [23]

Conclusion

Acute abdomen is a commonly encountered, usually a surgical emergency. In our study the most commonly encountered pathologies were appendicitis, bowel

obstruction, bowel perforation and acute pancreatitis. It is essential to make a speedy and accurate diagnosis in these patients to decide on the management as to subject them to surgery or treat conservatively. For this purpose we need to employ a robust diagnostic tool. The clinical examination and laboratory parameters have very poor sensitivity and specificity, hence cannot be dependent upon. Very good sensitivity and specificity of MDCT makes it an ideal tool in the evaluation of acute abdomen. Recent advances in hardware, software and computation speed have made MDCT a powerful diagnostic tool in acute abdomen. MDCT scores over all other imaging modalities because of its speed and versatility.

Limitations of the study: Our study employed relatively small sample size, mainly because many patients were taken up for surgery based on ultrasound/radiography findings alone without CT. Though ultrasound may not give a specific diagnosis, these patients were taken up for surgery without CT, in the background of a given clinical scenario, like presence of guarding and rigidity in a suspected case of hallow viscus perforation where ultrasound showed free fluid and radiograph showed pneumoperitoneum which necessitated immediate laparotomy. Baring few specific conditions like gallbladder pathology and gynecological pathology MDCT is the primary modality of choice for evaluating acute abdomen.

Evaluation of acoustic radiation force impulse (ARFI) elastography as a tool for non invasive detection and grading of liver fibrosis with histopathology correlation

Viyannan Maheswaran, Vinu Adithi Vaishnavi and Balalakshmoji Devanand

DOI: http://dx.doi.org/10.33545/26644436.2020.v3.i1a.53

Abstract
Background: Chronic insult caused by viral infection, autoimmune disease, alcohol and other toxins can damage the liver parenchyma and ultimately lead to liver fibrosis and cirrhosis. Acoustic Radiation Force Impulse (ARFI) elastography is emerging as a valuable tool in the detection and grading of fibrosis in liver.
Materials and Methods: It is a prospective comparative study performed in 36 patients between December 2016 and March 2018 who presented with deranged liver function test and referred for ultrasonography, ARFI elastography of liver followed by liver biopsy. The findings of Elastography were correlated with histopathology.
Results: When compared with histopathology ARFI had a sensitivity of 82%, specificity of 85%, positive predictive value of 90% and negative predictive value of 75% in detecting liver fibrosis when we used optimum cut values of ARFI.
Conclusion: ARFI elastography is a valuable tool in non-invasively detecting liver fibrosis and can be included as part of routine ultrasonic examination protocol of liver. ARFI technology allows the quantification of liver fibrosis and can be effectively used to stage fibrosis. Hence ARFI can be used as an alternative to liver biopsy and it might substitute liver biopsy in future.

Keywords: Elastography, ARFI, liver fibrosis grading

Introduction
The incidence of chronic liver parenchymal disease is constantly on the raise. The major underlying causes are alcoholism and viral hepatitis [1]. In response to continuous inflammation and injury there is fibrosis [2, 3, 4] and regeneration which result in liver cirrhosis and the attendant complications like portal hypertension, variceal bleed, ascites, liver failure, hepatic encephalopathy and even development of hepatocellular carcinoma[1]. Generally cirrhosis is considered to be irreversible, however accumulating evidence suggests that it could be reversible to some extent, especially when targeted therapy is given [1, 3, 5]. Hence, early detection and grading the severity of liver fibrosis is of utmost importance for treatment. The degree of hepatic fibrosis is an important factor which influences the treatment and determines the prognosis of the underlying liver disease [1]. Therefore, there is tremendous need for quantitative assessment and grading of hepatic fibrosis. The method used traditionally for assessing the degree of liver fibrosis is liver biopsy. Which is considered as gold standard method for determining the extent of liver fibrosis. However it is an invasive procedure which is associated with patient discomfort and occasionally severe complications like bleeding, infection and rarely death [1]. Histopathological examination (HPE) of liver fibrosis is greatly dependent on the size of the sample and segment from which the sample is obtained. Generally a biopsy specimen of size 1.5-2cm is required by the pathologist for accurate evaluation. The distribution of fibrosis within the liver is very non-uniform and sampling errors are bound to happen. [4, 6, 7]These disadvantages associated with liver biopsy have been the thrust behind pursuing alternate methods to assess liver fibrosis. ARFI Elastography is a recently introduced technology to evaluate tissue stiffness non-invasively.

The technology of ARFI Elastography involves the mechanical excitation of tissue using short-duration acoustic pulses (push pulses) in a region of interest, producing shear waves that spread away from the region of interest, perpendicular to the acoustic push pulse, generating localized, micron-scale displacement of the tissue [8, 9]. Simultaneously, detection waves of lower intensity than that of the push pulse (1:100) are generated. By recording the shear wave front at several locations and correlating these measurements with the elapsed time, the shear wave velocity (SWV) can be quantified in meter per second unit. Generally, the stiffer a region in the tissue, the greater the SWV as it travels through this region. This technique can be used in various organs and it is well suited for liver in view of the size and relative superficial location of the organ. The advantage of this technology is that it is incorporated in an ultrasound machine and the operator can use the ultrasound to measure the stiffness of the tissue of interest in real time.

Materials and Methods

It is a prospective study performed from December 2016 to March 2018. Before starting the study necessary clearance was obtained from the institutional ethics committee and informed written consent was obtained from the patients. The study population includes 36 patients with clinical and laboratory features of altered liver function who were referred to radiology department for further evaluation with ultrasound. All the patients underwent liver sonography, ARFI Elastography and subsequently, with in a period of two weeks, liver biopsy. The findings of Elastography were correlated with HPE. Inclusion criteria: patients under evaluation for altered liver function parameters, nonalcoholic-steatohepatitis, chronic viral infections, patients undergoing liver biopsy for assessment of fibrosis. Exclusion criteria: Patients with bleeding disorders, altered coagulation parameters, patients unable to hold their breath and uncooperative. Ultrasound protocol: Examination was performed in SEIMENS S2000 machine in supine position. B mode Ultrasound: to assess the size, echogenicity and echo-texture of liver. ARFI Elastography: Total of 8 measurements of shear wave velocity were taken, at least 2 from each segment of right lobe. Measurement was calculated by placing a 0.5 x 1cm box at least 1.5 to 2cm deep to the liver capsule (Fig. 1) and away from major vessels. The velocity was calculated in meter per second and the mean and median velocity of all 8 measurements were used to grade the stiffness of the liver.

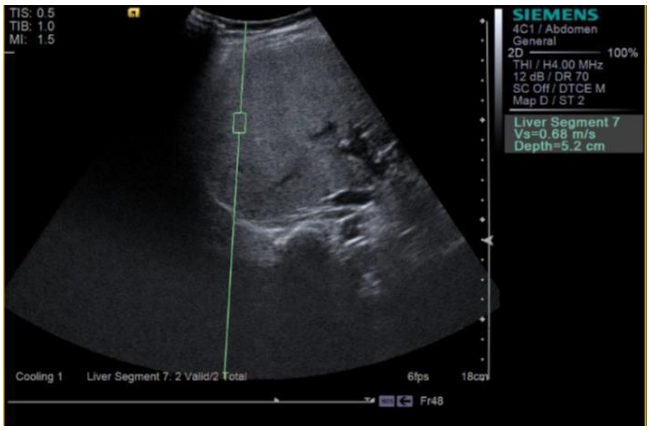

Fig 1: Measurement of ARFI by placing an ROI in each segment of the right lobe of liver.

Biopsy: Biopsy of the liver was obtained using 18G fully automatic gun (Bard MaxCore) with 22mm long cutting needle harvesting a 20mm long core. The specimen was fixed in formalin and sent for HPE. Fibrosis was scored in histopathology using the METAVIR scoring system. The cut of value [10] of shear wave velocities corresponding to METVIR grades is shown in Table 1:

Table 1: METAVIR Score and corresponding mean SWI in ARFI

Metavir Score	Histopathology	Mean Shear Wave Velocity
F0	No fibrosis	1.09+/- 0.42m/s
F1	Portal fibrosis without septa	1.22+/- 0.41m/s
F2	Portal fibrosis with few septa	1.37+/- 0.48m/s
F3	Numerous septa without cirrhosis	1.70+/- 0.59m/s
F4	Cirrhosis	2.23+/- 0.71m/s

Results

In this study 36 patients were evaluated with Ultrasonography and Elastography, the findings were compared with the HPE findings. In our study out of 36 patients 10 (28%) patients were female and 26 (72%) were male who presented with liver disease and altered liver function tests with different underlying pathologies like Nonalcoholic steatohepatitis (NASH), chronic viral hepatitis, storage disease and Cryptogenic cirrhosis. Our study had patients ageing from 11 years to 60 years with an average of 30 years. We had 14 (39%) patients below the age of 30 and 22(61%) patients more than 30 years of age. The distribution of various grades of fibrosis in the study population is shown in figure 2. The number of patients in the study population with various grades of fibrosis in ARFI and HPE is shows in table 2.

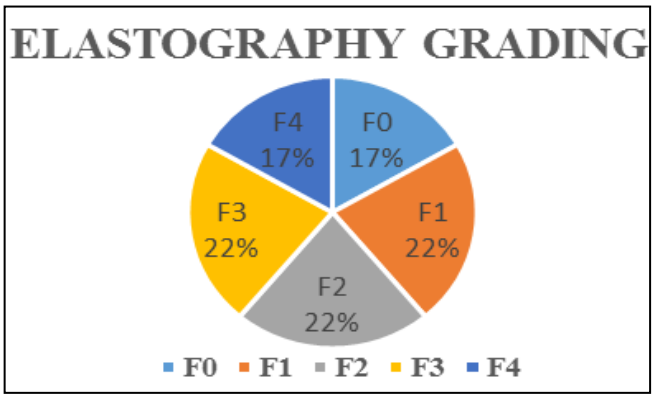

Fig 2: Distribution of various degrees of fibrosis in the study population in ARFI.

Table 2: Grading of fibrosis

	ARFI		HPE	
	Frequency	Percent	Frequency	Percent
F0	6	17	10	28
F1	8	22	4	11
F2	8	22	8	22
F3	8	22	4	11
F4	6	17	10	28
Total	36	100	36	100

B mode ultrasound findings of liver are shown in Table 3. Out of the 36 patients 4 had normal appearing liver, majority showed diffuse fat infiltration in the liver and 8 patients had altered echo-texture of liver parenchyma.

Table 3: Ultrasound findings in study population

Frequency		Percent
Normal	4	11
Steatosis	24	67
Altered echo texture	8	22
Total	36	100

In our study of 36 patients, ARFI showed clinically insignificant fibrosis in 16 patients with a METAVIR score of F0, F1 which was commonly seen with patients of acute hepatitis and nonalcoholic steatohepatitis. Clinically significant fibrosis (F2, F3, and F4) was seen in 20 patients with a majority of them affected by chronic viral hepatitis. (Tables 4).

Biopsy showed clinically insignificant fibrosis (F0, F1) in 14patients (39%) and clinically significant fibrosis (F2, F3, F4) in 22 patients (61%). Of the 14 patients who had insignificant fibrosis, different underlying etiologies such as NASH, storage diseases and autoimmune hepatitis were found, patients with significant fibrosis had viral hepatitis. (Tables 4).

Table 4: Significance of fibrosis in ARFI and HPE

	ARFI		HPE	
	Frequency	Percent	Frequency	Percent
Significant fibrosis	20	56	22	61
Insignificant fibrosis	16	44	14	39
Total	36	100	36	100

The cross tabulation comparing various grades of fibrosis in ARFI and HPE are shown in table 5.

Table 5: Elastography Grade Vs Histopathology Grade Cross Tabulation

			HPE Grade					Total

Discussion

Generally fibrosis is thought to be an irreversible process till the discovery of hepatic stellate cells (HSC) in the 1980s. HSCs play an important role in fibrosis. Following chronic liver injury HSC under inflammatory milieu proliferate and activate to produce pro inflammatory and fibrogenic factors. Activated HSC produce large amounts of extracellular matrix (ECM). The extracellular matrix accumulates and distorts the liver architecture and forms a fibrous scar along with regeneration of hepatic tissue which subsequently lead to formation of the nodules. Studies carried out in the 1990s demonstrated that hepatic fibrosis was a reversible process if the cause was to be treated [2, 3, 4]. Since then researchers have taken keen interest in developing therapies for reversing/slowing down progression and severity of liver fibrosis. Thus, assessing the stage and severity of fibrosis precisely has taken the center stage in the management of chronic liver disease. In fibrosis and cirrhosis the pathological changes in tissue lead to alteration of mechanical properties like stiffness which can be measures noninvasively. The gold standard for assessing liver fibrosis

is biopsy and HPE. Liver biopsy, though safe, is an invasive procedure with a small risk of complications like severe hemorrhage. The risk of significant bleed is more when there is alteration of the coagulation parameters or in the presence of significant ascites. Both these risk factors are seen more frequently in patients with liver parenchymal disease, which in the first place is the indication for doing a biopsy. Percutaneous liver biopsy yields only a tiny fragment of the liver (1 in 50000 of the total volume of the liver) [11] which may lead to errors in staging of fibrosis, since there can be non-uniform distribution of fibrosis with in the liver. Bedossa *et al* [12] proved that the chance of under diagnosis of the stage of fibrosis, when the length of biopsy core is less than 2.5 cm can reach up to 25%. They have also proved that in almost half of the cases where liver fragments obtained from both the lobes of liver in the same session showed different stages of fibrosis. Hence in many ways liver biopsy is a flawed gold standard. For the past 10-15 years, enormous efforts have been made by several groups for establishing a reliable and reproducible noninvasive marker for liver fibrosis as a substitute to the invasive liver biopsy technique. In our study of 36 patients we have attempted to study the efficacy of ARFI compared to histopathology. The accuracy of ARFI elastography for assessing the severity of liver fibrosis and grading was evaluated. Calculating the sensitivity, specificity, positive predictive value and negative predictive value of the noninvasive test ARFI demonstrated a good sensitivity and specificity. Accurately grading and quantifying the severity of hepatic fibrosis secondary to an underlying disease is of great importance for planning appropriate treatment strategies. Studies comparing the non-invasive methods for evaluating the severity of fibrosis in chronic liver disease to liver biopsy are being performed to assess if these techniques would replace the invasive test. Virtual touch tissue imaging application enables ARFI technology to evaluate the deep tissues. SWI in meter per second can be quantified in a region of interest with ARFI technology in a precise anatomical location, which represents the elasticity property of the tissue. In our study we encountered 4 false negative patients. One of them was hepatitis B patient and another one patient with Hepatitis C. In these cases we presume values taken in the areas of necrosis may have contributed to low values. Another 2 patients were cases of alcoholic hepatitis, in whom the steatosis may have contributed to the falsely low values. We also had 2 false positive patients encountered in our study. One of them had hepatitis B acute stage and another one patient had hepatitis A. Hepatitis is known to have both inflammation and fibrosis, one of which may predominate depending upon the stage of disease [13, 14]. In acute stage because of inflammation, we can get erroneous high values [15, 16]. There are no possible means to differentiate the high values due to inflammation from that due to fibrosis. This may explain the false positivity in the hepatitis patients.

A study by Takahashi *et al*. [17] of 80 patients with mixed etiologies using ARFI (Siemens Healthcare), had a sensitivity and specificity of 91% and 80% respectively for F>2 stage of fibrosis. This is in concordance with the results in our study. In a similar study by Sporea at al. [18] using 114 patients with mixed etiologies, also had a sensitivity and specificity of 89% and 68% respectively. We attempted to study whether ARFI was sensitive in patients with NASH, who form the majority of the mixed etiology liver disease without viral hepatitis group. 10%-15% of NASH patients show a progression in the severity of fibrosis and architectural remodeling, and liver cirrhosis is seen in 15%-25% of cases. Three to 5% of people with fatty liver may develop cirrhosis. Cirrhosis due to NASH and cryptogenic cirrhosis have risk of developing HCC. HCC may rarely occur in a non-cirrhotic NASH patient. Hence lies the importance of detecting early fibrosis in patients with NASH [18, 19]. In a study conducted by Fraqueli *et al* [20] using 200 patients with mixed etiology liver diseases other than viral hepatitis, the sensitivity and specificity of ARFI was 72% and 84% respectively. In a study of 106 patients with HBV and HCV conducted by Friedrich-Rust *et al* [21] the sensitivity and specificity was 69% and 92% respectively. In our analysis of 28 HBV and HCV patients, we had a sensitivity of 90% and specificity of 75%. The liver stiffness assessment is challenging in patients with viral hepatitis because of the nature of underlying disease. There may be increased necro-inflammatory changes in the acute phase of the disease which undergoes fibrosis later on. The necrotic areas will give lower stiffness values compared to the other areas of inflammation thus may decrease overall sensitivity. The higher sensitivity in our study may be because these patients were assessed in the advanced stage of the disease. Review of previous publications and our own study has shown that US elastography definitely has a role in the staging of fibrosis where it has the potential of replacing liver biopsy. Another upcoming and exciting non-invasive modality to evaluate liver fibrosis is MR Elastography which has the advantage of avoiding sampling errors and operator variability. New MR imaging contrast agents that target specifically the collagen and other extracellular matrix macromolecules may be developed in the near future. A collagen-specific MR imaging contrast agent and also contrast agents that selectively target hepatic stellate cells and other cells involved in the pathogenesis of liver fibrosis may permit imaging of fibrogenesis or fibrolysis. All such data may provide valuable information for guiding antifibrotic therapy development and monitoring patients in clinical trials. Thus these noninvasive methods may help in the assessing the severity of fibrosis.

Conclusion

Acoustic Radiation Force Impulse (ARFI) elastography is a promising noninvasive tool to quantify liver fibrosis. It also has the advantage of routine ultrasound assessment of the liver during the same session of elastography study. ARFI measurements are done in real time under vision. As many number of measurements as the operator wishes can be obtained in a single study. The assessment can be repeated frequently as and when required. The technique has good sensitivity and specificity and less operator dependent when compared with other ultrasound techniques as the calculation is done automatically by the system and there are tools which are useful to obtain a good quality study. The technique has good sensitivity and specificity which has the potential to replace invasive biopsy. Limitations: Our study is limited by the relatively small sample size. The small sample size is primarily due to limitation in the number of patients undergoing biopsy. ARFI elastography is a relatively new technology that has not been extensively investigated, hence large prospective studies are needed to ascertain its efficacy and to form strict cut off values for the shear wave velocity. Different technologies and

measurement calculations are adopted by different ultrasound venders. Because of this standard values are not available for comparison across different ultrasound systems [22], which needs to be addressed by various ultrasound manufacturing vendors and an amicable consensus to be arrived at.

Abstract

Hereditary hemorrhagic telangiectasia (HHT) or Osler–Weber–Rendu syndrome is a rare condition which can result in significant *systemic and hepatobiliary* abnormalities. Liver involvement in HHT consists primarily of the consequence of various intrahepatic shunts. Even though these vascular shunts are present in the majority of patients with HHT, symptoms occur only in *minority* with clear predilection to *female gender*. The symptoms and imaging findings of liver vascular malformations can be easily overlooked or misdiagnosed which can result in delay in treatment or potentially harmful vascular interventions. In this case report, we discuss the pathophysiology of HHT in liver involvement, role of imaging in diagnosis, and the possible role of interventional radiologist in the treatment.

Key words: Embolization for shunt reduction; hereditary hemorrhagic telangiectasia; intrahepatic shunts; liver vascular malformation

Introduction

Hereditary hemorrhagic telangiectasia (HHT) is an autosomal dominant disorder seen approximately in one in 5000–8000 individuals.[1] It presents with vascular malformations (VM) in the nose, skin, liver, gastrointestinal tract, brain, and lung. Telangiectasia is the VM seen in HHT where there is direct communication between the arterioles and venules without the intervening capillaries. This abnormal communication can result in shunts between various vascular beds in the solid organs and hallow viscera. Definitive clinical diagnosis of HHT can be made based on the presence of at least three of four Curacao criteria,[2] published in 2000. They are 1. Epistaxis, 2. Cutaneous or mucosal VM, 3. Presence of visceral telangiectasia, and 4. Positive family history. Liver involvement is seen in approximately 75% of people with HHT.[2] Although only a small 8%–10% of these patients develops symptomatic liver pathology, the rest remains asymptomatic.

Case Report

We are presenting a patient who presented with upper gastrointestinal (GI) bleed and epistaxis with anemia. On further evaluation, she was found to have telangiectasia in the nose and multiple angioectasias in the stomach and in the duodenum in upper GI endoscopy. This

triad of findings, 1. Spontaneous recurrent epistaxis, 2. Telangiectasia of nose, and 3. Visceral telangiectasia, fulfill 3 Curacao criteria to qualify for definitive diagnosis of HHT. Further evaluation with contrast-enhanced computed tomography (CECT) was done to rule out chronic liver parenchymal disease. The CECT revealed heterogenous enhancement of the periphery of the liver in the arterial phase [Figure 1A] which becomes homogenous in the venous phase [Figure 1B]. In addition, there was moderately enlarged proper hepatic artery measuring 10 mm in diameter (normal <7 mm) and abnormally dilated intrahepatic branches of the hepatic artery and early filling of the portal venous branches [Figures 2A, B and 3]. There were abnormal tortuous vascular channels along the ligamentum teres with early filling of the branches of portal vein [Figures 3 and 4]. There were faintly enhancing tortuous vascular channels along the intrahepatic branches of the hepatic artery. There was slight reduction in the volume of the left lobe of liver. The surface of the liver was smooth. All these imaging features were suggestive of intrahepatic arterio-portal shunts with possible secondary chronic liver parenchyma disease. She was treated symptomatically with cauterization of the nasal telangiectasia, nasal packing, and blood transfusion for anemia. Few small telangiectasia lesions in the stomach showed active bleed during endoscopy and these lesions were treated with argon plasma coagulation.

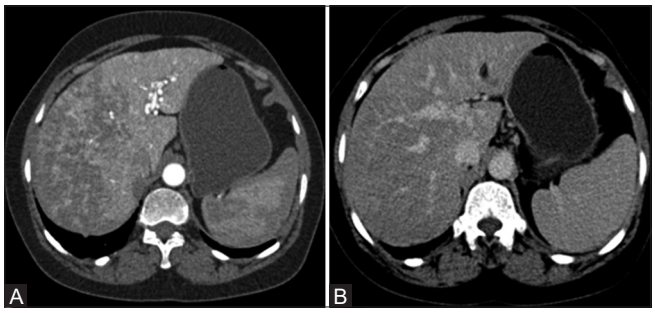

Figure 1 (A and B): Contrast-enhanced CT axial section shows heterogenous enhancement of the liver parenchyma in the arterial phase (A) which becomes homogenous in the venous phase (B)

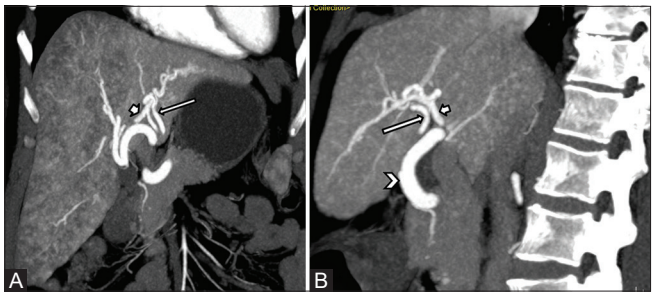

Figure 3 (A and B): Coronal (A) and sagittal (B) maximum intensity projection (MIP) images showing enlarged hepatic artery branches—long thin arrows (in A and B)—and early filling of the portal venous branches—short thick arrow (in a and B). The enlarged main hepatic artery is marked with arrow head in B

Discussion

In HHT, clinical symptoms occur in approximately 8% of the people.[3] There is a distinct female preponderance in symptomatic patients, with majority of the patients presenting in their fourth decade.[3] Presenting features are secondary to high-output cardiac failure (most common),[3] portal hypertension, GI bleed either from varices due to portal hypertension or angioectasia of the mucosa of the GI tract, and biliary disease. Other less common forms of clinical presentation in the liver and GIT are portosystemic encephalopathy and abdominal angina. The basic pathophysiology in liver involvement is development of intrahepatic VMs. Liver vascularity is unique by the way of presence of dual arterial supply and presence of dormant, potential portosystemic shunts, like paraumbilical vein, which can open up in any form of disturbance in the equilibrium of liver circulation.

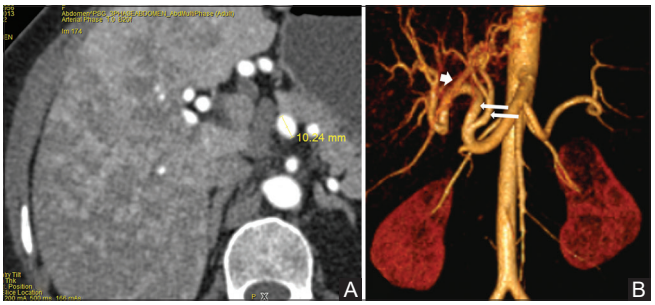

Figure 2 (A and B): Axial CT image in the arterial phase acquisition (A) and 3D volume rendered image (B) showing enlarged hepatic artery proper, measuring more than 10 mm. There is enlarged proper hepatic artery and its branches (long thin arrows in B) and early filling of the portal venous branch (short thick arrow in B) seen with fuzzy margins

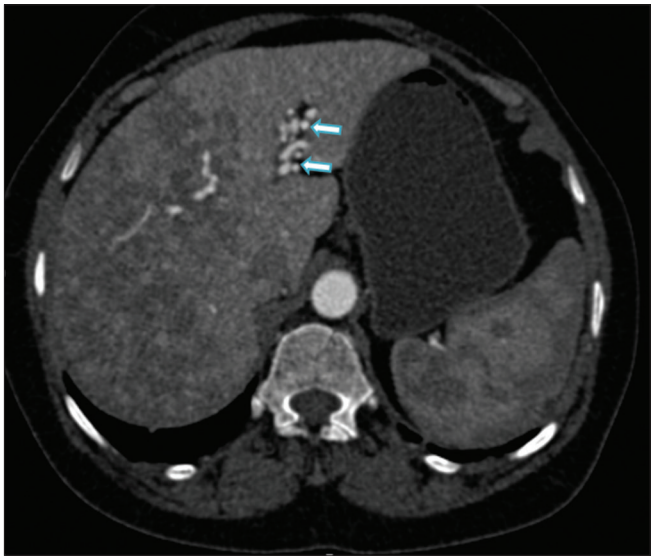

Figure 4: Axial CT image showing multiple tortuous early filling portal venous branches along the ligamentum teres (arrows) seen along with the left hepatic artery branches

The VMs in the liver can lead to three different types of vascular shunts.[3,4] These are 1. Arterio-venous (AV) shunt (between the hepatic artery and hepatic vein), 2. Arterio-portal (AP) shunt (between the hepatic artery and portal vein), and 3. Portal venous (PV) shunt (between portal vein and hepatic vein).[1] Shunts are usually extensive. The shunts can be visualized by imaging studies if they are macroscopic. Frequently they can be microscopic and not seen in imaging. Each predominant type of shunt gives rise to distinct clinical manifestation.

AV shunt

This is the most common symptomatic VM. It usually affects women. The presenting clinical feature is related to high-output cardiac failure.[1] AP shunt can also involve liver leading to biliary ischemia and ischemic necrosis of the bile duct[5] due to steal phenomenon. The loss of integrity of the bile duct due to ischemia can lead to biliomas and intrahepatic biliary cysts mimicking Caroli's disease. In chronic cases, *secondary sclerosing cholangitis* develops with stricture and abnormal dilatation of intrahepatic bile ducts. Biliary ischemia-related complications are seen *exclusively* in women.[3]

AP shunt

This is the second most common shunt after AV shunting. Shunting of blood from the hepatic artery to the portal vein causes *portal hypertension*. Secondary to portal hypertension, there can be ascites, varices formation, and GI bleed. In addition, there can be formation of focal nodular hyperplasia and *nodular regenerative hyperplasia in the liver*. It equally affects men and women. The diagnosis is made based on hepatic venous pressure gradient which should be more than or equal to 10 mmHg.

PV shunt

This is the least common type of shunt and usually causes high-output cardiac failure. Rarely, this can cause focal nodular hyperplasia and nodular regenerative hyperplasia in the liver which can lead to portal hypertension and cirrhosis.

Diagnosis of HHT is made based on the Curacao criteria.[2] Imaging is indicated to confirm the diagnosis if three of the four clinical criteria are not met. In addition, imaging has to be done to look for associated complications like liver cirrhosis. In a known case of HTT, the presence of ascites, GI bleed, and abdominal pain should raise the suspicion of liver involvement and imaging should be performed. Doppler study can show abnormal tortuous vessels in the liver. CECT and MRI can reveal multiple liver VMs. There can be enlarged hepatic artery, normal ≤7 mm,[1] heterogenous enhancement of the liver in the arterial phase of contrast study which becomes homogenous in the venous phase.

CT is the recommended *imaging modality* of choice. In CECT, the type of shunt can be determined in two-third of patients. The majority of patients with liver disease will show AV shunt. Biliary disease is generally seen in the late phase of the disease. The gold standard to establish the type of shunt is angiography.[3] Angiography can clearly demonstrate the early, subtle VMs and mesenteric steal syndrome. However, in the majority of the patients, the diagnosis can be established with less invasive imaging methods like CECT.

Treatment

No treatment needed in asymptomatic patients with liver involvement. Primarily, the management is medical with treatment of anemia and correcting coagulation abnormalities.[6] High-output cardiac failure and complications of portal hypertension are treated in the standard way like treating cardiac failure and portal hypertension due to other etiologies. It should be noted that trans-jugular intrahepatic porta systemic shunt (TIPS) creation may not be effective in the treatment of GI bleed secondary to telangiectasia of the GI tract. Shunt reduction procedures like embolization may be considered in patients with cardiac failure and mesenteric ischemia.[7] However, these procedures are associated with high morbidity and mortality and have only transient therapeutic effect. In carefully selected patients, few sessions of endovascular embolization may be effective in reducing portosystemic shunt and alleviating mesenteric ischemia. Ultimately patients might require liver transplantation, which can be curative.

Conclusion

HHT is a rare cause of vascular dysplasia involving many organs and systems. Although the majority of the patients remain asymptomatic, high index of suspicion should be kept not to miss liver involvement by the disease. Radiologists should be aware of the imaging findings and possible treatment options like shunt reduction embolization offered by us. Life-threatening complications like high-output cardiac failure not responding to maximum medical therapy and severe biliary ischemia should be recognized and these patients should be referred for an early liver transplant.

Abstract

Background: Resistive index (RI), derived from color Doppler imaging (CDI), is a marker of vascular resistance used widely in varied clinical settings. The aim of this study was to analyze the association between RIs of the orbital vessels in a pure cohort of type 2 diabetic patients with or without retinopathy using CDI. **Materials and Methods:** Fifty patients having type 2 diabetes and 50 age-matched controls were evaluated in this prospective study. Diabetic retinopathy (DR) was diagnosed based on seven-field stereo fundus photography and diabetic patients were divided into two. Patients with no DR ($n = 26$) were taken as Group 1, while patients with DR ($n = 24$) were taken as Group 2. CDI was performed and the RIs of the ophthalmic artery (OA), posterior ciliary artery (PCA), central retinal artery (CRA), and central retinal vein (CRV) were measured. **Results:** Significant differences were observed in the mean RI values of all orbital arteries between controls and patients with DR ($P < 0.05$). Comparison of RI values between controls and Group 1 showed no significant differences. Mean RI values of the PCA and CRA were found to be significantly higher in the patients in Group 2 than in Group 1 ($P = 0.03$ and $P < 0.001$, respectively). The duration of diabetes correlated with the mean RI of all the orbital vessels. RI of the CRA was a reliable predictive indicator for DR ($P = 0.001$). **Conclusion:** RIs of the orbital arteries are significantly higher in patients with DR. RI of the orbital vessels can be a potentially useful biomarker in the early diagnosis and follow-up of patients with DR.

Keywords: Color Doppler ultrasonography, diabetic retinopathy, vascular resistance

Introduction

Color Doppler imaging (CDI) is a convenient noninvasive method that gives information about the velocity of blood and vascular resistance at various sites of complex vasculature using simultaneous B mode ultrasound and Doppler images. The resistive index (RI), calculated from CDI, is a universally used measure of resistance to the arterial blood flow. In the recent past, RIs of the orbital arteries have been studied extensively to gain diagnostic and prognostic insight into a variety of clinical conditions, such as chronic obstructive pulmonary disease, hypertension, chronic kidney disease, and diabetes-related micro and macrovasculopathies.[1-5]

Usefulness of RI of the retrobulbar vessels in risk stratification and management of ophthalmic diseases such as diabetic retinopathy (DR), age-related macular degeneration, glaucoma, retinal vein occlusion, and thyroid-associated orbitopathy has been documented in the literature.[6,7]

Several studies have evaluated the RI of the retrobulbar vessels in diabetic patients with or without retinopathy and have shown inconsistent results. While few studies have shown significant correlation between RI of the orbital vessels and severity of DR,[8,9] few others suggest that the hemodynamic alterations observed in the orbital arteries reflect macrovascular changes and are not related to DR.[5,10] The observed inconsistencies can be attributed partly to the differences in sample sizes, patient characteristics, duration of diabetes, methods of assessment of DR, and probe positions used for color Doppler

measurement. Further, most of these studies included patients with comorbidities such as hypertension and coronary artery disease as well as those patients on cardiac or antihypertensive drugs, which might alter the vascular resistance.

The aim of this study was to analyze the association between RIs of the orbital vessels in a pure cohort of type 2 diabetic patients with or without retinopathy using CDI.

Materials and Methods

This prospective study was conducted between March 2017 and May 2019 from a tertiary care institution in South India. The institutional human ethical committee approval was obtained before the initiation of the study, and the principles of Declaration of Helsinki were adhered to. Informed, written consent was obtained from all the study participants. Fifty consecutive patients of type 2 diabetes (as per definition of the American Diabetes Association) were recruited for the study. Exclusion criteria were the presence of associated systemic hypertension, nephropathy, dyslipidemia, and cardiovascular diseases. Patients on medications known to affect systemic hemodynamics such as angiotensin-converting enzyme inhibitors, calcium channel blockers, and antimigraine drugs were excluded. Patients with a history of any ocular disease that might affect ocular blood flow such as retinal diseases, high myopia, glaucoma, previous ocular surgery, or panretinal photocoagulation were also excluded from the study. A control group of 50 age-matched subjects were included. None of the controls had any ocular or systemic disease.

Data regarding age, gender, body mass index (BMI), duration of diabetes and antidiabetic medications were obtained from all the study participants. Blood pressure and serum glycosylated hemoglobin (HbA1c) levels were determined.

All participants underwent a comprehensive eye examination and the presence/absence of retinopathy was diagnosed through dilated fundus examination and 30° stereoscopic fundus photograph of seven standard early treatment DR study fields using a digital fundus camera (TRC-50 DX Mydriatic Retinal Camera; Topcon Medical Systems, Oakland, NJ, USA). Diabetic patients were divided based on retinopathy into two groups. Group 1 contained patients with no DR; Group 2 included patients with DR. One eye (right eye, unless another ocular pathology was identified) was included from each study participant.

A masked expert radiologist performed CDI of the eye for all study participants using a color Doppler unit and a 12–5 MHZ linear-array transducer (Philips iU22 xMATRIX ultrasound system). The CDI was performed with patients lying in the supine position with a 30° head tilt and any undue pressure on the eye was avoided. Examiner's hand was rested on the orbital margin, and sterile coupling gel was applied over closed eyelids. Angle of the transducer was taken as 30°–60° during the examination. CDI was performed after exclusion of any other ocular or orbital pathologies by B mode, and optic nerve was considered as a reference for all further measurements. The velocity of blood flow in the ophthalmic artery (OA) was measured 20–30 mm behind the globe after crossing of the optic nerve in the nasal aspect. Blood flow velocity in the central retinal vein (CRV) and central retinal artery (CRA) was measured within the optic nerve around 5 mm behind the posterior margin of the eyeball. Blood flow velocity from the temporal branch of the short posterior ciliary artery (PCA) was determined approximately 5–10 mm posterior to the globe. The peak systolic velocity (PSV) and end diastolic velocity (EDV) measurements were taken for OA, CRA, PCA, and CRV. With the help of PSV and EDV, we calculated the vascular resistance based on the RI using Pourcelot's formula:

$$RI = (PSV - EDV)/PSV.$$

Statistical analysis

Statistical analysis was carried out using Statistical Package for the Social Sciences (SPSS, SPSS Inc., Chicago, IL, USA) Version 24. Data were reported as mean ± standard deviation. The normality of data distribution was assessed by Kolmogorov–Smirnov test. One-way analysis of variance with a *post hoc* Bonferroni was used for analysis of normally distributed continuous data. Kruskal–Wallis analysis was used for analyzing nonnormally distributed data. Bivariate analysis using Pearson's correlation coefficient was used to study the relationship of RIs with biochemical and demographic variables of patients with diabetes. Receiver operating characteristic (ROC) curve analysis was used to explore the predictive indicators of DR. A $P < 0.05$ (two-tailed) was considered statistically significant.

Results

The study consisted of 51 males and 49 females. The age of the participants ranged from 41 to 76 years. Duration of diabetes ranged between 6 months and 20 years. Among the diabetic patients studied, 26 had no DR and constituted Group 1. Group 2 consisted of 24 patients with DR. In Group 2, three patients had mild nonproliferative DR (NPDR) characterized by only few microaneurysms, seven had moderate NPDR (presence of more than just microaneurysms but less than severe NPDR), six had severe NPDR (presence of more than 20 intraretinal hemorrhages in each of four quadrants or definite venous beading in 2+ quadrants or prominent intraretinal microvascular abnormalities in 1+ quadrant), and eight had proliferative DR (presence of neovascularization of disc or elsewhere in the retina).

There were no statistically significant differences in the age, BMI, and blood pressure between controls and diabetic groups. Duration of diabetes and HbA1c levels were found to be significantly increased in Group 2 patients with DR ($P < 0.001$). Significant differences were observed in the RI values of all orbital arteries between controls and diabetic groups. Table 1 shows the demographic data and clinical attributes of controls and diabetic subjects.

Subgroup analysis with *post hoc* comparison revealed significantly higher RI values in OA, PCA, and CRA in Group 2 compared to controls ($P < 0.001$, $P < 0.001$, and $P = 0.03$, respectively). Comparison of RI values between Group 1 and controls showed no significant differences. When diabetic Groups 1 and 2 were compared, statistically significant differences were observed in the mean RI values of CRA and PCA ($P < 0.001$ and $P = 0.03$, respectively).

In bivariate analysis, the mean RI values of all orbital vessels, namely OA, CRA, PCA, and CRV, had a significant correlation with the duration of diabetes ($R = 0.396$, $P < 0.001$; $R = 0.282$, $P = 0.005$; $R = 0.334$, $P = 0.001$; and $R = 0.290$, $P = 0.003$, respectively) [Figure 1]. In addition, the mean RI of the OA correlated significantly with HbA1c levels ($R = 0.321$, $P = 0.001$) [Figure 2].

ROC analysis showed that the RI of CRA was a definitive predictive indicator for DR. RI of the CRA ≥ 0.79 indicated the existence of DR with a sensitivity of 75% and a specificity of 73% (area under the curve = 0.780 [95% confidence interval: 0.650–0.909]) [Figure 3].

Discussion

DR, a common microvascular complication of diabetes, is one of the leading causes for preventable blindness in people of the working age.[11] There has been conflicting evidence on the ocular hemodynamics as to whether blood flow is increased or decreased in diabetics. Curtis *et al*. have proposed a hemodynamic framework which states that there is an initial reduction in the perfusion of retina before the onset of DR which later increases as DR progresses.[12]

The various hematological changes observed in diabetes such as increased aggregation of erythrocytes and platelets, increased blood viscosity, and reduced deformability of

Table 1: Demographic and clinical characteristics of controls and diabetic subjects

erythrocytes contribute to increased peripheral vascular resistance.[13] RI, an indirect measure of vascular resistance, can be useful to identify individuals at higher risk for developing DR. Further, RI, being independent of Doppler angle, has been shown to be reliable and reproducible with least coefficient of variation.[14]

Our study results demonstrate that significant changes occur in the RIs of the orbital vessels in patients with diabetes. The orbital vascular resistance (as reflected by RI) was found to be significantly increased in patients with DR as compared to controls and those in Group 1. Our observations are in agreement with certain other published studies.[15,16]

We observed no significant differences in the mean RI values between controls and those without DR. Our findings are similar to that of Basturk *et al*., who evaluated the RI of the orbital arteries in type 2 diabetics with microalbuminuria. No significant differences were observed in the mean RIs of OA, CRA, and PCA between controls and no DR group.[9]

In contrast, Dimitrova *et al*. have noted higher RI in the PCA in patients with no DR than controls.[17] However, their study included patients with hypertension and longer duration of diabetes than ours. In patients with hypertension, the RI of the PCA is reported to be high and correlates with duration of hypertension.[18] Moreover, CDI was performed in erect posture, which might have influenced the results. Few other investigators have noted increased RI values in the OA and CRA in patients with diabetes but without DR compared to that of controls, suggesting that even before the appearance of overt DR, there is increased resistance to blood flow in the peripheral vascular bed.[19,20]

We found significantly greater RI in the PCA and CRA ($P = 0.03$ and $P < 0.001$, respectively) in patients with DR compared to those without DR. While the inner layers of the retina are perfused by the CRA, the choroidal vasculature (derived from PCA) is responsible for the nourishment of outer retina. The various pathological changes observed in DR, such as loss of pericytes, thickening of the capillary basement membrane, and vascular smooth muscle cells, lead to compromised arteriolar integrity and autoregulation of blood flow. Loss of capillaries is critical to the pathogenesis of progressive retinal ischemia in DR and is a ubiquitous retinal finding from histopathological specimens.[21] Dropout of capillaries could be responsible for the increased vascular resistance observed in the RI of CRA and PCA in patients with DR. Further, the RI of the CRA was found to be a reliable predictive indicator of DR in our study. In this context, our findings are partly in agreement with that of Krasnicki *et al*., who have noted significant differences in the RI of CRA in subjects with DR and concomitant coronary artery disease.[5] The CRA, one of the major feeding vessels of the retina, reflects the identified vascular changes that have been associated with DR more sensitively. It has been suggested that hemodynamics in OA, a medium-sized muscular artery with many branches, is unlikely to be influenced by isolated alterations in blood flow in one of the branches.[22]

However, with progression of DR, the RI of the OA can eventually increase due to ensuing vascular changes related to diabetes in both retinal and choroidal vasculature.

Our finding of positive correlation between RI of all orbital vessels and the duration of diabetes is in concordance with that of Karami *et al*.[23] With prolonged duration of diabetes, alterations in blood vessel diameter and perfusion pressure occur due to disturbed autoregulatory mechanisms, subsequently leading to changes in the resistance of all retrobulbar vessels. We identified a statistically significant correlation between RI of the OA and the levels of HbA1c ($P = 0.001$). Clermont *et al*. have demonstrated reduction in the blood flow to retina with increasing HbA1c in subjects with type 1 diabetes without DR.[24]

Nagaoka *et al*. evaluated subjects with type 2 diabetes for changes in the retinal circulatory parameters using laser Doppler velocimetry and found significantly higher HbA1c in patients with the least retinal blood flow quartile, suggesting that poor glycemic control is associated with lowering of the retinal blood flow.[25]

Our study has several strengths. None of the patients had any associated vascular diseases such as hypertension. The presence of DR was assessed through seven-field stereo fundus photography for accuracy. A single experienced radiologist performed the CDI studies of the entire study participants, thereby eliminating interobserver variability. All examinations were performed with least pressure on the globe.

Limitations of our study include cross-sectional design and a small sample size. However, we intentionally excluded patients with other comorbid conditions to focus the effects of diabetes on retrobulbar circulation. Subgroup analysis of patients with different stages of retinopathy could not be performed because of limited sample size.

Conclusion

RIs of the orbital arteries are significantly higher in subjects with DR. RI of the orbital vessels can be a potentially useful biomarker in the early diagnosis and follow-up of patients with DR. This may be particularly helpful in patients with opacities in the ocular media.

Abstract

Background Acute ureteric colic is one of the most commonly encountered acute abdominal conditions. Diagnosis of obstruction caused by ureteric calculus occasionally becomes challenging if there is inadequate dilation of the urinary tract proximal to obstruction. In such a situation, intra-renal artery Doppler parameters can be used as a diagnostic tool. Our study compared intra-renal arterial Doppler in patients with obstructed and non-obstructed kidneys presenting within 24 h of onset of symptoms of unilateral acute renal colic.

Results The resistivity index (RI) in the segmental arteries of all 54 patients with obstructed kidneys was significantly higher than in those with non-obstructed kidney: 0.75 vs. 0.56, with a p value less than 0.001, a sensitivity of 85% and a specificity of 93%.

Conclusion Doppler ultrasound is a useful diagnostic tool in the evaluation of acute renal obstruction, thus enabling practitioners to avoid ordering unnecessary CT and exposing patients to ionizing radiation. An RI value > 0.7 has good sensitivity and specificity in our study. The results obtained in the study were comparable to those of pioneer studies conducted worldwide.

Background

Acute renal colic (ARC) is one of the common causes of patients presenting to the emergency room (ER). It accounts for 30–35% of urologic emergencies [1, 2]. The recurrence rate over a period of 5 years is 30–40% [2]. Ultrasonography (US) remains the most commonly used modality in the initial evaluation of patients presenting with acute abdomen, especially in children [3], and the utility of ultrasound in the diagnosis of ARC cannot be overstated in cases where ARC is one of the most common pathologies presenting as acute abdomen. Absence of significant dilatation of the pelvicalyceal system, in spite of severe obstruction being present, is a well-recognized finding in some patients. In some

Published online: 18 November 2020

Author's personal copy

studies, the absence of significant dilation in ARC has been reported in up to 30% [4] of patients. The dilated collecting system seen in US need not always be due to obstruction in the downstream urinary tract. These conditions include a baggy extra-renal type of pelvis, a compound upper pole calyx, due to over-distended urinary bladder, vesico-ureteric reflux, congenital type of mega calyces, infection and residual dilatation due to previous obstruction. Very rarely, pseudo-aneurysms of intra renal arteries can mimic renal pelvi-ectasis. This kind of vascular pathology can also be easily diagnosed with CDUS [5]. Acute complete ureteric obstruction is associated with changes in renal blood flow, as well as with an increase in renal pelvic pressure. In the first few hours, renal blood flow increases, and after 3 to 5 h, renal blood flow decreases, probably because of efferent arteriolar vasoconstriction produced by prostaglandins and other vasoactive substances [6, 7]. These changes can be effectively demonstrated by the RI of intra-renal arteries, as measured by Doppler ultrasound.

Methods

A prospective study was done on 54 patients who were referred to the department of radiology with clinical features of ARC for further evaluation with ultrasound or non-contrast CT. The study period is from January 2015 to December 2017. Prior to the commencement of the study, necessary clearance was obtained from the institutional ethics committee, and informed written consent was obtained from all the participating patients.

Inclusion criteria

All patients with symptoms of acute ureteric obstruction presenting to the emergency department within 24 h of onset of unilateral ARC were included.

Exclusion criteria

(a) Patients with history of renal parenchymal disease, chronic renal obstruction, renal trauma, or bilateral renal obstruction; (b) patients with a single kidney; and (c) patients in whom ureteric obstruction could not be confirmed either with USG or with CT were excluded.

All patients underwent gray-scale ultrasonography (US) and Doppler evaluation of intra-renal arteries. Computed tomography (CT) was done for those patients in whom US could not confirm the cause of obstruction.

Evaluation by ultrasound and Doppler study

The kidney on the side of obstruction was treated as the case kidney, and the contralateral normal (non-obstructed) kidney served as control. All patients underwent B-mode US and color doppler ultrasound (CDUS) with Philips iU22 using a C 1–5 transducer and Siemens Acuson S3000 using a 6C1 HD transducer. The presence or absence of pelvicalyceal system dilatation in each kidney was assessed using the gray-scale images. At least three Doppler spectra were obtained from inter-lobar arteries along the border of the medullary pyramids, and their mean was taken (Fig. 1).

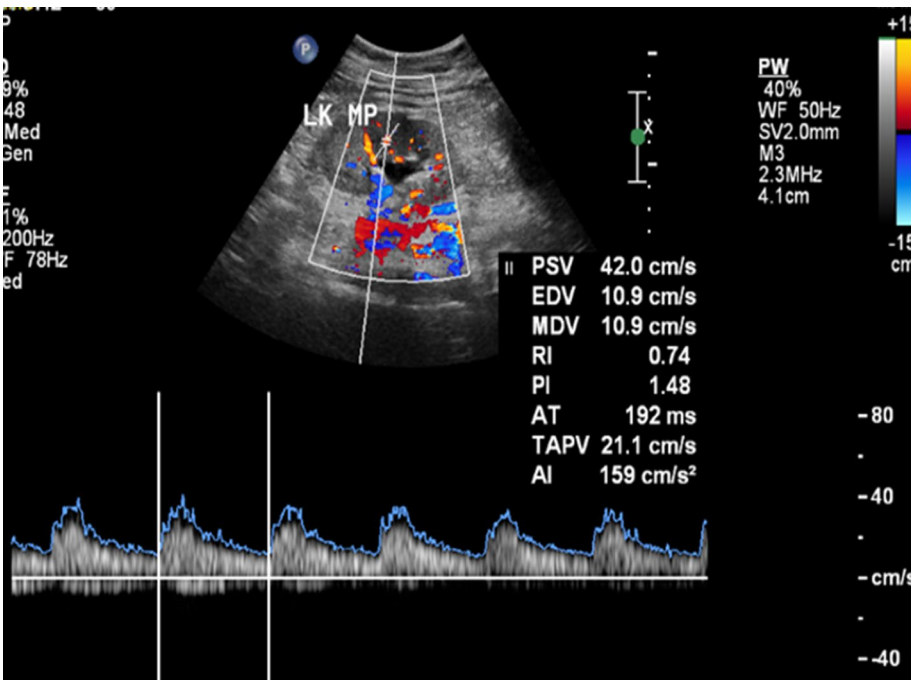

Fig. 1 Doppler US demonstrating an RI value of 0.74 in the mid pole of left kidney (obstructed kidney)

Author's personal copy

The Doppler waveforms were made using the lowest pulse repetition frequency possible without aliasing. This maximized the size of the Doppler spectrum and decreased the percentage error in the measurements. In addition, the lowest possible wall filter for each ultrasound scanner was used. The Doppler sample width was set at 2–3 mm. The renal RI was calculated using the standard formula. The mean RI value was calculated for each kidney.

Evaluation by computed tomography

Siemens SOMATOM Definition Edge 128 slice Computerized Tomography (CT) equipment was used for the study. Non-enhanced CT of the abdomen, extending from the dome of the diaphragm to the pubic symphysis, was performed in all patients in whom the site and cause of obstruction could not be confirmed with US. Raw data was acquired with 0.6 mm thickness and pitch of 0.8. Reconstruction from the raw data was done in 5 mm thickness for viewing purposes and in 1 mm thickness for coronal and sagittal multi-planar reconstruction (MPR) (Fig. 2). The sites of ureteric obstructions were identified. Those patients not confirmed to have obstructions by CT were excluded from the study.

Statistical methods

All data were systematically collected, tabulated and analyzed using Microsoft Excel and Strata 6 for Windows. The Student *t* test was used in univariate analysis for the continuous variables, and Chi square test was used for analysis of noncontiguous variables. A *p* value of less than 0.05 was considered to be statistically significant.

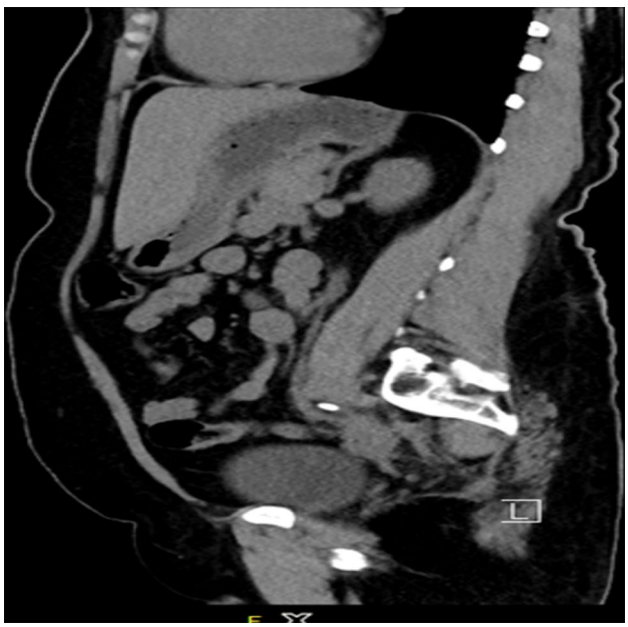

Fig. 2 Sagittal reconstruction of non-enhanced CT showing a calculus in the left distal ureter who presented with acute left renal colic

Results

This study evaluated 54 patients who had presented to the EMD with unilateral ARC within 24 h of the onset of symptoms. All the patients underwent B-mode US, CDUS and CT if the obstruction could not be confirmed in US. The presence or absence of PCS dilatation in each kidney was assessed using the grey-scale images. In this study population, 34 patients were males and 20 were females, as shown (Fig. 3). The mean age of the male patients was 46.8 years and that of the female patients was 38.5 years. The age range of the male patients was 19–79 years, and that of the female ones was 18–61 years.

The modalities used in the diagnosis and the site of obstruction are shown in Tables 1, 2.

Out of 54 patients, 26 cases proximal obstructions, while 28 had distal obstructions. The mean RI of the obstructed kidneys was higher in cases of distal obstruction (0.79 ± 0.004) than in those of proximal obstruction (0.76 ± 0.006).

Of the 54 patients, 45 patients had mild hydronephrosis, FIVE patients had moderate hydronephrosis and four patients did not have any dilatation of the collecting system despite the presence of ureteric obstruction (Fig. 4).

Of the 54 patients who were included in this study, 27 patients had elevated renal parameters, but did not have history of chronic renal impairment (Table 3).

In our study, we found that the RI in obstructed kidneys was significantly higher than in unobstructed kidneys (0.75 vs. 0.56; $p < 0.001$). The RI was higher in obstructed kidneys in all cases. The difference in RI between the obstructed and unobstructed kidneys (delta RI) ranged from 0.09 to 0.38, with a mean delta RI of 0.24 (Table 4).

The RI values in obstructed kidneys ranged from 0.68 to 0.84 (Fig. 5). The mean RI value in obstructed kidneys was 0.75, compared to 0.56 in unobstructed kidneys.

The group statistics of RI are shown in Tables 5, 6. The receiver operating characteristic curve (ROC) curve depicting the sensitivity of RI in ureteric obstruction is shown in Fig. 6.

By using a cut off RI value of > 0.70 in acute unilateral renal obstruction, the sensitivity obtained in the study was 85% and the specificity was 93% (Table 7).

Discussion

Grayscale ultrasound is the investigation method of choice in the initial evaluation of ARC, as it is easily available, portable and involves no ionizing radiation [8, 9]. However,

urinary system dilatation seen on conventional gray-scale USG has been shown to be sensitive (90%), but not specific (65–84%), in the diagnosis of renal obstruction.

The most sensitive, gold standard test for diagnosing obstructive uropathy is renal scintigraphy. However the availability of scintigraphy and radiation associated with it continue to be problematic [10]. Traditionally, the evidence of renal obstruction provided by US has been indirect and dependent on the anatomical criterion of dilatation of the pelvicalyceal system and ureter proximal to the level of obstruction. However, US fails to reveal hydronephrosis in acute obstruction of the kidney in up to 35% of cases [11]. More direct functional evidence of obstruction usually requires scintigraphy, but recently Doppler US techniques have been used to obtain functional information in suspected renal obstruction [11]. US imaging may miss (false negative) the diagnosis of obstruction in a variety of situations. Mild dilatation may be overlooked or considered clinically insignificant. Some patients with obstructive renal failure may show no pelvicalyceal system (PCS) dilatation. The reasons for this are unclear; in some patients, it may be related to dehydration or due to decompression of the pelvicalyceal system by rupture of a calyceal fornix [12]. It is commonly explained by urologists to be caused by the use of non-steroidal anti-inflammatory drugs (NSAIDs), by dehydration or by the renin angiotensin effect [13]. If that is true, such impairment will be detected through measurement of glomerular filtration rate (GFR). Measurement of GFR is commonly done using Technetium c-99 m diethylene-triamine-penta-acetate (DTPA), and does not require blood or urine sampling [14]. There is a growing evidence that renal impairment in acute unilateral ureteric obstruction is due to absorption of obstructed urine, with its high amount of creatinine, back into systemic circulation. This is considered false renal impairment with normal GFR [15]. In a study, El-Shazly et al. [16] measured renal function through measurement of estimated GFR (eGFR) usingTc-99 m DTPA. The authors showed that differences between eGFR on admission and after passage of stone or relieve of obstruction were non-significant. Their results support the hypothesis of false impairment in this clinical scenario. This tends to change the practice, as there is no need to embark on urgent intervention to relieve the ureteric obstruction, and conservative medical management is justifiable.

Routine B-mode US can be falsely positive or negative in acute ureteric obstruction [10]. PCS dilatation may be missed if the system is filled with blood clots, calculus, tumors or pus, in which case the usual anechoic appearance

of the PCS is lost. Intermittent ureteric obstruction, particularly that caused by ureteric calculi, may also lead to a failure to visualize dilatation of collecting system with US. On the other hand, in an attempt not to miss the diagnosis of obstruction in patients with only mild PCS dilatation, the false positive rate was found to be as high as 26% Causes of a false positive diagnosis include: (i) dilatation of non-obstructed PCS, when there are anatomical variants such as extra-renal pelvis; (ii) over-distended urinary bladder, with or without diuresis; (iii) vesico-ureteric reflux (VUR), (iv) residual dilatation of PCS due to previous obstruction or infection; (v) advanced pregnancy; and (vi) central renal fluid collections other than in the PCS, including in normal vessels, renal artery aneurysms and para-pelvic cysts.

Acute unilateral ureteric obstruction results in a complex sequence of changes in renal blood flow and ureteric

Author's personal copy

Cut off RI	Sensitivity	Specificity
> 0.70	85%	93%

pressure [17]. In the first two hours, the renal blood flow increases, because of afferent arteriole vasodilatation and the ureteric pressure increases. From two to six hours after obstruction, the renal blood flow decreases, secondary to vasoconstriction of the efferent arterioles, and the ureteric pressure remains elevated. Subsequently, at 6 to 18 hours, the renal blood flow remains reduced because of vasoconstriction of the afferent arterioles, and the ureteric pressure decreases.

The role of renal CDUS in the evaluation of ARC has been vigorously debated. Rodgers et al. [18] found an elevated RI in acutely obstructed kidneys, especially when compared with the RI in normal contralateral kidneys and with a control group of healthy subjects. Similar results were obtained by Platt et al. [19] in a study of 23 patients with acute unilateral ureteric obstruction. However, others have reported that Doppler ultrasound is highly insensitive for detecting ARC. Tublin et al. [20] correlated the results of Doppler USG with those of urography in 32 patients presenting with symptoms of renal colic. The RI value of normal kidneys is usually less than 0.7 [21, 22]. When the published discriminatory thresholds for obstruction (mean RI ≥ 0.70 and ΔRI ≥ 0.10) were applied, the sensitivity and specificity of Doppler USG were only 44% and 82%, respectively.

In our study of 54 patients, we found that the RI in obstructed kidneys was significantly higher than in the unobstructed kidneys (0.75 vs. 0.56; $p < 0.001$). The RI was higher in obstructed kidneys in all cases. The difference between the obstructed and unobstructed kidneys (delta RI) ranged from 0.09 to 0.38, with a mean delta RI of 0.24.

Saboo et al. [6] stated in their study that delta RI ≥ 0.006 was highly sensitive and specific, and with a higher delta RI specificity remained the same whereas the sensitivity fell rapidly. Our results correlate well with those reported in earlier studies by Badr et al. [23] and Miletic et al. [24].

We also studied the effect of the level of obstruction on RI values. When we compared levels of ureteric obstruction (proximal vs distal), distal obstructions had a higher mean RI value (0.79) than proximal obstructions (0.76), and the values were not statistically significant. However, the study done by de Toledo *et al.* [25] showed that patients with proximal ureteric obstructions have RIs higher than those with distal obstructions.

We also analyzed the utility of CDUS in patients who did not show dilatation of the PCS on ultrasound. Patients who did not have PCS dilatation on US were later confirmed to have obstruction on CT. RI values were higher in all these patients (0.71), with a delta RI of 0.24. Discriminatory RI ≥ 0.70, which is higher than the delta RI found in the study done by Platt JF et al. [26], was found to be highly sensitive (85%) and specific (93%) in this study.

Conclusion

Using the discriminatory threshold RI of ≥ 0.70, the overall sensitivity of CDUS in diagnosing acute ureteric obstruction is 85% and the specificity is 93%. CDUS is a useful tool for demonstrating altered renal perfusion in acute ureteric obstructions before pelvicalyceal system dilatation occurs, thus increasing the sensitivity and specificity. Gray-scale US should therefore, be complemented by CDUS as an adjunctive test in patients presenting with acute renal colic, as it is a very simple, noninvasive and easy-to-calculate parameter. The utility of this tool cannot be overemphasized in special cases like pregnant women and children, in whom a dilated pelvicalyceal system without acute obstruction is encountered more frequently. It is mandatory to differentiate obstructive and non-obstructive causes with US alone in this subset of patients, as further evaluation with CT is not desirable due to the hazard of ionizing radiation. Given the high propensity of any group of patients with urinary tract calculi to undergo frequent imaging studies due to recurrent ureteric colic and the presence of significant residual hydronephrosis, we should strive hard to minimize radiation dosage by avoiding frequent CT studies. At the same time, maintaining acceptable diagnostic accuracy is of paramount importance.

Author's personal copy

Limitations of the study: US is an operator-dependent examination and the results are affected by patients' body habitus and availability of good window. An increase in the RI of intra-renal vessels is also found in case of vascular or parenchymal diseases (renal vein thrombosis, acute renal insufficiency, etc.). The CDUS changes can return to normal after 48 h [27], after which its utility is doubtful with reduced sensitivity and specificity.

Abstract

Purpose: To study the impact of an early clinical exposure program designed to provide a wide variety (cognitive, affective and psychomotor) of learning experiences for the preclinical year students.

Method: One hundred and fifty preclinical students were posted in small groups to selected departments – Transfusion medicine, Catheterization lab, Simulation Lab, Radiology, Neurology, Nephrology, Respiratory Medicine and General Surgery, . Each student had atleast 10 hours of clinical exposure under this program. The program was evaluated through a series of pre and post test questionnaires, which were designed based on the learning objectives of each session. Students were also asked to give their written open comments about the program.

Results: There was a significant increase in the post-test scores when compared to the pretest scores for all the sessions. Analysis of the open feedback showed that the program had significant impact on the cognitive, psychomotor and affective domains. "Application of basic

ACCEPTED MANUSCRIPT

sciences in clinical practice", "motivation to learn", "got familiar with various specialties", "insight about what the patient undergoes" were the themes identified from the open comments.

Conclusion: Implementation of an early clinical exposure program has been left to the discretion of individual institutions. The innovative use of Early Clinical Exposure program to teach/learn clinical skills like phlebotomy and Basic Life Support had been well appreciated by the students. The present design involving a variety of learning experiences has been successful in introducing the various dimensions of medical profession like scientific, ethical, interpersonal, professional and social to the new entrants in addition to enhancing their motivation to learn. A well designed ECE program could be the ideal first step in the making of a holistic doctor.

Keywords: attitude, learning, simulation lab, medical education, curriculum.

1. Introduction

In India, students enter medical schools at an early age with little priming towards the profession. Entry of students in most of the medical colleges is entirely based on their academic performance with no weighting for humanistic attitude and communication skills. [1, 2] Due to lack of adequate exposure, most students do not realize what to expect in the medical profession. A few enter the medical college purely due to parental pressure. [3] Large classes, intense competition, exploding vocabulary and voluminous content delivered over a short time are some of the challenges faced by the first year MBBS students. [3, 4] Insufficient level of guidance and problems pertaining to transition from school to college life can also be included to this list of problems faced by the students during this period. Some students find the abrupt shift of medium of instruction from vernacular language to English difficult to cope. All these, along with the traditional curriculum, where the students are engaged in long hours of classroom and laboratory teaching with no exposure to the clinical setup, plays a major role in dousing the enthusiasm of the upcoming doctor. Under these circumstances, students often find their preclinical year to be tough, dreary and most importantly, they fail to understand the relevance of basic sciences in the clinical setting.

There has been an urgent call for curricular reforms with emphasis towards vertical and horizontal integration and competency based training.[5] Many parts of the world have responded to these needs by shifting away from discipline-based curriculum. In line with these changes, Medical Council of India (MCI) developed the 'Vision 2015' document. MCI vision 2015 aims to produce a new generation of medical graduates of global standards through curricular reforms. "The roles of this new age doctor are recognized as clinician, communicator, life-long learner, team leader and professional".[6] Required curricular changes begin early in the form of a

foundation course; early clinical exposure; properly designed integrated teaching and programs to develop the correct attitude and communication skills (ATCOM module). [6]

Early clinical exposure (ECE) needs to be a coordinated effort by the preclinical, paraclinical and clinical faculty. If implemented effectively, it has the potential to improve motivation for learning and promote deep learning, better understanding and longer retention of the knowledge. It can facilitate the students to understand the application of basic sciences in clinical practice and aid in effective learning of clinical skills. It could also serve as a platform for students to improve their communication skills and get initiated into inculcating professionalism at a very early and impressionable stage of their medical education.[7] Above all, it provides an opportunity for them to see the illness from the patient's perspective. All this can foster the development of a holistic doctor who will be competent, communicative, humanistic and empathetic towards the patients.

To offer this experience, 'Clinical observership' program was started in PSG Institute of Medical Sciences and Research (PSGIMSR) in the year 2000. In this program, the first year MBBS students had the opportunity to spend half a day in the following selected specialties in small groups: cardiology, gastroenterology, radiology, nephrology and transfusion medicine. This initiative was highly appreciated by the students.[8] This program has now been modified and expanded to include more departments and implemented readily to suit the mandates from MCI as Early Clinical Exposure. The impact of this program was evaluated.

2. Methods

2.1 Participants

Accepted manuscript

ACCEPTED MANUSCRIPT

One hundred and fifty first year MBBS students participated in early clinical exposure program conducted in the year 2015-16. Students were divided into 3 batches (A, B, C) based on their roll numbers. Each batch was further divided into 5 small teams comprising of 10 students. Each team spent an hour (from 4pm to 5 pm) in the clinical departments every day of the week in turns, ensuring that there were no more than 10 students in an ECE session. Though attendance for the ECE program was compulsory as per MCI and University guidelines, participating in the program evaluation and giving feedback was strictly on voluntary basis. Informed consent was obtained from the participants. The study was approved by the Institutional Human Ethics committee (No: 15/343)

2.2 Materials

The program was implemented in two cycles of three weeks duration. Five clinical departments were covered in each cycle. The first cycle of ECE sessions were conducted in the months of Nov-Dec 2015 and included rotations in Clinical simulation laboratory (for phlebotomy training), blood bank, and departments of neurology, radiology and surgery. During the second rotation of the program, which was conducted in Mar 2016, the students were posted once again in Clinical simulation laboratory (for Basic life support training) and radiology in addition to the departments of nephrology, respiratory medicine and cardiology (Catheterization Laboratory).

2.3 Procedure

An orientation session for the students was conducted by the program coordinator prior to starting the rotations, wherein the objectives of the program, clear directives regarding the conduct of the sessions and the expected goals of this innovative venture were highlighted.

Accepted manuscript

ACCEPTED MANUSCRIPT

Clinical department postings were coordinated by a faculty in each department. The designate faculty drew out the learning objectives for this session based on the student's prior knowledge and availability of clinical materials. This arrangement was kept uniform for the entire class. Based on the learning objectives, questionnaires were formulated for all the sessions and used as pretest and posttest for the students. Students who wished to participate in the program evaluation gave informed consent, took part in the pretest and post test and were also encouraged to give their written open comments anonymously.

2.4 Data collection and analysis:

The questionnaires were designed in a five point Likert scale with 6-10 items to assess the effectiveness of ECE sessions. The scores used were 1 = not aware, 2 = not sure, 3 = know vaguely, 4 = know with reasonable clarity and 5 = know confidently. The questionnaire was meant to assess the impact of the program on the students. This was achieved by comparing the scores obtained by the students in pre-post tests. The scores were expressed as mean ± standard deviation and were compared by paired't' test using IBM SPSS software version 19.

The open comments regarding the program were analyzed through inductive approach. [9] Specific themes were identified and the comments were assigned to the appropriate theme.

Accepted manuscript

3. Results

Among the one hundred and fifty participants, one hundred and forty four participants submitted their filled in pre and post test questionnaires. There was a significant increase in the post-test scores when compared to the pretest scores for all ECE sessions (Table 1).

4. Discussion

Regulatory bodies of the medical education have spelled out clearly that the medical education needs to be geared to train professionals capable of providing holistic care to patients with compassion.[6] Early clinical exposure, if implemented effectively could very well initiate the changes in the medical education system in the right direction to achieve the stipulated goal.

ACCEPTED MANUSCRIPT

There have been no clear directives to implement this program in terms of content, duration and mode of delivery. This has left the challenging responsibility of designing ECE entirely to the individual institutions, and the resultant programs would certainly depend upon the resources and initiatives available. Reports on the details of the conduct of ECE are scanty.[11-13] Interactive lectures, case scenarios, case based learning and occasional hospital visits have been implemented by a few of the institutions, as part of ECE.[11-13] In PSGIMSR, this program has been implemented as postings to selected departments of not less than an hour's duration per session. Each student gets an exposure of at least ten hours of this experience. The posting involves a variety of experiences like observing an interventional or investigative procedure, seeing a patient in ward or observing the doctor-patient interaction in the outpatient clinics, observing the demonstration of clinical signs, learning and practicing skills like phlebotomy or Basic Life Support (BLS) on manikins in the Clinical simulation laboratory.

First year MBBS students have a demanding schedule with enormous course content being delivered in just 10-11 months. In such a crucial situation finding time for ECE is a challenge. Last hour of the working day was selected for this program without interfering the conventional teaching sessions. Keeping the program at the end of the day also gave an opportunity to extend the session beyond the allotted hour when required and accommodated the availability of the patients for a particular procedure.

Selection of departments were done with an intention to expose the students to a variety of learning experiences involving all the three domains of learning- cognitive, psychomotor and affective. The central theme was to make students relate the basic science subjects they were learning in lecture classes to the clinical practice. The program also included super specialty departments like cardiology, nephrology and neurology for which the students would not have

Accepted manuscript

ACCEPTED MANUSCRIPT

the opportunity to be exposed in their regular curriculum. This provided a chance for the new entrants to interact with veteran specialists and super specialists, thus giving the students a peek at the prospects that lay ahead of them.

The departments to which the students were posted in each rotation were selected based on the subject matter covered in basic sciences until the time of the program. For example, the first rotation concurred with the completion of lower limb in anatomy, hence visiting the surgery department to see a case of varicose veins/ peripheral vascular disease was more pertinent than visiting Catheterization Lab. Catheterization Lab was reserved for the second rotation, which was scheduled when the students were learning or just finished learning thorax and abdomen in anatomy.

The learning objectives for each session were chosen carefully in view of student's prior knowledge, the availability of clinical material and relevance. In departments like nephrology, radiology, simulation lab, blood bank the content was fixed and all students were uniformly exposed. For example in nephrology, the students witnessed a patient undergoing dialysis. The principle of dialysis, biochemical alterations in the blood before and after dialysis was discussed. In other departments like respiratory medicine, surgery, neurology the experience was more impromptu, based on the availability of cases. In cardiology, the objective was to give the students an experience of observing coronary angiogram followed by a discussion on the relevant anatomical aspects. If there were no patients scheduled for angiogram at the time of ECE session they were allowed to view the recorded procedure.

Most students appreciated the ECE experience as 'inspiring', 'motivating', 'interesting' 'awesome', 'useful', 'good way of learning', 'evoked self interest'. They felt it helped them see

Accepted manuscript

ACCEPTED MANUSCRIPT

the relevance of basic science in clinical practice. Interested students also contacted the clinicians in the specialty of their choice later and pursued their interest in the subject. For students who enter the medical profession without prior exposure, this program provided a bird's eye view of the opportunities that lay ahead of them as evidenced from their comments like 'Knew about various departments/ specialties in the hospital, their functioning & infrastructure' 'Made us familiar with various fields'

In the Clinical simulation Laboratory students had instructions in Phlebotomy in the first rotation and hands-on training in BLS in the second rotation. BLS enables a person to recognize and support people in life threatening emergencies until full medical care can be provided. Any trained person can perform this if the need arises. Introducing BLS training as early as possible is considered essential and may help to increase their eagerness to learn and passion for the profession.[10,14] ECE could be the ideal platform to introduce BLS training to the medical students. Students in their feedback expressed that learning BLS empowered them and made them feel more confident.

The program seemed to have helped students to develop a humanistic attitude towards the patients as evidenced by their comments like –'developed an insight about what the patient undergoes', 'learnt how to behave kindly with patients', 'learnt the importance of human life'. They also commented that they gained an insight about the various roles/duties of a doctor. Students were of the opinion that more departments need to be incorporated in the program and the duration of the program should be increased. Authors fully endorse these views and feel that time factor could probably be a major restriction for expanding this program as per the students' wishes.

Accepted manuscript

ACCEPTED MANUSCRIPT

Conclusion:

ECE can serve as a platform for providing the preclinical year students a cosmic variety of experiences involving all the three domains of learning. It can also be adapted as the teaching strategy to introduce the various dimensions of medical profession like scientific, ethical, interpersonal, professional and social. This program if implemented effectively has the potential to be the ideal first step in the making of a holistic doctor.

Acknowledgements

The authors thank Dr. R. Karthick Prabhu (MD Pathology) and Dr. S Hemachandran (MS General Surgery), for their support in implementing the program.

ABSTRACT

Background: Chronic abdominal pain is a common gastrointestinal symptom in children that significantly lowers their quality of life. In adults, Gall bladder (GB) hypomotility / dyskinesia is associated with many functional abdominal disorders but there is scarcity of evidence on its role in childhood gastro-intestinal disorders. Aim of the study is to evaluate the GB motility in children with chronic functional abdominal pain (FAP).
Methods: Children aged 5-15 years with chronic abdominal pain fulfilling ROME-III criteria and healthy controls were included and all study participants were subjected to ultrasonographic evaluation of the gall bladder volume in fasting state and post - Fatty test meal (FTM) and its ejection fraction was calculated.
Results: Sixtysix children including 31 with chronic FAP underwent sonographic evaluation for GB motility. The mean ejection fraction (EF) of cases and controls were 51.72±17.76% and 57.3±23.26% (p value - 0.158). The mean EF of cases with upper abdominal pain and lower/peri-umbilical abdominal pain were 41.7±17.1% and 57.2±15.9% respectively (*p* value < 0.0001). Increasing BMI had no significant association with GB motility among the participants.
Conclusions: There is lack of significant association between children with chronic FAP and GB hypomotility. Children with upper abdominal pain have lesser GB EF, suggesting a possible abnormal GB motility.

Keywords: Childhood functional abdominal pain, Gallbladder, Ultrasonography

INTRODUCTION

Chronic abdominal pain is a common gastrointestinal symptom in children presenting to outpatient department. In United states and Europe, its prevalence rates ranges from 0.3 – 19% among school-going children and accounts for about 2% to 4% of all pediatric office visits.[1,2] Though it is not associated with any organic gastrointestinal pathology, children with FAP have a significantly lower quality of life and it contributes for school – absenteeism.[3] In 1999, the term abdominal pain related-functional gastrointestinal disorders in pediatric ROME II criteria, which included functional dyspepsia, functional abdominal pain (FAP), irritable bowel syndrome and abdominal migraine. These terminologies were further redefined based on duration of symptoms before diagnosis in ROME III criteria.[3]Many functional gastrointestinal disorders like functional dyspepsia, irritable bowel syndrome and disorders of Gall bladder (GB) has been studied for any possible association with abnormalities in GB motility, but the results are inconclusive.[4] In adults, GB hypomotility/dyskinesia is well established in idiopathic constipation and functional dyspepsia, but there is scarcity of evidence on its role in childhood functional abdominal disorders.[5,6] Our study

was designed to study the GB motility in children with functional abdominal pain.

METHODS

This crosssectional study was done in the outpatient department of pediatrics, PSG institute of medical sciences from January 2016 to August 2017. Children aged 5-15 years attending the OPD of the institution with chronic abdominal pain fulfilling ROME-III criteria, without any obvious cause for abdominal pain and with no previous abdominal surgeries were included in the study. Healthy children who visited the hospital for routine health visit or vaccination were included as controls. Institutional Human ethical committee approved the study and all study participants were included after obtaining informed consent. A detailed history including dietary and allergy history was obtained and clinical assessment was done. They were documented in a pre-designed data collection tool.

A total of 31 cases and 35 controls were recruited in the study and all study participants were subjected to ultrasonographic evaluation of the gall bladder in fasting state. A radiologist experienced in pediatric Sonography performed the evaluation using Philips iU22 xMATRIX ultrasound system. The Gall bladder was assessed for its area, thickness and volume, where area was derived by trace method and maximum GB width and length were measured using transverse and longitudinal images of the GB.

The volume of GB was calculated in fasting and 30-minutes following a fatty test meal using Dodd's formula, Volume (in cm^3) = 0.52 x [L x W x A], where L is the greatest length, W- greatest transverse width, and A-greatest anteroposterior diameter of the GB. The gallbladder ejection fraction (EF) for each examination was obtained from two-volume data using the following equation. Where V_0 = gallbladder volume in fasting state, Vn = gallbladder volume after the fatty test meal,

$$EF\ (\%) = [(Vo-Vn) / Vo] \times 100$$

For the purpose of this study, Children with ejection fraction of less than 40% were considered to have gallbladder hypomotility.

Statistical analysis was done using statistical package for the social science version-19 (SPSS) software. The fasting and post-prandial GB volume was expressed as mean ± SD and students t test was used to compare their means between groups. Chi-squared testing was applied to look for possible association between EF and BMI. A p-value less than 0.05 was considered significant.

RESULTS

There were a total of 66 children included in this study. The mean age of cases and controls were 10.14±2.71 years and 11.54±1.94 years respectively. The mean height of the cases group was 132.9±15.9 (range – 100 to 165cms) and that of controls was 145.14±11.6 (range – 110 to 159cms). The mean weight of cases and controls were 27.3 ± 10.5 Kg and 33.8 ± 6.6 Kg respectively. The mean body mass index (BMI) was 14.9±2.8 kg/m^2 (range of 11.3 to 26.3 kg/m^2) in case group and 15.9±1.8 kg/m^2 (range from 11.9 to 19.5 kg/m^2) in the control group. Out of 31 cases there were 11 boys (35.5%) and 20 (64.5%) girls respectively and in 35 controls there were 23 (65.7%) boys and 12 (34.3%) girls respectively (Table 1).

Table 1: Baseline characteristics in the study groups.

Clinical parameters	Cases (n=31)	Controls (n=35)	P value*
Age (in years)	10.14±2.71	11.54±1.94	0.08
Gender ratio	1:2	2:1	-
Height (in m)	1.34±0.15	1.43±0.11	0.06
Weight (in Kg)	27.3±10.8	34.31±6.3	0.03
BMI (Kg/m^2)	14.60±3.1	16.59±1.60	0.03
Abdominal pain			
Predominantly Upper (%)	11 (40%)	-	
Predominantly Lower (%)	19 (60%)		

*Student's T-Test

The mean fasting and post-prandial gallbladder volumes of cases and controls were 8.20±3.97 (cm^3), 7.52±3.13(cm^3) and 3.51±1.57 (cm^3) and 2.94±1.59 (cm^3) respectively. Though the fasting GB volumes were greater than post-test meal, in both groups, yet there was no statistical significance (P value – 0.390) (Table 2). The mean ejection fraction of cases and controls were 51.72±17.76% and 57.37±23.26% (p value – 0.158).

Table 2: Comparison of GB Volume and Ejection fraction in study groups before- and following a fatty test meal (FTM).

Groups	GB Volume (in mm^3)		Ejection Fraction (%)
	Fasting	Post-FTM	
Cases	8.20±3.97	7.52±3.13	51.95±18.02
Controls	3.51±1.57	2.94±1.59	57.04±23.03
P-value*	0.797	0.127	0.239

*Student's T-Test

The ejection fraction of GB were compared among children with functional abdominal pain who presented predominantly with upper or lower / peri-umbilical regions, to identify any possible association between the site of abdominal pain with GB motility. The mean ejection fractions of cases with upper abdominal pain and lower/peri-umbilical abdominal pain were 41.7±17.1% and 57.2±15.9% respectively (p value <0.0001), but the former did not qualify for the definition of GB hypomotility i.e. EF<40% (Table 3).

Table 3: Comparison of GB Volume and Ejection fraction based on the site of abdominal pain.

Site of Abdominal pain	GB Volume (in mm^3)		Ejection Fraction (%)
	Fasting	Post-FTM	
Predominantly Upper	7.41±3.13	4.17±2.15	41.73±17.13
Predominantly Lower	8.67±4.40	3.13±1.0	57.87±16.12
P-value*	0.497	0.25	0.019

*Student's T-Test

In order to identify any possible association between increasing BMI and GB contractility among cases, they were sub-grouped as, BMI<16 and BMI ≥ 16. There was equal number of children (n=4) in each subgroup with EF<40%, suggestive of GB dysmotility and their mean EF were 54.28 ± 17.99 % and 48.19 ± 17.53 % respectively (*p*-value < 0.001) (Figure 1).

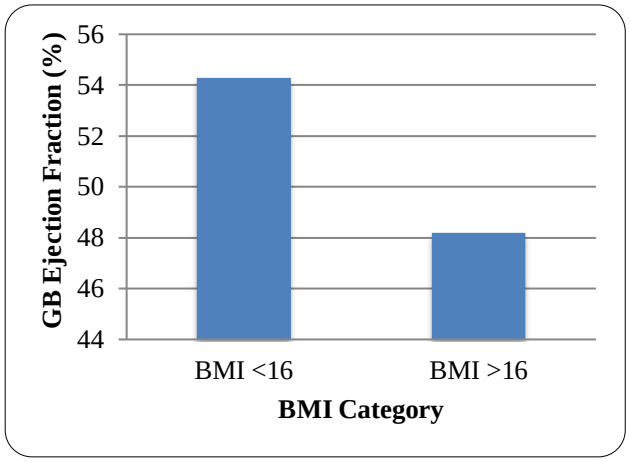

Figure 1: GB ejection fraction among bases grouped based on BMI.

DISCUSSION

In our study, we found no significant difference in the gall bladder volume (in fasting state and post Fatty test meal) among the cases and controls with equal number of children in both groups with GB ejection fraction <40%. Children who presented with upper abdominal pain had significantly lesser ejection fraction than those with lower abdominal pain. Many adult studies have recognized GB hypomotility in obese patients than non-obese patients. Sari et al found a positive correlation between fasting gallbladder volume and body mass index and body fat weight in obese women than non-obese women, but no such studies were available for comparison in children.[7] In the present study there existed no significant association in GB dysmotility and increasing BMI among cases.

The exact pathogenesis for FAP remains unclear, but visceral hypersensitivity, abnormal brain - gut interaction, immune dysregulation and altered gut motility has been postulated for the occurrence of the symptoms.[8,9] Gall bladder dyskinesia has been associated with various gastrointestinal symptoms like bloating, dyspepsia, post prandial epigastric pain and upper abdominal fullness.[10]

Mehra et alm observed gall bladder hypomotility in children with functional constipation, thus strengthening the claim of GB dyskinesia as a possible claim for functional abdominal symptoms in children.[11] Several imaging modalities like oral choledochocystography and syntigraphy are utilized to assess GB contraction but Sonography has been reliably used for assessing the GB area and volume, their changes following a fatty meal.[12] Ultrasonography could be preferred for its noninvasive nature and no radiation exposure that accompanies other modalities.

In our study we found 8 (26.7%) of the children with FAP healthy and 9 (25%) controls with mean GB Ejection fraction <40% suggesting that GB hypomotility could possibly be unrelated for the abdominal pain. Interestingly children who had predominant upper abdominal pain had low GB Ejection fraction compared to the children with lower abdominal pain (41.73±17.13% vs 57.87±16.12%) as noted by Hofeltd et al, in their study where a majority of children (96.67%) who underwent laproscopic cholecystectomy for biliary dyskinesia had upper quadrant pain.[13] A similar study with more subjects with FAP localized predominantly to upper abdominal could establish an association with GB motility.

Few limitations in our study are firstly the children were consecutively enrolled and sample size of the study is too small for drawing strong conclusions. Secondly the co-existing infection like H. pylori or parasitic infection of gut could possibly have an impact on the abdominal pain that was under evaluation. Nonetheless the present study is the first of its kind that has meticulously evaluated the GB volume and contractility in children with FAP and has found a possible association of GB dyskinesis with upper abdominal pain.

CONCLUSION

To conclude, abnormality in GB motility could be a cause for FAP presenting predominantly as upper abdominal pain in children thus necessitating its evaluation and a larger well-controlled study might help in better understanding of the entity.

Evaluation of retrobulbar circulation in type 2 diabetic patients using color Doppler imaging

K Divya, Vikrant Kanagaraju[1], B Devanand[1], C Jeevamala, A Raghuram, D Sundar

Purpose: To investigate the retrobulbar circulatory parameters in type 2 diabetes mellitus patients with color Doppler imaging (CDI) and compare the results with nondiabetic controls. **Methods:** This prospective study included 50 type 2 diabetic patients and 50 age-matched controls. Seven field stereo fundus photography was used to diagnose and classify diabetic retinopathy (DR). Diabetic patients were further divided into two: Group 1, consisted of patients with no DR, mild and moderate non-proliferative DR (n = 36); Group 2, severe nonproliferative and proliferative DR (n = 14). CDI was performed using Philips iU22 xMATRIX ultrasound. The peak systolic velocity (PSV), end-diastolic velocity (EDV), resistivity index (RI) and pulsatile index (PI) of ophthalmic (OA), posterior ciliary artery (PCA), and central retinal artery (CRA) along with central retinal vein (CRV) were recorded. **Results:** RI in the ophthalmic artery was significantly higher in both DR groups than the control group (P = 0.000). Diabetic Group 1 had decreased blood flow velocity (PSV and EDV) in PCA compared to controls (P = 0.046 and P = 0.010, respectively). Group 2 DR had significantly reduced EDV and increased RI in CRA compared to Group 1 (P = 0.015). Binary logistic regression analysis revealed glycosylated hemoglobin and RI of OA to be independent risk factors of DR. **Conclusion:** Significant changes in resistivity index and flow velocities were observed in the retrobulbar vessels, especially in ophthalmic artery in diabetics compared to controls. CDI with results of increased resistance or decreased flow could be useful to predict individuals at higher risk for developing severe DR.

Ocular manifestations of diabetes are numerous and among them, diabetic retinopathy (DR) is a major clinical issue for ophthalmologists. DR is the most frequent cause of preventable blindness in working-age adults (20–74 years) and is therefore considered as a major public health issue.[1] Though treatable in appropriate stages, the prevention of retinal complications of diabetes and consequent visual impairment is vital to reduce the burden of DR. There is a felt need for better diagnostic modalities and surrogate markers in the evaluation and management of DR.

In spite of decades of research, the mechanisms behind the onset and progression of DR still remain unclear. From a hemodynamic point of view, evidence has shown that there is an early reduction in blood flow to retina before the onset of DR followed by a gradual increase as the retinopathy progresses.[2] Color Doppler imaging (CDI) is an established, safe, and noninvasive ultrasonic method useful for qualitatively and quantitatively assessing the blood flow velocities and indirect blood flow.[3] CDI has been suggested to be valuable in the diagnosis and management of several ocular diseases with altered hemodynamics such as glaucoma, retinal vascular diseases, ischemic optic neuropathy, and ocular ischemic syndrome.[4] An analysis of retrobulbar hemodynamics in diabetes using CDI can provide insight into the pathogenesis and prospective treatment for DR as well as predict those at higher risk of developing vision threatening DR. Several authors have evaluated the circulatory changes in diabetics using CDI and reported conflicting results. While few studies have reported a reduction in the retrobulbar blood flow velocities,[5-7] others have noted an increase[8] or no change.[9] Studies on the resistive index (RI) of orbital vessels which is a measure of peripheral vascular resistance have also shown significant discrepancies.[10,11] Factors such as demographic variables, duration of diabetes, methods of DR assessment, positions of CDI, and sample sizes account for the observed discrepancies. Moreover, most studies have not excluded patients with hypertension and those on medications affecting systemic blood flow which can influence the results. Studies on orbital hemodynamic alterations among type 2 diabetics from India are relatively few. The diabetic population in India is close to hitting the alarming mark of 69.9 million by 2025 and 80 million by 2030, denoting an expected increase of 266%. Hence, India is deemed as the world's capital of diabetes.[12] With increasing prevalence of diabetes and DR, it is important to know the hemodynamic alterations among diabetics from the Indian population.

The objective of this study was to evaluate the flow velocities and vascular resistance of orbital blood vessels using CDI in a pure cohort of type 2 diabetic patients from India and compare the results with healthy controls.

Methods

This prospective hospital-based study was carried out at a tertiary care institution from south India between March 2017 and April 2019. The study included consecutive patients of type 2 DM (as per definition of the American Diabetes Association) attending the ophthalmology outpatient clinic for the screening of retinopathy. Exclusion criteria were history of any ocular disease that might affect ocular blood flow such as glaucoma, nondiabetic retinal vascular occlusion, ocular inflammation, high myopia, previous ocular surgery, or panretinal photocoagulation. Patients with systemic hypertension, dyslipidemia, nephropathy, and cardiovascular diseases were excluded from the study. Pregnant and breastfeeding women were not included. Patients taking medications known to affect systemic hemodynamics such as Angiotensin-converting enzyme inhibitors, calcium channel blockers, and anti-migraine drugs were also excluded.

50 age-matched healthy subjects were enrolled as a control group. The control subjects were recruited from individuals attending the department of ophthalmology for a routine eye examination. They were not on any medication and did not have ocular or systemic disease. The study was conducted according to the principles of the Declaration of Helsinki and the study protocol was approved by the institutional ethics committee. Informed consent was obtained from all participants.

Information regarding age, gender, body mass index, duration of diabetes, antidiabetic medications, and blood pressure were obtained from all participants. Serum glycosylated hemoglobin (HbA1c) was determined from fasting venous blood sample.

All study participants underwent a comprehensive ophthalmic examination including dilated fundus with slit-lamp biomicroscope using a 90 diopter lens and indirect ophthalmoscopy. A 30° stereoscopic fundus photograph of 7 standard early treatment diabetic retinopathy study (ETDRS) fields was taken from both eyes of diabetic patients using a digital fundus camera (TRC-50 DX Mydriatic retinal camera; Topcon Medical Systems, Oakland, NJ).

The presence, as well as the severity of diabetic retinopathy, was determined by grading of color fundus photographs following the international clinical disease severity scale for diabetic retinopathy which is based on the findings of WESDR (Wisconsin Epidemiological Study of Diabetic Retinopathy) and ETDRS.[13] The diabetic patients were assigned to one of the following groups namely no retinopathy, mild nonproliferative diabetic retinopathy (NPDR), moderate NPDR, severe NPDR, and proliferative diabetic retinopathy (PDR). The

eye with worse retinopathy was included in the study. If both eyes had equal retinopathy, the right eye was assigned to the study.

Color Doppler sonography of the eye was performed for cases and controls by a masked expert Radiologist using a color Doppler unit and a 12 to 5 MHZ linear-array transducer (Philips iU22 xMATRIX ultrasound system). The patients were examined in the supine position and care was taken to avoid any undue pressure on the eye. Examiner's hand was rested on the orbital margin and sterile coupling gel was applied over closed eyelids. The Doppler signal was registered online after the cursor was positioned on the region of interest. To reduce errors in measurement of velocities, angle correction was applied to the pulsed Doppler recordings.

The peak systolic velocity (PSV) and end-diastolic velocity (EDV) readings were obtained from the ophthalmic artery (OA), central retinal artery (CRA), and the posterior ciliary artery (PCA). Since the velocity wave in a central retinal vein (CRV) is not in direct relation to the cardiac cycle its hemodynamic parameters were expressed as maximum (V max) and minimum (V min) blood velocity. Signals from the ophthalmic artery were obtained from the medial aspect of the eyeball, superior to the optic nerve. The central retinal artery and vein were located within the optic nerve, around 10 mm behind the eyeball. [Fig. 1] Signals from the temporal branch of the short posterior ciliary artery were located lateral to the optic nerve.

With the help of PSV and EDV, we calculated the vascular resistance expressed by the resistivity index and pulsatile index using Pourcelot's formula.

Resistive index (RI) = (PSV-EDV)/PSV; Pulsatile index (PI) = (PSV-EDV)/Vmean

Statistical analysis

For statistical analysis diabetic patients were further divided into two groups; Group 1 included patients with no retinopathy, mild NPDR, and moderate NPDR while Group 2 consisted of patients with severe NPDR and PDR.

Statistical analysis was performed using statistical package for social sciences (SPSS, SPSS Inc, Chicago, IL, USA) version 24. Data were expressed as mean ± standard deviation. The normality of data distribution was tested by the Kolmogorov-Smirnov test. One-way analysis of variance (ANOVA) with a *post hoc* Bonferroni was used for the analysis of normally distributed continuous data. Kruskal-Wallis analysis was used for analyzing non-normally distributed data. A comparison between hemodynamic parameters was calculated by ANOVA followed by Tukey-Kramer *post hoc* comparison. Pearson's coefficient was used to study the correlation between variables.

Table 1: Demographic and clinical characteristics of controls and diabetic subjects

Characteristic	Controls (*n*=50)	Group 1 (*n*=36)	Group 2 (*n*=14)	*P*
Age (years)	56.5±9.00	55.5±8.60	51.9±5.64	0.209

Binary logistic regression analysis was performed to determine independent risk factors for retinopathy. All tests for statistical significance were two-tailed and performed assuming a type I error probability of <0.05.

Results

Demographic and clinical parameters

The study included 52 males and 48 females. The age of patients ranged from 41 to 76 years. The duration of diabetes ranged from 6 months to 20 years. Among the diabetic patients, 29 were on oral hypoglycemic agents, 9 were on insulin, and 12 were on combination therapy. Group 1 (n = 36) consisted of 16 patients with no DR, 13 with mild NPDR, and 7 with moderate NPDR. Group 2 (n = 14) consisted of 6 patients with severe NPDR and 8 with PDR. There were no statistically significant differences in the age, body mass index and blood pressure between controls and diabetic groups. Glycosylated hemoglobin (HbA1c) levels were found to be significantly higher in Group 2 diabetic patients (P = 0.014). No significant difference was noted in the duration of diabetes among diabetic groups. The demographic and clinical characteristics of controls and diabetic subjects are presented in Table 1.

Hemodynamic parameters

Table 2 shows the hemodynamic parameters of retrobulbar blood vessels among controls and patient groups.

Ophthalmic artery

Significant differences were noted in the RI and PI values of the ophthalmic artery between controls and diabetic patients with various DR grades. OA flow velocities did not vary between groups.

Table 3: Pearson correlation coefficients between the duration of diabetes, HbA1c, and hemodynamic parameters

Variable	Duration of diabetes	HbA1c
OA PSV	0.021 (0.885)	-0.120 (0.407)
OA EDV	-0.141 (0.328)	-0.055 (0.706)
OA RI	0.314* (0.026)	0.097 (0.504)
OA PI	0.299* (0.035)	0.078 (0.588)
CRA PSV	-0.135 (0.349)	-0.269 (0.059)
CRA EDV	-0.464* (0.001)	-0.299*(0.035)
CRA RI	0.375* (0.007)	-0.046 (0.753)
CRA PI	0.487* (0.000)	0.131 (0.370)
PCA PSV	-0.052 (0.722)	0.170 (0.239)
PCA EDV	-0.234 (0.102)	0.196 (0.172)
PCA RI	0.332* (0.019)	-0.075 (0.606)
PCA PI	0.321*(0.023)	-0.085 (0.556)
CRV V max	0.134 (0.354)	0.128 (0.375)
CRV V min	-0.143 (0.322)	-0.058 (0.687)
CRV RI	0.390* (0.005)	0.172 (0.233)
CRV PI	0.415*(0.003)	0.210 (0.144)

Corresponding P values are shown in brackets. HbA1c=Glycosylated hemoglobin; OA=Ophthalmic artery; CRA=Central retinal artery; PCA=Posterior ciliary artery; CRV=Central retinal vein; PSV=Peak systolic velocity; EDV=End diastolic velocity; V max=maximum blood velocity; V min=minimum blood velocity; RI=Resistivity index; PI=Pulsatility index; *P<0.05

Central retinal artery and vein

The hemodynamic parameters of CRA were significantly different between controls, DR Group 1, and Group 2 whereas no such difference was seen in the CRV. *Post hoc* comparison revealed a significantly reduced PSV and EDV of CRA (P = 0.005 and 0.000, respectively) along with increased PI (P = 0.003) in DR group 2 compared to controls. Patients with group 2 DR also demonstrated a significant decrease of EDV and increased RI of CRA compared to group 1 (P = 0.015). PSV, EDV, and RI of CRA did not differ significantly between controls and DR group 1.

Posterior ciliary artery

The EDV and PI of PCA were found to vary significantly between controls and diabetic groups. Significant reduction in PSV and EDV of PCA was noted in DR group 1 compared to controls (P = 0.046 and P = 0.010, respectively after *post hoc* comparison).

Relation between duration of diabetes, HbA1c, and hemodynamic parameters

Duration of diabetes correlated positively with the resistive and pulsatile indices of all retrobulbar vessels studied namely ophthalmic artery, CRA, PCA, and CRV. HbA1c levels, as well as the duration of diabetes, were found to correlate negatively with EDV of CRA. No correlation was found between duration of diabetes and HbA1c levels (R = 0.183, P = 0.203). Table 3 shows the relationship between duration of diabetes, HbA1c levels, and hemodynamic parameters.

Binary logistic regression analysis revealed that HbA1c levels and RI of OA were independent risk factors of retinopathy.

Discussion

The main observations of our study are as follows: (1) RI in the ophthalmic artery was significantly higher in both DR groups than the control group and was an independent risk factor of retinopathy, (2) Patients with Group 1 DR had decreased blood flow velocity (PSV and EDV) in the posterior ciliary artery compared to control group, (3) Patients with Group 2 DR had significantly reduced EDV and increased RI in the CRA compared to Group 1, (4) Compared to the control group, patients with Group 2 DR had slower flow velocities and increased PI in CRA but RI values did not vary significantly.

Our finding of decreased EDV in the posterior ciliary artery in patients with Group 1 DR supports the hypothesis that choroidal blood flow is affected in the early stages of DR. Laser Doppler flowmetry has shown decreased choroidal blood flow in the foveal region in early DR.[14] Choroidal vascularity index (CVI) analysis by swept-source optical coherence tomography (OCT) has also shown reduced CVI in patients with mild/moderate NPDR.[15] Cao *et al.* have reported a 4 times more choriocapillary loss in diabetic eyes compared to non-diabetic eyes in histopathologic studies.[16] Ferrara *et al.* have demonstrated the loss of intermediate and large blood vessels in the Sattler's layer and Haller's layers in diabetic eyes in choroidal OCT.[17] Our observation of decreased EDV in the PCA suggests increased peripheral vascular resistance of the choroidal circulation in early DR and is in concordance with these studies. Dimitrova *et al.* reported decreased EDV and increased RI in PCA in patients

[Downloaded free from http://www.ijo.in on Thursday, June 4, 2020, IP: 192.168.70.71]

with background DR compared to controls in CDI of diabetic patients performed in sitting posture.[6] The authors have suggested that erect posture during CDI measurement is essential to appreciate significant alterations in posterior ciliary circulation. Supine posture has been suggested to increase EDV and decrease the RI.[18] As autoregulation and autonomic nervous responses are altered in diabetics, the correlation of change in circulatory parameters between normal individuals and diabetics associated with postural variation may not be expected to be equal. However, CDI was performed in supine posture in our patients. Our observations could be attributed to the shorter duration of diabetes in our patients than theirs.

RI in OA was higher in both DR groups compared with controls in our study. These findings are similar to those of previous studies.[5,19] Basturk *et al.* evaluated the association between the resistivity index of orbital arteries and DR in 91 types 2 diabetics with microalbuminuria using CDI. The authors have demonstrated increased RI values of all orbital arteries in patients with DR compared to those without DR and controls. RI value of ≥ 0.72 in OA indicated the presence of DR with 78.4% sensitivity and 70% specificity.[10] Our finding of increased RI in the OA in both DR groups can be attributed to the statistically nonsignificant reduction in EDV observed in diabetic subjects because of downstream vascular changes in the retina and choroid. We did not observe significant differences in CRA parameters between controls and DR Group 1. Hence, we believe that the OA hemodynamic parameters in our study probably represent alterations in choroidal blood flow. It has been suggested that of the total ocular blood supply from OA, less than 10% flows to the retina while the remainder is directed to choroid via the ciliary circulation due to the high metabolic demand of photoreceptors.[20] Moreover, the diastolic blood flow of PCA is higher than CRA since these vascular channels of choroid have low resistance.[21]

Khatri *et al.* assessed the correlation between RI of OA and topographic alterations of retinal pigment epithelium (RPE) on spectral-domain optical coherence tomography (SD-OCT).[22] In their study involving 75 patients with type 2 diabetes and 24 controls, a significant increase in OA RI was noted with the severity of DR ($F = 14.23$, $P < 0.001$). A positive correlation was noted between RI of OA and grades of RPE alterations on SD-OCT suggesting that decreased blood flow contributes to RPE dysfunction. Studies demonstrating early retinal damage in experimental diabetes have reported morphological changes in RPE and animal studies have also shown reduced choroidal blood flow in young diabetic animals suggesting that blood flow deficit could be an early pathological change in DR.[23,24] Although it is difficult to propose a causal association it can be postulated that changes in choroidal circulation (as reflected by increased RI of OA) lead to downregulation of antiangiogenic PEDF (pigment epithelial-derived factor) and upregulation of VEGF (vascular endothelial growth factor) thereby contributing to progression of DR. Differential expression and secretion of these growth factors derived from the retinal pigment epithelium have been suggested to lead to nonproliferative and proliferative DR.[25]

Patients with Group 2 DR had significantly reduced EDV in the CRA compared to Group 1 DR as well as healthy controls. Our observations are in line with previous studies.[5,6,8] These can be attributed to the increased peripheral vascular resistivity with the progression of DR. Pathological findings in DR such as capillary basement membrane thickening, retinal capillary leukostasis, loss of retinal capillaries, and altered blood rheology support this circulatory feature.[2,26,27]

Another observation of our study was that DR Group 2 had significantly reduced flow velocity in the CRA but an increase in RI was not statistically significant compared to the control group. This can be due to the concomitant decrease of both PSV and EDV in patients with Group 2 DR. Neudorfer *et al.* evaluated the long-term changes in the retrobulbar circulation of 138 eyes of diabetic subjects at a 10-year follow-up.[28] Patients were divided into four groups, namely, nondiabetic controls, diabetics without DR, nonproliferative DR, and proliferative DR. RI values of CRA and PCA had increased in the two no retinopathy groups and in the nonproliferative DR group, with a surprising nonsignificant decrease in the proliferative DR group. The authors have concluded that an increase of resistance in the retrobulbar blood vessels due to DR can decrease over time and may even be reversed. It has been suggested that the decrease in resistance reflects the beginning of an increase in retinal blood flow with the progression of DR due to the short-circuiting of the obstructed retinal capillary network.[28] This is supported by histopathologic studies, which have shown areas of capillary closure being traversed by preferential dilated anastomotic channels.[29]

Our finding of a positive correlation between duration of diabetes and RI of all retrobulbar vessels was similar to the observations of Karami *et al.*[30] We found negative correlation between EDV of CRA and duration of diabetes as well as HbA1c levels ($R = -0.464$, $P = 0.001$; $R = -0.299$, $P = 0.035$, respectively). Poor glycemic control (as reflected by increased HbA1c) and longer duration of diabetes can be associated with increased peripheral vascular resistance and thus reduced EDV in CRA. Our findings of HbA1c and RI of OA as independent risk factors of DR are similar to that of Basturk *et al.*[10]

Table 4 shows the various published studies on ocular circulation in diabetic patients using CDI.

Our study has several strengths. None of the diabetic patients had associated vascular diseases. Hypertension as well as antihypertensive medications significantly alter the resistive indices of blood vessels and therefore confound the results. We intentionally excluded these patients to study the influence of diabetes alone on ocular hemodynamics. A single masked, experienced radiologist performed all the Doppler examinations gently with the least pressure on the globe thus eliminating interobserver variability. The presence and severity of DR were graded based on seven field stereo fundus photography for accuracy.

To our knowledge, this study is the first of its kind in a pure cohort of diabetics from India.

There are a few limitations to our study. The sample size was small which accounts for the limited subgroup analysis. CDI provides information on blood flow velocity only and absolute volumetric blood flow cannot be quantified since it is not possible to study the diameter of retrobulbar vessels with CDI accurately. In spite of this limitation, blood velocity is probably a good indicator of blood flow within a given vessel.[31,32] Moreover, measurement of retinal blood flow is difficult and no accurate method to quantitatively assess perfusion is currently used clinically.

Conclusion

In conclusion, significant changes in the blood flow velocities and RI were observed in the retrobulbar vessels, especially in an ophthalmic artery in diabetics compared to controls. RI could be potentially useful for early diagnosis and follow-up of DR. CDI with results of increased resistance or decreased flow can be of help to identify diabetic individuals at higher risk for developing severe DR. This is especially useful in patients with opaque media where conventional methods are of little use.

Utility of ultrasound elastography in evaluation of thyroid nodules and correlation with cytology

Vikrant Kanagaraju, S. Sukithra, N. Jayaprakash, B. Devanand

Department of Radiology, PSG Institute of Medical Sciences and Research, Coimbatore, Tamil Nadu, India

Abstract

Background: Ultrasound elastography (USE) has emerged as a potentially useful tool in the evaluation of thyroid nodules. The aim of this study was to assess the efficacy of elastography in differentiating benign from malignant thyroid nodules with fine-needle aspiration cytology (FNAC) analysis as reference standard.

Materials and Methods: This was a cross-sectional prospective study carried out at a tertiary care center in South India between May 2014 and March 2015. Consecutive patients with solid nodule in the thyroid gland on conventional ultrasound (US) underwent USE, followed by US-guided FNAC of the thyroid nodule. The findings of B-mode images and USE were correlated with cytology. Statistical analysis was performed using SPSS version 24. Descriptive statistics were presented as mean ± standard deviation. The diagnostic sensitivity, specificity, positive predictive value, and negative predictive value of USE were calculated.

Results: A total of sixty patients with sixty solid thyroid nodules were enrolled in the study. The mean age of the patients was 48.27 ± 16.10 years. About 83.3% were females. The frequency of benign nodules on cytopathologic analysis was 60% (n = 36). Seventy-five percent of the malignant lesions had irregular or poorly defined borders with lobulated margins on US. The sensitivity, specificity, positive predictive value, and negative predictive value of USE were 91.7%, 77.77%, 73.33%, and 93.3%, respectively, with FNAC as reference standard. Higher elastography scores were found to be significantly associated with malignant cytology (P = 0.0001).

Conclusion: Elastography, with its fairly high diagnostic accuracy and correlation with malignant cytology, can be an effective noninvasive adjunctive tool in distinguishing benign from malignant thyroid nodules.

Keywords: Elastography, thyroid nodules, ultrasound

INTRODUCTION

The prevalence of thyroid nodules which are clinically palpable is about 2%–6% in the general population.[1] Although majority of these nodules are benign, up to 7% can be malignant.[2,3]

On palpation, a hard or firm nature is associated with an increased risk of malignancy. However, palpation is a highly subjective method and its value is limited in patients with multinodular goiter or deep-seated nodules. Ultrasonography (USG) is the most commonly used imaging modality to diagnose thyroid nodules. The utility of

USG in differentiating benign from malignant lesions has been established by several studies.[4-6] However, no USG feature has been shown to have both high sensitivity and high specificity in detecting malignancy in thyroid nodules.[7] Elastography is a newly developed noninvasive dynamic imaging technique analogous to manual palpation. This technique uses ultrasound (US) to estimate tissue stiffness by measuring the degree of distortion under application of an external force.[8] Several studies have used US elastography (USE) for evaluation of thyroid disorders.[9-11]

Fine-needle aspiration cytology (FNAC) is an efficient tool in distinguishing benign nodules that can be managed conservatively from those with suspicious or malignant features that warrant further intervention. Limited data exist on the utility of elastography in differentiating benign from malignant lesions of the thyroid and its correlation with FNAC, especially from India. The aim of this study was to assess the efficacy of elastography in differentiating benign from malignant thyroid nodules with FNAC analysis as reference standard.

MATERIALS AND METHODS

This prospective study was carried out at a tertiary care center in South India between May 2014 and March 2015. Consecutive patients of either gender who were found to have thyroid swelling/goiter on clinical examination and referred for USG were considered. Only those with solid thyroid nodules at least 8 mm in size on conventional US were included in the study. Cystic lesions with no solid component, multinodular goiters with coalescent nodules, and nodules with eggshell calcification were excluded from the study. A large nodule involving more than 75% of thyroid lobe volume was also excluded because of inadequate normal thyroid tissue to be used as reference. The institutional review board approved the study protocol, and the protocol complied with the tenets of the Declaration of Helsinki. Informed consent was obtained from all participants.

With a patient in supine position and neck fully extended, B-mode US of the thyroid gland was performed with SIEMENS ACUSON S2000 machine using high-frequency probes 9 L4 and 14 L5. US features studied included echogenicity, regularity of borders, presence of halo, vascular pattern, and calcification. Thyroid imaging reporting and data system (TIRADS) scoring was used to categorize the lesions[12] [Table 1].

USE was performed with SIEMENS ACUSON S2000 at the same time as the B-mode examination. The probe was placed over the region such that the lesion is in the center of the image, holding the scan plane perpendicular to the skin surface. At least 5 mm of normal adjacent tissue was included to assess the lesion stiffness in relation to the average elasticity of surrounding tissue. Patients were asked to hold their breath and avoid swallowing during examination in order to minimize the motion of the thyroid gland. The elasticity images were obtained by appropriate compression, followed by decompression of the transducer. The images were displayed on split-screen mode with US grayscale images on the left and USE images on the right. Multiple frames were acquired, and the best-fit B mode-USE image pairs were selected for examination [Figures 1 and 2]. The targeted lesion was scored as 1–4, using strain elastographic scores proposed by Asteria *et al*.[9] [Table 2].

US-guided FNAC of the thyroid nodule was done using a 22G needle, and the lesion was aspirated at least twice with the freehand technique. The aspirated contents were expelled onto glass slides and immediately fixed with 95% ethyl alcohol. The slides were stained with modified Papanicolaou staining and examined under light microscopy. The cytological results were classified

Table 1: Thyroid image reporting and data system scoring of thyroid nodules

Category	Description
TIRADS 1	Normal thyroid gland
TIRADS 2	Benign conditions
TIRADS 3	Probably benign nodules (<5% malignant)
TIRADS 4	Suspicious nodules (5%-80% malignancy rate)
TIRADS 5	Probably malignant nodules (malignancy rate >80%)
TIRADS 6	Biopsy-proven malignant nodules

TIRADS – Thyroid image reporting and data system

Table 2: Asteria's criteria of scoring of thyroid nodules on elastography

Elasticity Score	Description
Score of 1	Elasticity in the entire examined area
Score of 2	Elasticity in a large part of the examined area
Score of 3	Stiffness in a large part of the examined area
Score of 4	Nodule without elasticity

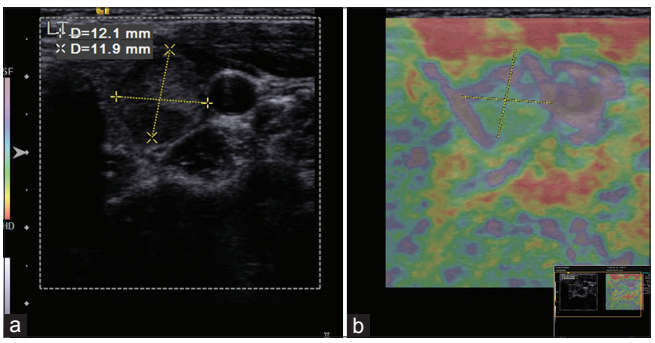

Figure 1: Thyroid nodule images obtained on conventional ultrasound (a) and ultrasound elastography with elasticity score 2 (b)

as benign, indeterminate/suspicious (follicular lesions), and malignant according to standard pathological criteria.

Statistical analysis

Statistical analysis was performed using the Statistical Package for the Social Sciences (SPSS, SPSS Inc., Chicago. IL, USA) version 24. Descriptive statistics were presented as mean ± standard deviation. Qualitative variables were presented in the form of frequency and percentages and compared using the Chi-square test. The diagnostic sensitivity, specificity, positive predictive value, and negative predictive value were calculated. Statistical significance was set at $P < 0.05$.

For statistical purposes, USE score of 2 was strongly predictive of a benign lesion and therefore considered sample negative for malignancy. Scores of 3 and 4 describing stiffness in a large part of the examined area and nodule without elasticity, respectively, were considered as positive for malignancy in our study. With regard to cytology, two groups were considered for evaluation: benign and malignant. Patients with fine-needle aspiration (FNA) reports of indeterminate/suspicious (follicular lesions) were also included in the malignant group for statistical purposes.

RESULTS

A total of sixty patients with sixty solid thyroid nodules were enrolled in the study. The age of the patients ranged from 19 to 85 years (mean: 48.27 ± 16.10 years). About 83.3% (n = 50) were female and 16.7% (n = 10) were male. The frequency of benign nodules on cytopathologic analysis was 60% (n = 36), whereas 40% (n = 24) were nonbenign (follicular lesions and malignant tumors). Of the 24 nonbenign thyroid nodules, 20 had been reported as papillary carcinoma, 2 as medullary carcinoma, and 2 as follicular neoplasm. Table 3 shows the presenting clinical features and cytologic diagnoses of patients with thyroid nodules.

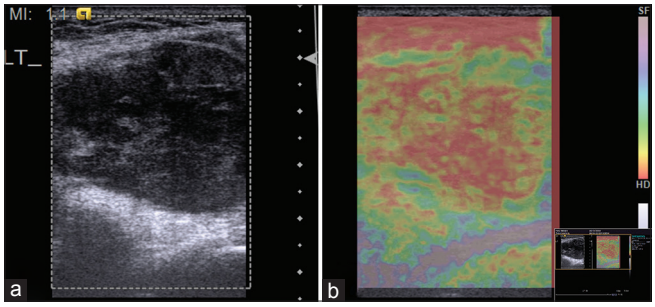

Figure 2: Heterogeneous nodule on conventional ultrasound (a) and ultrasound elastography with elasticity score 4 (b)

Seventy-five percent of the malignant lesions had irregular or poorly defined borders with lobulated margins on US and 68% had microcalcification. Seventy-seven percent of the benign nodules were hyperechoic. On TIRADS scoring, score of 2 was found in 24 cases, all benign lesions; score 3 in 14 cases, 8 benign and 6 malignant; score 4 in 12 cases, 4 benign and 8 malignant; and score 5 in 10 cases, all malignant lesions. Table 4 shows the correlation of USE scores and FNAC diagnoses of patients.

The sensitivity, specificity, positive predictive value, and negative predictive value of US elastography were 91.7%, 77.77%, 73.33%, and 93.3%, respectively, with FNAC as a reference standard [Table 5]. Higher elastography scores were found to be significantly associated with malignant cytology ($P = 0.0001$).

DISCUSSION

Thyroid nodules are common in the general population, and the reported prevalence varies depending on the identification method. Apart from serum markers and FNAC, USG plays an important role in the detection and evaluation of thyroid nodules. Being noninvasive conventional US provides information regarding the nodule dimensions, structure as well as parenchymal changes and is widely used to determine which nodules should be biopsied. Microcalcifications, hypoechogenicity,

Positive	22 (true positive)	8 (false positive)	30
Negative	2 (false negative)	28 (true negative)	30
Total	24	36	60

FNA – Fine-needle aspiration; USE – Ultrasound elastography

irregular or microlobulated margins, taller than wide shape, and increased intranodular vascularity have been reported as independent risk factors for malignancy.[13,14] Although these features are characterized by high specificity, their positive predictive value is lowered by their relatively low sensitivity.[15]

USE is based on the principle that the softer parts of tissues deform easier than the harder parts, under compression, thereby allowing an objective determination of tissue consistency. Malignancy is often associated with changes in the mechanical properties of a tissue, and USE has been used to differentiate benign from malignant lesions in the breast, liver, and prostate.[16-18] The two general criteria for evaluating the efficacy of USE are elasticity scores and strain ratio. Although elastography has been suggested to be of great use as an adjunctive tool in the diagnosis of thyroid cancer, studies have reported conflicting evidence on its additional value in predicting thyroid malignancy.[19-21]

This study was planned to assess the efficacy of elastography in differentiating benign from malignant thyroid nodules with FNAC analysis as a reference standard. The mean age of presentation for benign nodules was 44.31 ± 14.28 years, whereas that for malignant lesions was 54.21 ± 17.13 years ($P = 0.018$) A majority of our cases diagnosed with thyroid nodules were females (83.3%). Thyroid nodules are reported to be four times more common in women than men, and their frequency increases with age and low iodine intake.[22] The female preponderance has been explained by the hormonal influences of estrogen and progesterone, as increasing nodule size and new nodule development have been demonstrated to be related to pregnancy and multiparity.[23]

Of the sixty nodules studied, 60% were benign ($n = 36$) and 40% ($n = 24$) were nonbenign. Of the 36 benign nodules, 26 were colloid nodules and 10 were adenomatoid nodules. The 24 nonbenign lesions included 20 papillary carcinomas, 2 medullary carcinomas, and 2 follicular neoplasms. The most common clinical presentation was painless mass in the neck which was encountered in almost 47% of the patients. Majority of the patients who presented with significant weight loss, dysphagia, and hoarseness of voice were found to have malignant lesions. Dysphagia, dysphonia, reports of rapid growth, male gender, prior head-and-neck irradiation, and presentation at extremes of age have been reported as significant elements in the patient's history, which increase the likelihood of malignancy.[24]

Our study found that 75% of malignant lesions had irregular or poorly defined borders with lobulated margins, whereas 68% of malignant lesions had microcalcification. Seventy-seven percent of the benign nodules were hyperechoic, whereas 23% were hypoechoic. None of the hyperechoic nodules was malignant. Although none of these US features is sufficient to differentiate benign lesions from malignant ones, studies have shown that a combination of at least two of the features is better helpful in pointing out a subset of lesions at high risk for malignancy.[25,26]

With regard to TIRADS score, all the nodules with TIRADS score of 2 ($n = 24$) had benign FNA characteristics, whereas all the patients with TIRADS score of 5 ($n = 10$) were found to have malignant lesions on FNA. Among TIRADS 3 lesions ($n = 14$), 57% were benign, and among TIRADS 4 lesions ($n = 12$), 33% were found to be benign on FNA.

On US elastography, score of 2 was found in 30 nodules, 28 benign and 2 malignant; score 3 in 10 cases, 8 benign and 2 malignant; and score 4 in 20 cases, all malignant. The sensitivity, specificity, positive predictive value, and negative predictive value of US elastography were 91.7%, 77.77%, 73.33%, and 93.3%, respectively, with FNAC as a reference standard.

The elastography scores of 3–4 were achieved in 22 of the 24 malignant nodules in our study. Among the 20 nodules with cytologic diagnosis of papillary carcinoma, 18 were correctly scored as malignant by USE, thus achieving 90% diagnostic accuracy in terms of confirming the malignant etiology. Only two nodules were incorrectly given a USE score of 2. Both of the two nodules with medullary carcinoma thyroid had been scored as malignant on USE (score 4). We had eight false-positive nodules (score 3) which can be attributed to the fibrotic changes and calcification that lead to hardness of the nodule under study.

Our observations are in line with that of Mehrotra *et al.* who have reported the sensitivity and specificity of USE for thyroid malignancy to be 90% and 79.6%, respectively.[27] Of the 147 nodules examined by USE and US-guided FNAC, 122 were nonneoplastic, 5 were benign neoplasm, 10 had indeterminate cytologies, and 10 had malignant neoplasms. The observed positive and negative predictive values were 24.3% and 99.1%, respectively. In contrast, we found the positive predictive value of elastography to be 73.3% in our study. This can be explained by the high prevalence of malignant lesions among our study population.

The sensitivity and specificity of elastography based on elastography scores have been reported to vary from

86% to 97% and 66%–100% from various studies.[8,9,28] The observed wide differences are due to the fact that these studies involve different groups of populations, referral bias (patients referred for FNAC/surgery), varied inclusion and exclusion criteria, different machines as well as criteria for USE scoring. A recent comprehensive meta-analysis to investigate the diagnostic value of qualitative elastography in distinguishing benign from malignant thyroid nodules included 20 studies involving 3973 thyroid nodules.[29] Pooled results of elastography have shown a summary sensitivity of 85% (95% confidence interval [CI], 79%–90%) and specificity of 80% (95% CI, 73%–86%). The respective pooled negative predictive and positive predictive values were 97% (95% CI, 94%–98%) and 40% (95% CI, 34%–48%), respectively.

Despite the potential limitations of USE such as intra/interobserver variability and nodule characteristics such as calcification and follicular carcinoma (which appears soft), USE is considered to be reliable in the diagnosis of benign nodules in view of the high negative predictive values observed in most of the studies including ours.

FNAC is an essential diagnostic modality in the evaluation of thyroid nodules and features in all the guidelines in patient management.[30] Although the use of FNAC in the evaluation of thyroid nodules provides reliable results, it is invasive and the potential for complications such as postprocedural hematoma, increased patient morbidity, cost, and possibility of nondiagnostic specimen does exist. Unnecessary/repeat FNACs and FNA-induced changes can result in false-positive results on thyroid cytology and false-negative results or understaging of the tumor on thyroid pathology.[31,32]

Higher elastography scores were found to be significantly associated with malignant cytology ($P = 0.0001$) in our study. Merino *et al*. have also noted a statistically significant association between elasticity scores and cytological results, suggesting that malignant nodules could be excluded by elastography.[33]

Limitations of our study include small sample size and the fact that observations are from a single center.

CONCLUSION

With scanty literature comparing elastography with FNAC available from this part of the world, our study highlights that elastography has a fairly high diagnostic accuracy and correlation with malignant cytology. It can be an effective noninvasive adjunctive tool in distinguishing benign from malignant thyroid nodules and reduce the burden of unnecessary invasive procedures.

Role of Transrectal Ultrasound Elastography in the Diagnosis of Prostate Carcinoma

Vikrant Kanagaraju*, P. V. K. Ashlyin, N. Elango, B. Devanand

Department of Radiology, PSG Institute of Medical Sciences and Research, Coimbatore, Tamil Nadu, India

Abstract

Background: The purpose of this study was to evaluate the diagnostic value of transrectal real- time strain elastography (RTE) in identifying prostatic carcinoma (PCa). **Materials and Methods:** 60 patients suspected of having PCa based on abnormal digital rectal examination and raised prostate specific antigen levels underwent transrectal ultrasound (TRUS), color Doppler (CD) and RTE. Elastograms were scored on a five point scale based on distribution of strain in relation to hypoechoic area on TRUS. Twelve core systematic biopsy as well as targeted biopsy was performed from suspicious areas on TRUS and RTE. Diagnostic performance of sonoelastography was evaluated using histopathology as reference standard. **Results:** Histopathology revealed cancer in 28 out of 60 patients (47%) studied. Gleason score ranged from 6 to 9. The sensitivity, specificity, positive predictive value (PPV), and negative predictive value (NPV) of TRUS in detecting prostate cancer were 78.57%, 81.25%, 78.57%, and 81.25%, respectively. On CD evaluation 87.5% (n = 28) of benign lesions showed symmetric, radial flow compared to 14.3% (n = 4) of malignant lesions ($P < 0.0001$). The sensitivity and specificity of RTE was 89.29% and 56.25% with PPV and NPV being 58.13% and 82.35%, respectively. Higher elastography score was found to be significantly associated with malignant histopathology ($P = 0.004$). Cancer detection rate with RTE was greater for tumors with higher Gleason score. **Conclusion:** RTE was found to have better sensitivity than TRUS as well as combination of TRUS and CD. Although less specific, RTE can be an effective adjuvant tool to TRUS for guidance of biopsy and improve detection rate of PCa.

Keywords: Elastography, prostate cancer, ultrasonography

Introduction

Prostate carcinoma (PCa) is the second most frequently diagnosed cancer in males all over the world and is a major healthcare concern associated with significant morbidity and mortality. The burden of PCa is estimated to grow to 1.7 million new cases and 499000 new deaths by 2030 as a result of growth and aging of the global population.[1]

Digital rectal examination (DRE), screening for prostate specific antigen (PSA), and imaging techniques such as transrectal ultrasound (TRUS) and magnetic resonance imaging (MRI) are the methods commonly employed for detection of PCa. DRE is limited by its low sensitivity, subjective nature, and depends on the experience of the clinician. Although PSA testing has been widely used for screening of prostatic cancer, it is not disease specific and can be elevated in patients with prostatitis as well as benign prostatic hyperplasia.[2,3] In a patient with suspicion of prostatic cancer, current guidelines involve histopathologic examination of systematic biopsy cores to confirm or rule out cancer.[4] However, the conventional biopsy protocol misses significant cancer in a large proportion of patients.[5] Further many insignificant cancers that do not need immediate treatment are also detected leading to overdiagnosis and treatment.[6] Use of TRUS for detecting prostate cancer has limitations such as poor specificity of focal abnormalities, frequent multifocality of cancer within the prostate, and substantial percentage of isoechoic prostatic carcinoma (PCa).[7] Although MRI results are promising, it is expensive and not always available. In view of these limitations, improved noninvasive imaging modalities that

can provide better characterization of prostatic lesions and increase detection of prostatic cancer are needed.

Ultrasound elastography (USE) is a dynamic technique that uses ultrasound to estimate tissue stiffness by measuring the degree of distortion under application of an external force. As cancerous tissue has greater stiffness than a benign lesion USE has been used to differentiate malignant from benign lesions in breast, thyroid, liver, and cervix. Recent studies have demonstrated the utility of sonoelastography in detecting prostate cancer.[8-10]

Data on the usefulness of transrectal strain elastography (SE) in evaluation of prostatic cancer and its correlation with histopathology are relatively few, especially from India. The purpose of the present study was to evaluate the usefulness and diagnostic performance of transrectal SE in identifying prostatic cancer with histopathologic diagnosis obtained by needle biopsy of prostate as reference standard.

Materials and Methods

This prospective study was performed in a tertiary care center in South India between December 2014 and September 2016. 60 consecutive patients who were referred to the department of Radiology with suspicion of PCa based on abnormal DRE and elevated PSA levels (>4 ng/ml) were enrolled. The institutional review board approved the study protocol and the protocol was in compliance with tenets of the Declaration of Helsinki (IRB approval Number: 14/399). Informed consent was obtained from all participants. Exclusion criteria consisted of patients with bleeding disorders, inflammatory bowel disease and surgical absence of rectum or ileoanal pouch. All patients underwent TRUS (grey scale and Doppler) and SE as well as needle biopsy of prostate in the same session.

TRUS of prostate was done using an endocavitary transducer (Siemens Accuson S3000, Siemens Healthineers, Erlangen, Germany) with 9–4 MHz range and 174 degree field of vision, capable of user selectable multi hertz imaging. Xylocaine gel was applied over a probe cover applied onto the probe. All patients were examined in the left lateral decubitus position. Prostate was imaged in both axial and sagittal planes with assessment of volume, echogenicity, surface, calcification, vascularity, and the presence of nodules. Each nodule was assessed for size, margins, location in the gland, morphology, and echogenicity.

Glands with homogeneous echotexture or minimal heterogeneity on TRUS were labeled as benign while those with ill-defined echotexture abnormality, focal bulge or hypoechoic mass were categorized as malignant. For Color Doppler (CD) imaging, capsular/periurethral flow and symmetric radial flow from capsular branches were considered benign while asymmetric or increased flow with disorganized pattern was labeled malignant.[11]

Using the same probe transrectal real-time strain elastography (RTE) of prostate was done by a single experienced radiologist. The probe was placed over the region such that the lesion is in the center of the image. Elastograms were obtained by slight compression and decompression of the prostate. The appropriate frequency and pressure of the compression/decompression was optimized with the help of real time display of quality index. Elastograms obtained with quality index equal to or >60 were only included. At least a 5 mm thickness of normal adjacent tissue was included, to assess the lesion stiffness in relation with the average elasticity of the surrounding tissue. A standardized color coding system was used, where red indicated soft, more compliant areas and blue indicated stiff areas. Green color indicated average strain in the region of interest. The elastograms along with conventional B-mode images were displayed side by side on split screen mode. Multiple frames were acquired and the best fit B mode-elastography image pairs were selected for examination. The elasticity patterns were scored using a five point scale proposed by Kamoi *et al*.[10] [Table 1] The cut off for malignancy was set between scores of 2 and 3 [Figures 1-4].

Sampling of the prostate was performed either in the sagittal or in the axial plane. Biopsies were taken using an 18 G biopsy gun under strict aseptic precautions. Extended core biopsy protocol (12 cores) was used. Additional targeted biopsy was carried out on suspicious areas identified by B mode US and elastography. The grade (degree of aggressiveness) of prostate cancer was evaluated on the basis of the Gleason score. No major complications were encountered after the procedure.

The findings of TRUS, Doppler and RTE were interpreted by consensus by two experienced radiologists who were blinded to patients' clinical profile and biopsy results. The histopathologic results were considered as the reference standard, and utility of RTE was evaluated.

Statistical analysis

Data was entered in the Statistical Package for Social Sciences version 24 (SPSS Inc., Chicago, IL, USA). Descriptive statistics was presented as mean ± standard deviation. Qualitative variables were presented in the form of frequency and percentages. The diagnostic sensitivity, specificity, positive predictive value (PPV) and negative predictive value (NPV) were calculated with histopathologic analysis as reference standard. For analyzing the combined diagnostic performance of tests, the test was considered positive if either of them was

Table 1: Sonoelastography scoring system proposed by Kamoi *et al*.

Elastography score	Description
Score 1	Normal - homogeneous strain
Score 2	Probably normal - symmetric heterogeneous strain
Score 3	Indeterminate - asymmetric focal stiff lesion which is not related to any hypoechoic area
Score 4	Probably carcinoma (strain at the periphery of the hypoechoic lesion with sparing of the center
Score 5	Definitely carcinoma (no strain in the entire hypoechoic lesion or in the surrounding area)

suspicious for malignancy and negative if neither showed suspicious features. Pearson Chi-square test was used to study the association between categorical variables. $P < 0.05$ was considered as statistically significant.

Results

The age of the patients ranged from 53 to 88 years (Mean: 69.16 ± 9.40 years). Serum PSA levels ranged between 4.3 and 178.6 ng/ml (Mean 48.54 ± 56.69 ng/ml). No Significant difference in PSA levels were noted between patients with carcinoma and benign lesions of the prostate ($P = 0.083$). In 60 patients, 784 biopsy cores were harvested out of which 720 was according to the extended core biopsy protocol and 64 were targeted (36 and 28 targeted to areas found suspicious on B-mode US and RTE, respectively). Histopathology revealed cancerous focus in at least one biopsy core in 28/60 (47%) patients. Gleason score ranged from 6 to 9 (Mean: 7.42 ± 1.13). Among the 32 patients with benign histopathology results, 20 (62.5%) were found to have benign prostatic hyperplasia and 12 (37.5%) had prostatitis. The mean prostatic volume was 38.20 ± 18.25 cm^3 (range: 8–89 cm^3). The mean age of patients with benign and malignant lesions were 66.78 ± 9.56 years and 71.89 ± 8.59 years, respectively ($P = 0.035$).

Out of the 60 patients, 28 (47%) were suspected of having prostate cancer by TRUS. The sensitivity, specificity, PPV, and NPV of TRUS in detecting prostate cancer were 78.57%, 81.25%, 78.57%, and 81.25%, respectively, with histopathology as reference standard. On CD evaluation 87.5% ($n = 28$) of benign lesions showed symmetric, radial flow compared to 14.3% ($n = 4$) of malignant lesions ($P < 0.0001$).

Table 2 shows the correlation of elastography scores and histopathologic diagnoses of lesions. Out of the 32 patients

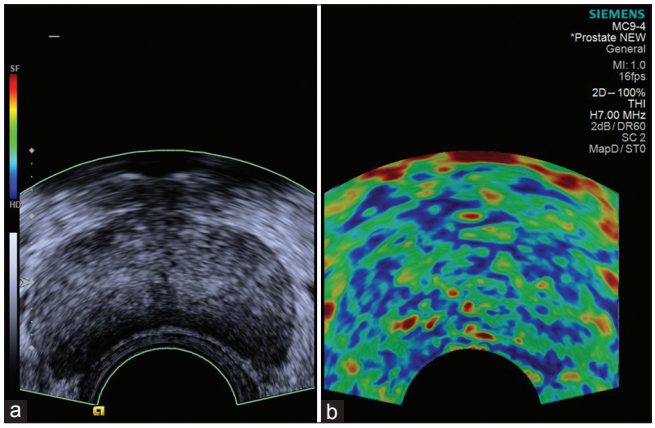

Figure 1: (a) Transrectal ultrasonography image showing mild enlargement of prostate. (b) Sonoelastography showing heterogeneous appearance with symmetrical mosaic pattern of green and blue (Score 2 – probably normal). Histopathology revealed hyperplasia of prostate with benign glandular pattern

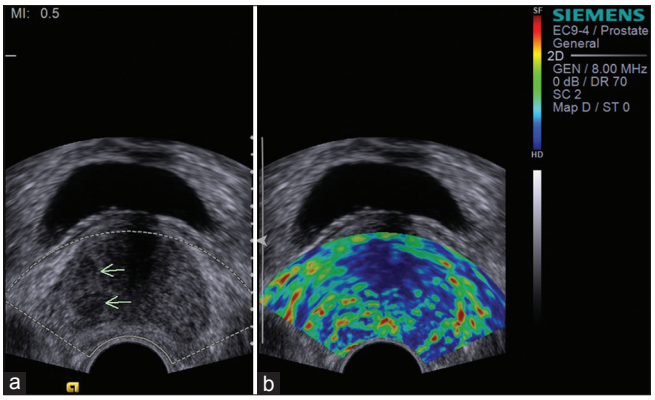

Figure 2: (a) Transrectal ultrasonography image showing hypoechoic lesion in the right peripheral zone (arrows) of prostate. (b) Sonoelastography showing focal asymmetric stiff lesion not related to hypoechoic area (score 3 – indeterminate). Histopathology was suggestive of adenocarcinoma prostate

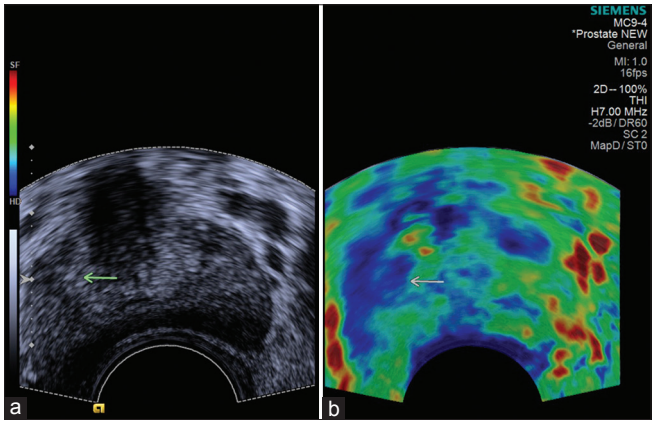

Figure 3: (a) Transrectal ultrasonography image showing hypoechoic lesion in the right peripheral zone (arrow) of prostate. (b) Sonoelastography showing stiffness in the center of the lesion and strain at the periphery; the peripheral part of lesion appears green and the central part appears blue (score 4 – probably carcinoma). Histopathology confirmed adenocarcinoma prostate

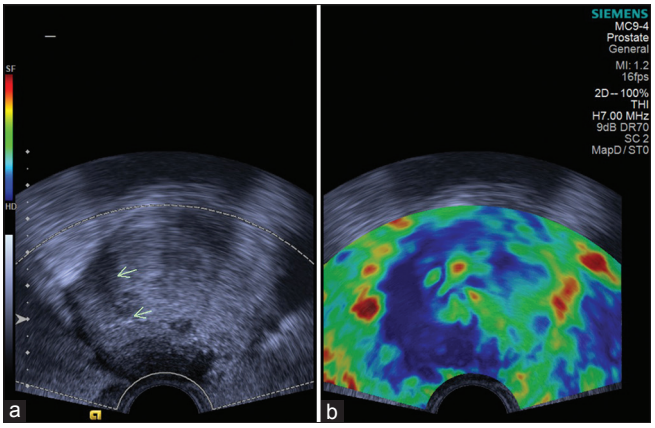

Figure 4: (a) Transrectal ultrasonography image showing hypoechoic lesion with irregular margin in the right peripheral zone (arrows) of prostate. (b) Sonoelastography showing stiffness in the entire hypoechoic lesion and in the surrounding area; the entire lesion appears blue (score 5 – definitely carcinoma). Histopathology confirmed adenocarcinoma prostate

with benign histopathology, 14 were judged as negative for malignancy at RTE. There were 3 false negative patients on elastography with score of 2. The sensitivity and specificity of RTE was 89.29% and 56.25% with positive and NPV of 58.13% and 82.35%, respectively. Higher elastography score was found to be significantly associated with malignant histopathology ($P = 0.004$).

Table 3 shows the relation between Gleason score and elastography scores. Approximately 84% of patients with a Gleason score ≤6 were detected by RTE whereas for scores 8–9, the detection rate was 100%.

The diagnostic performance of TRUS, combined modalities (TRUS and Doppler) and RTE are shown in Table 4.

Discussion

In this prospective study from South India, we evaluated the diagnostic performance of transrectal real-time elastography (RTE) in detection of prostatic cancer in patients with abnormal DRE and elevated PSA levels. RTE showed superior sensitivity of nearly 90% versus sensitivity of 79% by TRUS and 86% by a combination of TRUS and CD ultrasound.

Table 2: Correlation between elastography score and histopathologic diagnosis of lesions

Elastogram pattern	Benign ($n=32$)	Malignant ($n=28$)	Total ($n=60$)
1	0	0	0
2	14	3	17
3	18	4	22
4	0	9	9
5	0	12	12

Table 3: Relation between Gleason score and elastography scores

Gleason score	ES 1	ES 2	ES 3	ES 4	ES 5
≤6	0	1	0	2	3
7	0	2	2	6	2
8	0	0	0	1	1
9	0	0	2	0	6

ES: Elastography score

Table 4: Diagnostic performance of transrectal ultrasound, combined modalities (transrectal ultrasound and Doppler) and real-time strain elastography

Performance measure	TRUS	TRUS and doppler	RTE
Sensitivity (%)	78.57	85.71	89.29
Specificity (%)	81.25	75	56.25
Positive predictive value (%)	78.57	75	58.13
Negative predictive value (%)	81.25	85.71	82.35

TRUS: Transrectal ultrasound, RTE: Real-time strain elastography

Ever since the description of principles of elastography by Ophir *et al*., elasticity imaging has been applied to a wide variety of tissues such as breast, thyroid, liver, lymph nodes and prostate.[12]

The two US elastography techniques in clinical use are SE and shear wave elastography. Several studies have evaluated the utility of SE in diagnosing prostatic cancer and have shown varied results. While few have compared the diagnostic accuracy with needle biopsy of prostate,[13-15] others have used histopathologic examination of radical prostatectomy specimen as the reference standard.[8,9,16] The heterogeneous results can be attributed to the varied inclusion criteria, demographic characteristics of patients, serum PSA levels, location of tumors, reference standard, number of biopsy cores, systematic or targeted biopsies and Gleason score of the tumors examined.

The age of patients with malignancy of prostate was significantly higher compared to those with benign lesions in our study ($P = 0.035$). Age is considered to be an established risk factor for prostatic cancer and study of age-specific incidence curves have shown that risk of prostate cancer begins to rise sharply after 55 years of age and peaks at 70–74, declining slightly thereafter.[17]

In our study, TRUS revealed hypoechoic/focal lesions in 28 patients (47%). Out of these, 22 were confirmed as adenocarcinoma prostate while 6 turned out to be benign on histopathology. The results from our study in terms of specificity and PPV of TRUS in detecting prostatic cancer are similar to that of Ferrari *et al*. who had evaluated 84 patients suspected of prostatic cancer by TRUS, RTE and transperineal prostate biopsy.[18] B-mode US demonstrated 56% sensitivity, 80% specificity, 70% PPV and 67% NPV in diagnosing prostatic cancer. A hypoechoic lesion in the peripheral zone of prostate is suggested to be more likely malignant, the proposed cause being replacement of normal loose glandular tissue by a packed mass of tumor cells which results in fewer reflecting interfaces. Hyperplasia, prostatitis, fibrosis and cysts of prostate are other lesions that appear hypoechoic on TRUS.[19] Nearly 25%–40% of prostate cancers are isoechoic and missed by TRUS.[20]

CD and Power Doppler (PD) have been reported to be useful in detecting isoechoic tumors which may be missed by conventional ultrasound.[21,22] In 2 patients with prostatic cancer in our study, Doppler evaluation revealed asymmetric, increased flow while TRUS was not suspicious for malignancy. Few authors have shown that increased CD signal correlates positively with grading and staging of prostate cancer as well as risk of recurrence after treatment.[23,24]

On CD evaluation, 87.5% ($n = 28$) of benign lesions showed symmetric, radial flow compared to 14.3% ($n = 4$) of malignant lesions ($P < 0.0001$) in our study. A combination of TRUS and Doppler revealed superior diagnostic performance with sensitivity and NPV of nearly 86% compared to TRUS. However, benign lesions like prostatitis can also show

increased flow on CD and CD does not reveal microscopic vessels of prostatic cancer that do not possess enough flow to cause Doppler shift.[25,26] Despite these limitations, our findings indicate that CD imaging can be a useful adjunct to improve tumor detection by TRUS.

Prostatic cancer tends to be stiffer than benign lesions due to replacement of normal glandular tissue by neoplastic cells.[27] Stiffer tissues demonstrate less strain to deformation, and RTE helps in differentiation of benign and malignant tissues based on distribution of strain. Miyagawa *et al*. evaluated the usefulness of RTE in detecting prostatic cancer prior to systematic biopsy and have noted a diagnostic sensitivity of 72.6% for elastography and 89.5% for combination of TRUS and elastography.[14] Kamoi *et al*. used a five point subjective scale based on degree and distribution of strain in relation to hypoechoic area and found that RTE had 68% sensitivity and 81% specificity in detecting prostatic cancer. The combination of RTE with PD US further increased the sensitivity to 78%.[10]

Using the cutoff value of 3 (suggesting focal asymmetric lesion without strain unrelated to hypoechoic lesion) proposed by Kamoi *et al*., RTE was found to have sensitivity of 89.29% and specificity of 56.25% in our study. Of 43 patients with RTE findings suspicious for carcinoma, 25 were confirmed to be malignant on histopathology. Benign entities such as benign prostatic hyperplasia, adenomyomatosis, fibrosis and prostatitis can be associated with increased tissue stiffness and therefore may be difficult to distinguish from carcinoma prostate. This can be responsible for the relatively low specificity and PPV observed in our study. Because of the high frequency of false-positive results, RTE should be used in combination with TRUS to increase the detection rate.

In 5 of 28 patients with prostatic cancer (17.9%), B mode US was normal but RTE was suggestive of carcinoma. While systematic biopsy picked up malignancy in 3 patients, targeted biopsy based on RTE findings resulted in detection of cancer in 2 patients. The role of RTE targeted biopsy in detecting prostatic cancer has been reported by several authors. Pallwein *et al*. compared a 5-core RTE targeted biopsy with a 10-core systematic biopsy and concluded that cancer detection rate per patient was not significantly higher for targeted approach compared to systematic approach but an RTE targeted core was 2.9 fold more likely to be positive for cancer than a systematic core.[28] Salomon *et al*. analyzed the incremental detection rate of 4-core RTE targeted biopsy in addition to randomized 10-core in 1024 patients.[29] Additional use of RTE resulted in an incremental detection rate of 18.3%. 34 patients who harbored high-grade PCa (Gleason score ≥4) were diagnosed by RTE targeted biopsy only. A recent meta-analysis on the role of RTE targeted biopsy has shown that the detection rate of malignancy is enhanced when systematic biopsies are combined with RTE targeted biopsies.

Further RTE targeted biopsy can make a nearly equivalent diagnosis with fewer cores.[30]

In our study RTE detected 5 of 6 patients with prostatic cancer of Gleason score ≤6, 10 of 12 with score 7 and all with Gleason score 8 or 9. Our observations are similar to that of other authors who have noted that RTE detection rate of prostate cancer with higher Gleason score was greater than that of prostatic cancer with a lower Gleason score.[9,31] This might be explained by the greater cell density in high grade tumors resulting in stiffer tissue. In contrast, Tsutsumi *et al*. have noted a lower RTE detection rate for high grade tumors.[32]

Our study has few limitations. The sample size was small and no interobserver variability was studied since the RTE findings were interpreted by consensus. Another main limitation of RTE is that the degree of manual compression influences the elasticity image and may compromise diagnostic accuracy of RTE. However all examinations were performed by a single experienced radiologist and only images with optimal compression as displayed by the quality index were included in the study. Recent literature suggests that multiparametric MRI has greater sensitivity and specificity for detection of clinically significant prostate cancer.[33]

Although the incidence of prostatic cancer is low in Asian countries compared to the west, demographic and epidemiological transition in recent times have resulted in increase in the burden of various cancers including prostate in India. Prostate is reported to be the second leading site of cancer among males in several cities in India and cancer projection data estimate that the number of cases will become doubled by 2020.[34]

Conclusion

In this initial study from South India, RTE was found to have better sensitivity than TRUS as well as combination of TRUS and CD. With its greater sensitivity and NPV, RTE can be an effective adjuvant tool to guide biopsy and thereby increase the detection rate of prostatic cancer. Further prospective studies with larger sample size are needed before recommending RTE along with conventional TRUS for routine use in the evaluation of suspected prostatic malignancy in India.

Department of Radiology, PSG Institute of Medical Sciences and Research, Coimbatore, Tamil Nadu, India

Abstract

Background: The purpose of this study was to evaluate the usefulness of strain elastography and acoustic radiation force impulse (ARFI) imaging in the differentiation of benign and malignant cervical lymph nodes (LNs). **Materials and Methods:** In this prospective study, 50 enlarged cervical LNs (33 benign and 17 malignant) were examined by B-mode ultrasound (US), color Doppler, and strain elastography. Elastographic patterns (1–5) were categorized based on distribution of hard area within LN. The shear wave velocity (SWV) of LNs was evaluated by ARFI imaging. Diagnostic performance of sonoelastographic parameters was compared taking histopathology of LN as a reference standard. Optimal cutoff value of the mean SWV values for predicting malignancy was determined using receiver operating characteristic curve analysis. **Results:** Among US parameters, borders of LN had the highest diagnostic accuracy (80%), while echogenicity had the least (48%). Majority of benign LNs ($n = 31$) had elastography patterns 1 and 2, while majority of malignant LNs ($n = 16$) had patterns 3–5 ($P = 0.000$). The sensitivity, specificity, and accuracy of elastography were 94.1%, 93.9%, and 94%, respectively. The mean SWV of benign LNs (1.670 ± 0.367 m/s) differed significantly from malignant LNs (2.965 ± 0.826 m/s; $P = 0.000$). A cutoff value of 2.05 m/s predicted malignancy with 88.2% sensitivity and 84.8% specificity and gave an area under the curve of 0.949 (95% confidence interval: 0.70–1.20). **Conclusion:** Elastography has high diagnostic accuracy in differentiating benign and malignant cervical LNs and can be potentially useful in selecting the LN with high probability of malignancy, on which fine-needle aspiration cytology/biopsy can be performed.

Keywords: Acoustic radiation force impulse imaging, elastography, lymph nodes, ultrasound

Introduction

Cervical lymphadenopathy, a common condition encountered by physicians in clinical practice, could be caused by a variety of pathologic processes such as infections, vasculitis, and malignancies such as lymphoma and metastases. Metastatic cervical lymphadenopathy is a common problem in head and neck oncology. Depending on the primary site, up to 80% of patients with upper aerodigestive mucosal malignancy have been reported to have cervical nodal metastasis at presentation.[1] The differentiation of malignant from benign lymph nodes (LNs) is essential because it predicts the patient prognosis and helps in decision-making and planning of management.[2]

High-resolution ultrasound (US) is the extensively used imaging technique for evaluating the morphology and internal architecture of cervical LNs. Color Doppler sonography is used to assess the pattern of intranodal vessels, blood flow velocity, and vascular resistance.[3] Although Gray-scale sonography in combination with Doppler has been suggested to be useful in differentiating metastatic LNs from reactive ones based on various criteria, there is no single US criterion for diagnosing malignant LNs with satisfactory sensitivity and specificity.[4,5]

Real-time elastography (RTE) is a novel, noninvasive imaging modality that assesses tissue elasticity by comparing local tissue displacement from US signals before and after the application of a compressive force.[6] Stiff tissues show less deformation (strain) than soft tissues under the compression of a transducer. Since malignant tissues are stiffer than their benign counterparts at many

sites, several reports have documented the utility of US elastography in differentiating malignant from benign lesions in the breast, prostate, liver, thyroid, and cervix.[7-11] There are two types of elastography techniques, namely strain elastography and shear wave-based elastography. Recent studies have shown the usefulness of strain elastography in differential diagnosis of benign and malignant cervical LNs.[12-14] However, some authors have questioned its additional value over conventional US in predicting malignancy and decision-making in terms of selection of LNs for biopsy.[15-17] Shear wave elastography with acoustic radiation force impulse (ARFI) imaging is an emerging sonographic technique in the assessment of malignant cervical nodes.[18,19]

Data on the utility of elastography in the evaluation of cervical LNs are relatively few, especially from India. The purpose of the present study was to evaluate the utility and diagnostic performance of strain elastography compared to conventional B-mode US and color Doppler in the differentiation of benign and malignant cervical LNs. We also investigated the usefulness of ARFI imaging in differentiating benign and malignant LNs.

Materials and Methods

This prospective study was performed at a tertiary care center in South India between August 2016 and February 2018. Fifty LNs of 50 consecutive patients who were referred for ultrasonogram of enlarged cervical LNs were enrolled. The Institutional review board (IRB) approved the study protocol, and the protocol complied with the tenets of the Declaration of Helsinki (IRB Approval No. 16/334). Informed consent was obtained from all participants. Patients with suboptimal image quality and those with completely necrotic nodes without solid component were not included. Patients who had received specific treatment (chemotherapy/radiotherapy) were also excluded from the study.

High-resolution US imaging was performed in the supine position with a high-frequency linear probe 9 L4 (Siemens Accuson S3000, Siemens Healthineers, Erlangen, Germany) by a single expert radiologist, blinded to patient's clinical profile. In gray-scale US, the LNs were evaluated for short-axis diameter and short-to-long axis diameter ratio (S/L ratio) in the longitudinal plane, borders (regular or irregular), echogenicity (homogeneous/heterogeneous), and hilum (present or absent). Intranodal vascular pattern was evaluated using color Doppler imaging. Absent flow signals or blood flow limited to the hilum was categorized as benign. Nonhilar blood flow with spotted, peripheral, or mixed types of vascularization was categorized as malignant. RTE was performed for the targeted node using the same probe. Manual light compression and decompression of the target LN by the transducer were performed to achieve an optimal image. Patients were asked to hold their breath and avoid swallowing during the examination to minimize motion of LNs. The elastographic box contained the LN and adjacent sternocleidomastoid muscle for each patient. Elastograms obtained with quality factor score ≥60 were included in the study. Color map settings with red coded as hard area and blue coded as soft area were used. The images were displayed on split screen mode with US gray-scale images on the left and elastogram images on the right. The best-fit B-mode US elastogram image pairs were selected for analysis. The elasticity patterns were categorized on a 5-point scale described by Alam *et al*.[12] [Table 1]. LNs showing type 1 and 2 elastography patterns were considered benign, while those with types 3, 4, and 5 were categorized as malignant.

For ARFI imaging, the targeted LN on B-mode image was identified using a region of interest, characterized by a fixed box [Figures 1-5]. Three measurements of shear wave velocity (SWV) were performed, and the average was calculated. SWV was expressed in meter/second.

Table 1: Elastographic patterns of lymph nodes

Patterns	Description
1	Absent or very small hard area
2	Small, scattered hard areas, hard area <45% of LN
3	Hard area ≥45% of LN
4	Peripheral hard area and central soft area
5	Hard area occupying entire LN

LN: Lymph node

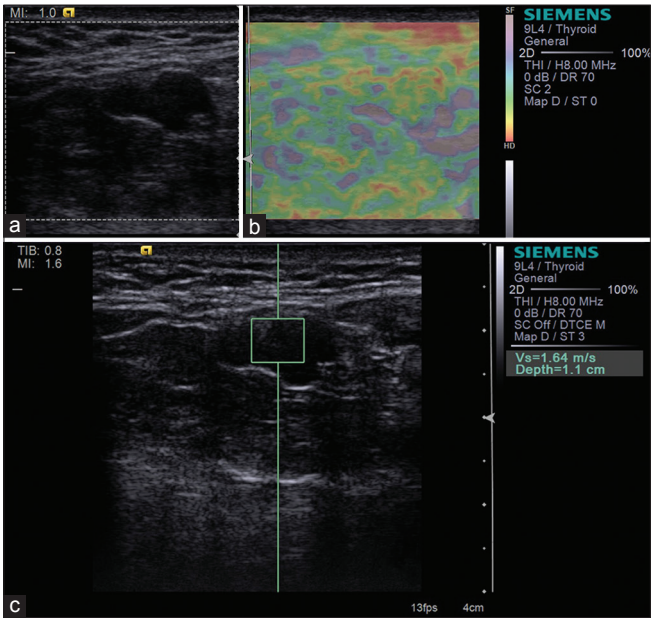

Figure 1: (a) B-mode ultrasound showing oval hypoechoic lymph node with irregular margins and absent hilum, (b) elastography image showing absent or very small hard area corresponding to pattern 1, and (c) acoustic radiation force impulse imaging shows a shear wave velocity of 1.64 m/s in the boxed area. Histopathology was suggestive of tuberculous lymphadenitis

[Downloaded free from http://www.jmuonline.org on Tuesday, December 17, 2019, IP: 10.232.74.23]

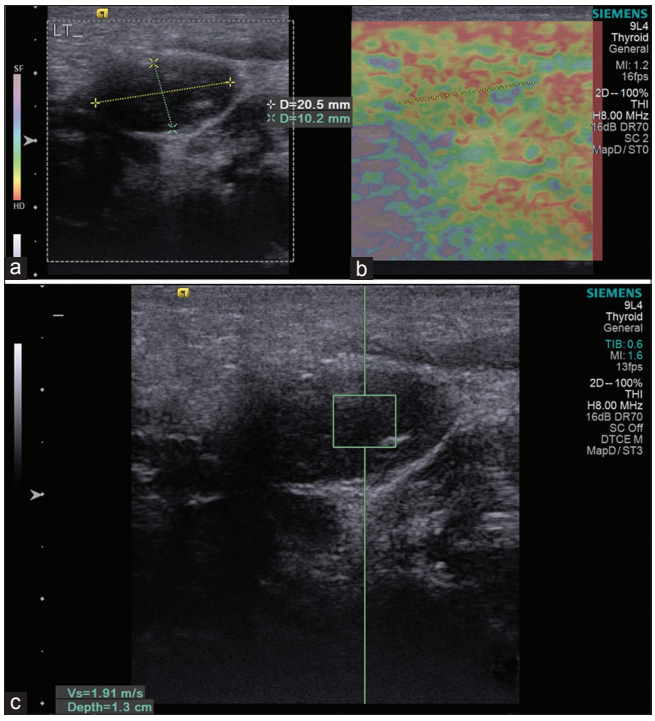

Figure 2: (a) B-mode ultrasound showing oval hypoechoic lymph node, (b) elastography image showing small, scattered hard areas corresponding to pattern 2, and (c) acoustic radiation force impulse imaging shows a shear wave velocity of 1.91 m/s in the boxed area. Histopathology was suggestive of reactive lymphadenitis

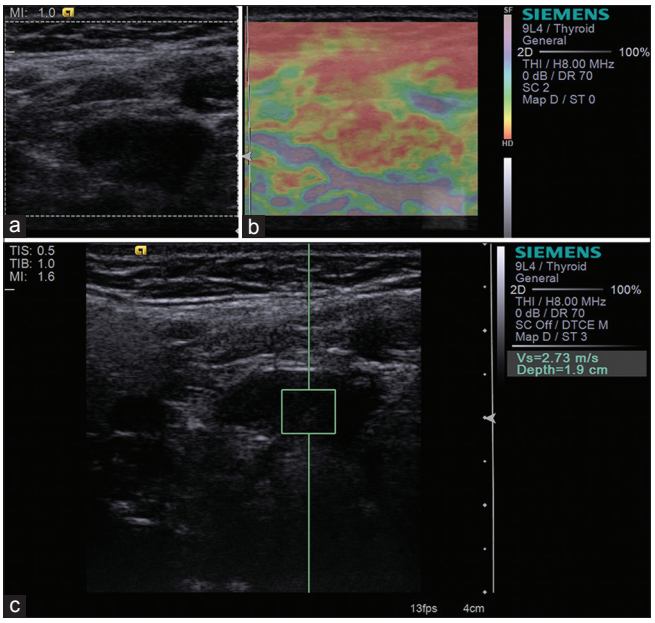

Figure 3: (a) B-mode ultrasound showing oval hypoechoic lymph node with loss of fatty hilum, (b) elastography image showing hard area ≥45% of lymph node corresponding to pattern 3, and (c) acoustic radiation force impulse imaging shows a shear wave velocity of 2.73 m/s in the boxed area. Histopathology revealed metastatic lymph node from carcinoma breast

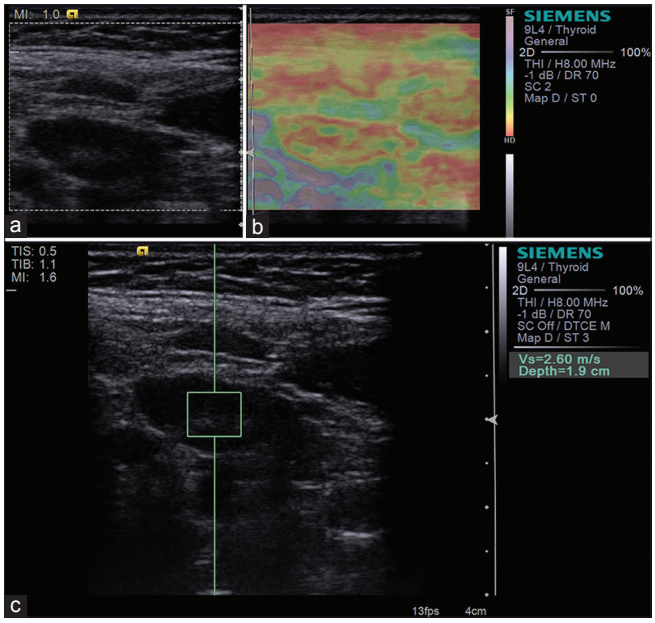

Figure 4: (a) B-mode ultrasound showing oval hypoechoic lymph node with loss of fatty hilum, (b) elastography image showing peripheral hard area and central soft area corresponding to pattern 4, and (c) acoustic radiation force impulse imaging shows a shear wave velocity of 2.60 m/s in the boxed area. Histopathology revealed metastatic lymph node from mucoepidermoid carcinoma parotid

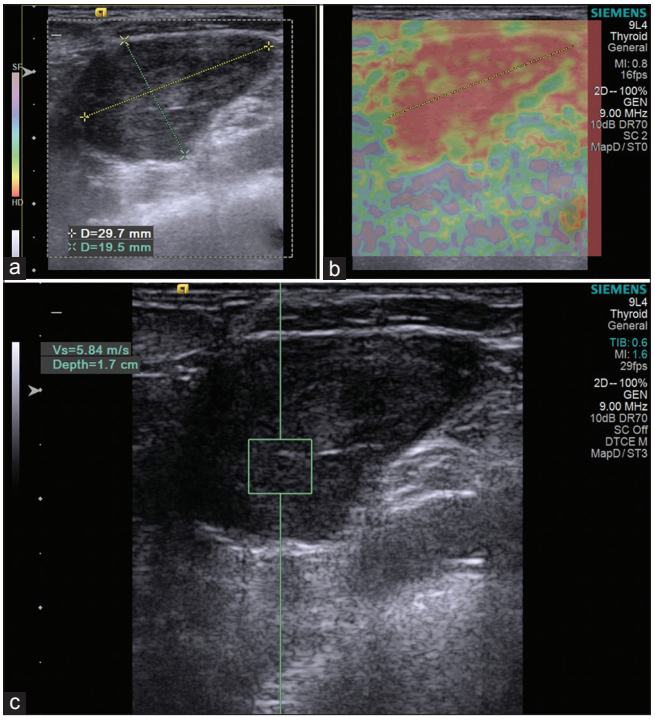

Figure 5: (a) B-mode ultrasound showing hypoechoic lymph node with irregular margins and absent hilum, (b) elastography image showing hard area occupying entire lymph node corresponding to pattern 5, and (c) acoustic radiation force impulse imaging shows a shear wave velocity of 5.84 m/s in the boxed area. Histopathology revealed metastatic lymph node from small cell carcinoma lung

Following elastography, all patients underwent surgical excision of the LN after cutaneous marking under US guidance. Histopathologic analysis of the LN was taken as the diagnostic standard of reference.

Statistical analysis

Statistical analysis was performed using the Statistical Package for Social Sciences version 24 (SPSS Inc., Chicago, IL, USA). Descriptive statistics was presented as mean ± standard deviation. Qualitative variables were presented in the form of frequency and percentages. Chi-square test was used to know the association between categorical variables. The diagnostic sensitivity, specificity, positive predictive value (PPV), negative predictive value (NPV), and accuracy were calculated with histopathologic analysis as reference standard. For analyzing the combined diagnostic performance of B-mode and Doppler, scores were assigned for five criteria: S/L ratio (ratio ≤0.5, score of 1: >0.5, 2), hilum (present, 1; absent, 2), borders (regular, 1; irregular, 2), echogenicity (homogenous, 1; heterogeneous, 2), and blood flow (hilar, 1; nonhilar, 2). The score for each LN was determined by adding the individual scores. A statistically supported cutoff line was set between scores 6 and 7. LNs with score <6 were categorized as benign, and 7–10 were categorized as malignant. Student *t*-test was performed to evaluate for significant difference in SWV values between benign and malignant LNs. A receiver operating characteristic (ROC) curve analysis was applied to obtain the optimal cutoff value for SWV to differentiate between benign and malignant LNs. Statistical significance was set at $P < 0.05$.

Results

The age of the patients ranged from 12 to 75 years (mean: 45.4 ± 16.9 years). About 52% (n = 26) were female and 48% (n = 24) were male. Of the 50 LNs examined, 33 (66%) were benign and 17 (34%) were malignant on histopathology. Of the 33 benign LNs, 27 had been reported as reactive and six as tuberculous lymphadenitis. Among the 17 malignant nodes, 15 were metastatic and two were due to lymphoma. Metastatic nodes were secondary to carcinoma lung, 4; parotid, 2; thyroid, 1; stomach, 1; breast, 1; poorly differentiated carcinoma from occult primary, 1; and head-and-neck squamous cell carcinoma, 5.

The US characteristics of the LNs and their diagnostic sensitivity, specificity, PPVs and NPV s, and accuracy are shown in Table 2. There were no significant differences between the benign and malignant LNs with respect to S/L ratio and echogenicity ($P = 0.273$ and $P = 0.623$, respectively). Hilum was found to be abnormal in all the 17 malignant LNs studied. Almost 81.8% of benign LNs (n = 27) had regular borders, whereas only 23.5% (n = 4) of malignant LNs had regular borders (P = 0.000). Among all B-mode parameters, borders of LN had the highest diagnostic accuracy (80%), while echogenicity was found to have the least accuracy (48%). On color Doppler evaluation, nearly 72% (n = 24) of benign nodes showed hilar flow compared to 35% (n = 6) of malignant nodes (P = 0.010).

Table 3 shows the correlation of elastographic pattern and histopathologic diagnosis of LNs. Majority of benign LNs (n = 31) had elastography patterns 1 and 2, while majority of malignant LNs (n = 16) had patterns 3–5. Higher elastographic pattern was significantly associated with malignant histopathology (P = 0.000).

The diagnostic performance of combined modalities (B-mode and color Doppler) and elastography is shown in Table 4.

The mean SWV of benign LNs was 1.670 ± 0.367 m/s. Metastatic LNs were significantly stiffer with mean SWV of 2.965 ± 0.826 m/s (P = 0.000). Figure 6 shows the ROC curve for SWVs measured using ARFI imaging in the differentiation of benign and malignant LNs. The best cutoff value for differentiating benign from malignant LNs was estimated to be 2.05 m/s with sensitivity of 88.2%, specificity of 84.8%, and area under the curve equal to 0.949 (95% confidence interval [CI]: 0.70–1.20).

Table 2: Ultrasound characteristics of lymph nodes and their diagnostic performance

US criteria	Benign LNs (n=33)	Malignant LNs (n=17)	Sensitivity (%)	Specificity (%)	PPV (%)	NPV (%)	Accuracy (%)
S/L ratio							
≤0.5	15 (45.4)	5 (29.4)	70.5	45.4	40	75	54
>0.5	18 (54.6)	12 (70.6)					
Hilum							
Present	22 (66.7)	0	100	66.6	60	100	78
Absent	11 (33.3)	17 (100)					
Borders							
Regular	27 (81.8)	4 (23.5)	68.4	87.1	76.4	81.8	80
Irregular	6 (18.2)	13 (76.5)					
Echogenicity							
Homogeneous	16 (48.5)	7 (41.2)	41.1	51.5	30.4	62.9	48
Heterogeneous	17 (51.5)	10 (58.8)					
Color Doppler							
Hilar	24 (72.8)	6 (35.3)	64.7	72.7	55	80	70
Nonhilar	9 (27.2)	11 (64.7)

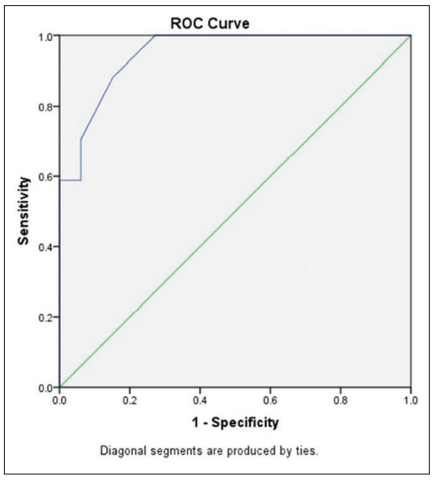

Figure 6: Receiver operating characteristic curve for shear wave velocities measured using acoustic radiation force impulse imaging in the differentiation of benign and malignant lymph nodes. The area under the curve was 0.949

Discussion

In this prospective study from India, we evaluated the performance of RTE in classification of benign and malignant cervical LNs. Our results indicate that RTE has a high specificity and diagnostic accuracy for identification of malignant LNs.

Although B-mode US is the most extensively used method for classification of cervical LNs because of its noninvasiveness and easy accessibility, specific criteria for distinguishing benign and malignant LNs are yet unclear. The association of signs often produces a highly suggestive appearance in most cases. In our study, the accuracy rate in distinguishing benign and malignant LNs was greatest for borders of LN (80%) and least for echogenicity (48%).

There were no significant differences between the benign and malignant LNs with respect to S/L ratio in our study. In contrast, several studies have noted S/L ratio >0.5 or a rounded shape to be associated with malignancy.[12,20] However, shape of LN can be misleading as nodes in nonmalignant conditions such as tuberculosis and Rosai–Dorfman disease have also been described as round.[21]

Our criterion of regular versus irregular borders revealed a diagnostic accuracy of 80%. Some other studies have categorized the LN borders as sharp and unsharp.[22,23] In a study by Khanna *et al*. from India, irregular margins were found in 7% of reactive LNs versus 55% of metastatic and 66% of tubercular nodes.[24] The absence of visible hilum due to replacement or effacement is considered as an important criterion for malignant LNs and has been reported by several authors.[12,13,25] In our study, all the 17 malignant LNs had no visible hilum, thus showing 100% sensitivity and NPV.

We observed a statistically significant difference in the vascular patterns between benign and malignant LNs ($P = 0.010$). Our observations can be comparable to that of Misra *et al*. and several other authors who have noted significant difference in vascularity between benign and malignant LNs.[13,26] In our study, the accuracy of vascularity of LN in predicting malignancy was 70%.

Table 3: Correlation of elastographic pattern and histopathologic diagnosis of lymph nodes

Elastogram pattern	Benign ($n=33$)	Malignant ($n=17$)	Total ($n=50$)
1	5	0	5
2	26	1	27
3	1	2	3
4	1	4	5
5	0	10	10

Table 4: Diagnostic performance of elastography and combined evaluation (B-mode and color Doppler)

Performance measure	Elastography	Combined B-mode and Doppler
Sensitivity (%)	94.1	94.1
Specificity (%)	93.9	81.2
PPV (%)	88.9	72.7
NPV (%)	96.9	96.4
Accuracy (%)	94	86

PPV: Positive predictive value, NPV: Negative predictive value

Even though combined B-mode US and Doppler could be potentially useful in differentiating reactive from malignant LNs, this modality may not have definite diagnostic value because of some overlapping sonographic appearances of benign and malignant nodes. Fine-needle aspiration cytology (FNAC) in the evaluation of cervical LNs has been reported to have a sensitivity of 82% and specificity of 97%.[27] However, FNAC is invasive and does not always provide a conclusive diagnostic result. Core needle biopsy from cervical LNs is also difficult owing to their relatively small size and potential injury to adjacent vascular structures.

RTE being noninvasive, has been suggested to be an adjunctive imaging tool to conventional US and could potentially reduce unnecessary biopsies.[28] Few prospective and retrospective studies concerning strain elastography of cervical LNs have been published in the literature.[29] While some have performed the measurement of elasticity scores (ES), some have measured both ES and strain ratio.

In our study, we used a 5-point scale described by Alam *et al*. to categorize the elasticity patterns. Accordingly, LNs showing types 1 and 2 elastography pattern were considered benign, while those with types 3, 4, and 5 were categorized as malignant. Nearly, 93.9% of benign LNs ($n = 31$) had a score of 1 or 2, while 94.1% of malignant LNs ($n = 16$) had a score of 3–5. The sensitivity, specificity, and accuracy of elastography were 94.1%, 93.9%, and 94%, respectively.

[Downloaded free from http://www.jmuonline.org on Tuesday, December 17, 2019, IP: 10.232.74.23]

Alam *et al*. evaluated 85 cervical LNs (53 metastatic and 32 reactive) using 5-point elasticity scale and documented 83% sensitivity, 100% specificity, and 89% accuracy in differentiating metastatic from reactive LNs.[12] Bhatia *et al*. evaluated 74 cervical LNs (37 malignant and 37 benign) using RTE.[17] Dynamic cine loops of elasticity imaging were qualitatively scored on a 4-point elasticity scale by three independent observers. Median ES for benign and malignant nodes was 2 and 3, respectively. A cutoff ES score of ≥2 achieved only 62.2% sensitivity, 83.8% specificity, and 73% accuracy for malignancy. Fair to good interobserver agreement was noted in their study.

Higher accuracy rates observed in our study can be attributed to the fact that there were very few cases of lymphoma ($n = 2$) and tuberculous adenitis ($n = 6$) in our study. Lymphomas have been reported to show low stiffness from an elastographic point of view because of the large size and homogeneous structure of LNs which can produce false-negative results for malignancy.[30] Granulomatous lymphadenitis associated with tuberculosis may demonstrate calcification, scarring, or necrosis and therefore show areas of greater stiffness (false positive).[14]

Ying *et al*. performed a meta-analysis to evaluate the performance of RTE for diagnosis of malignant LNs.[29] Nine studies including 835 LNs were analyzed. The pooled sensitivity and specificity for ES in diagnosing malignant LNs were 74% (95% CI: 66%–81%) and 90% (95% CI: 82%–94%), respectively.

In the present study, we were able to obtain greater specificity, PPV, and accuracy with RTE than conventional US and Doppler for detecting malignant LNs from diverse primary sites. Hence, RTE with its fairly high specificity and diagnostic accuracy can reduce unnecessary invasive procedures for diagnosis of malignant LNs. However, it cannot replace the conventional B-mode US and Doppler because it is dependent on the machine as well as operator's expertise since excessive compression can cause nonaxial displacement and change the tissue stiffness. This in turn can affect the accuracy of the software's correlation algorithms. Furthermore, elastography is not useful for calcified LNs and those with cystic degeneration.

Relatively, few clinical studies have evaluated ARFI in the assessment of malignant cervical LNs.

In our study, ARFI imaging revealed higher SWV for malignant LNs than benign ones. The cutoff value of 2.05 m/s had sensitivity of 88.2% and specificity of 84.8% in identifying malignant LNs. Our results are comparable to that of Fujiwara *et al*. who evaluated SWVs of 42 cervical LNs using ARFI.[31] Of the numerous cutoff values tested, a SWV cutoff value of 1.9 m/s best distinguished between reactive and malignant LNs. Their criterion of SWV >1.9 m/s had 95.0% sensitivity and 81.8% specificity. According to a recent meta-analysis of nine ARFI imaging studies that included 1084 LNs, the pooled sensitivity and specificity values for detecting malignancies were 87% (95% CI: 83%–91%) and 88% (95% CI: 82%–92%), respectively.[19]

Our study has few limitations. The sample size was small, and only enlarged LNs were included. Strain elastography using free hand compression is dependent on the compression technique, and excessive compression can alter tissue stiffness. A single expert radiologist performed all the elastograms, and no interobserver variability was studied. However, studies have reported fair to almost perfect interobserver agreement in strain elastography.[6]

Head-and-neck cancers account for nearly one-third of the cancer burden in India, and it is a well-known fact that status of cervical LN is the single most important prognostic factor in squamous cell carcinoma of the head and neck.[32] To the best of our knowledge, this is the first study from India to document the diagnostic performance of elastography in evaluation of cervical lymphadenopathy, and it has shown encouraging results.

Conclusion

Elastography has high diagnostic accuracy in differentiating benign and malignant cervical LNs and can be an effective noninvasive adjunctive tool in the evaluation of cervical lymphadenopathy. It is potentially useful in selecting the LN with high probability of malignancy, on which FNAC/biopsy can be performed, thereby reducing sampling errors. ARFI imaging can be a useful technique for differentiating benign from malignant cervical LNs.

Utility of Ultrasound Strain Elastography to Differentiate Benign from Malignant Lesions of the Breast

Vikrant Kanagaraju*, B. Dhivya, B. Devanand, V. Maheswaran

Department of Radiology, PSG Institute of Medical Sciences and Research, Coimbatore, Tamil Nadu, India

Abstract

Background: The purpose of this study was to determine the utility and diagnostic performance of strain elastography (SE) in differentiating benign from malignant lesions of the breast. **Materials and Methods:** In this prospective study, 50 palpable breast masses in 50 patients were examined by mammography, B-mode ultrasound (US) and SE. Lesions were categorized using Breast Imaging Reporting and Data System (BIRADS) scoring based on mammographic and sonographic features. Elasticity scores were assessed on a five-point scale based on the distribution of strain, and the lesion size on SE imaging and B-mode (elasticity imaging/B mode [EI/B] ratio) was compared. Findings were correlated with the BIRADS assessment and diagnostic performance of sonoelastography was evaluated taking histopathology as reference standard. **Results:** Histopathology revealed 29 (58%) malignant and 21 (42%) benign lesions. Infiltrative ductal carcinoma and fibroadenoma were the most common malignant and benign lesions, respectively. The sensitivity, specificity, positive predictive value, negative predictive value, and accuracy of SE was 100%, 76.1%, 85.2%, 100%, and 90%, respectively. Higher elasticity score was significantly associated with malignant histopathology ($P < 0.00001$). The mean EI/B ratio for malignant lesions was 1.36 ± 0.24 while that of benign lesions was 1.03 ± 0.30 ($P = 0.000$). **Conclusion:** Real-time SE of the breast, with its superior sensitivity and specificity, could provide improved characterization of benign and malignant breast masses compared with mammography and conventional US. Due to greater diagnostic accuracy, SE can be an effective adjunctive tool to B-mode US in predicting malignancy of breast, as well as in reducing the need for biopsies in benign breast lesions.

Keywords: Breast, elasticity imaging technique, sonoelastography

Introduction

Breast cancer is the most common malignancy in women all over the world and continues to remain a leading cause of cancer-related death in females. The incidence of breast cancer has been increasing steadily in both developing and developed countries.[1] Increased life expectancy, urbanization, changes in lifestyle, and delay in diagnosis contribute to the increasing incidence as well as mortality in the low- and middle-income countries. Early detection is critical to improve the breast cancer outcome and survival.

Current imaging techniques available for screening of breast cancer include mammography, ultrasonography, and magnetic resonance imaging (MRI). Although mammography is the current standard breast screening technique, its sensitivity is reduced in high-density breast tissue, in smaller tumors, and in young women.[2] Breast ultrasonography is widely used in the evaluation and categorization of breast lesions, owing to its high sensitivity. However, inability to image deeper lesions, limited ability to distinguish isoechoic lesions from surrounding fat, low specificity and increased biopsy rates resulting in patient discomfort and anxiety are some potential limitations of breast ultrasound (US).[3] Even though MRI is useful for screening of subjects with high breast cancer risk, its use for routine screening is limited because of high cost, time consumption and lack of widespread availability as well as need for experienced radiologists.

US elastography (USE) is a noninvasive imaging modality complimentary to US that detects tissue elasticity by the

application of an external stress. As malignant tissues are firmer than benign ones, the estimate of tissue stiffness by USE can aid in the differentiation between benign and malignant lesions. Recent studies have reported the utility of USE in the characterization of lesions in various tissues, such as thyroid, liver, prostate, lymph nodes, and breast.[4-8] It has been suggested that current elastography systems can evaluate histological information by depicting the distribution of tissue stiffness or strain which might have the potential to predict the therapeutic effect of treatment with anticancer agents.[9]

Published literature on the usefulness of strain elastography (SE) in the evaluation of breast lesions and its correlation with histopathology is limited, especially from India. The purpose of this study was to determine the utility and diagnostic performance of SE in differentiating benign from malignant lesions of the breast with histopathology as the reference standard.

Materials and Methods

This prospective study was conducted at a tertiary care center in South India from December 2014 to December 2017. The institutional review board approved the study protocol, and the protocol complied with the tenets of the Declaration of Helsinki. Informed consent was obtained from all participants. Fifty consecutive female patients aged 40 years and above referred to the department of radiology for the evaluation of palpable breast lump and sonography-guided biopsy were included in the study. Exclusion criteria consisted of those with cystic lesions of breast, history of prior biopsy, postsurgical status, prosthetic breast implants, and subcentimeter lesions. All patients underwent mammography, B-mode US, and SE followed by US-guided biopsy in the same session. All examinations and biopsy were performed by a single expert radiologist with over 10 years of experience in sonography.

Mammography was performed with SIEMENS MAMMOMAT 3000. Mediolateral oblique and craniocaudal views were taken in all patients, and in addition, coned-down or magnification views were used when necessary.

Ultrasonography of the breast was performed with SIEMENS ACUSON S3000 using high-frequency probe 18 L6. Sonographic features studied included size of the lesion, shape, margins, orientation, internal echogenicity, vascularity, calcification, and posterior acoustic shadowing. The lesions were categorized using the Breast Imaging Reporting and Data System (BIRADS) scoring based on mammographic and sonographic features as the following categories – category 2: benign; category 3: probably benign; category 4: suspicious for malignancy; and category 5: highly suggestive of malignancy.[10] BIRADS category 1 lesion was excluded from the study. Categories 2 and 3 were considered negative for malignancy and categories 4 and 5 were labeled as malignant.

SE of the breast was performed using the same probe in the supine position. The probe was placed over the region such that the lesion was at the center of the image. Holding the scan plane perpendicular to the skin surface, a slight compression–decompression movement was applied. The appropriate pressure and frequency of compression/decompression were optimized with the help of real-time display of quality index. Elastograms with quality index equal to or greater than 60 were included. The region of interest (ROI) included the lesion with subcutaneous layers and pectoralis muscle. It was ensured that the target tissue occupied no more than 25% of the total area of ROI. At least 5 mm thickness of normal adjacent tissue was included to assess the lesion stiffness in relation with average elasticity of surrounding tissue. Color map settings with blue coded as hard area and green coded as soft area were used. The images were displayed on a split screen mode with B-mode images on the left and elastographic images on the right. The best fit B-mode elastographic image pairs were selected for analysis. [Figures 1-4] The longest dimension of the lesion on elastographic image was compared with that of the corresponding B-mode image, and elasticity imaging/B mode ratio (EI/B ratio) was calculated.

The elasticity patterns were scored using the TSUKUBA scoring system [Table 1] described by Itoh *et al*.[11] The elasticity scores 1, 2, and 3 were considered benign, while scores 4 and 5 were labeled as malignant.

Biopsy of the lesion was performed under US guidance using an 18G tru-cut needle. Histopathology results were taken as the reference standard.

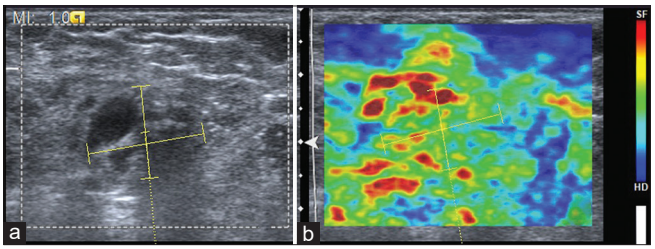

Figure 1: (a) B-mode ultrasound showing ill-defined hypoechoic lesion which was categorized as Breast Imaging Reporting and Data System category 4. (b) With strain elastography, entire hypoechoic lesion is deformable and evenly shaded green as surrounding breast tissue, corresponding to elasticity score 1. Histopathology was suggestive of nonspecific mastitis

Table 1: TSUKUBA elasticity score

Elasticity score	Description
1	Even strain in the entire lesion
2	Parts of the hypoechoic lesion does not show strain
3	Periphery of the hypoechoic lesion shows strain, no strain at the center
4	Entire lesion shows no strain
5	Entire lesion and surrounding area shows no strain

Statistical analysis

Statistical analysis was performed using Statistical Package for the Social Sciences (SPSS, SPSS Inc., Chicago, IL, USA) version 24. Descriptive statistics was presented as mean ± standard deviation. Qualitative variables were presented in the form of frequency and percentages. Chi-square test was used to know the association between categorical variables. The diagnostic sensitivity, specificity, positive predictive value (PPV), negative predictive value (NPV), and accuracy were calculated using 2 × 2 tables with histopathological analysis as the reference standard. Statistical significance was set at $P < 0.05$.

Results

Patients were aged between 40 and 72 years (mean: 48.96 ± 7.52 years). The mean age of the patients with benign and malignant lesions was 45.4 ± 5.47 and 51.5 ± 7.84 years, respectively ($P = 0.001$). On histopathological evaluation, 29 (58%) were found to be malignant and 21 (42%) were benign. Infiltrative ductal carcinoma and fibroadenoma were the most common malignant and benign lesions, respectively. Of the 29 malignant lesions, 17 (59%) were infiltrative ductal carcinoma, 11 (38%) were invasive lobular carcinoma and 1 (3%) was mucinous carcinoma. Among the 21 benign lesions, 7 (33%) were fibroadenoma, 4 (19%) were atypical ductal hyperplasia, 3 (15%) were breast abscess, 2 (9%) were sclerosing adenosis, and 2 (9%) were nonspecific mastitis. Granulomatous mastitis, complex cyst, and benign phyllodes tumor accounted for 1 (5%) each.

Mammography of 14 patients (28%) did not show any demonstrable lesion due to dense breast with predominantly fibroglandular tissue. 41% of the malignant lesions (12/29) had spiculated appearance on mammography, and microcalcification was encountered in 34% (10/29). 14% (4/29) showed architectural distortion.

Based on the BIRADS assessment, three were assigned BIRADS category 3, 18 were assigned category 4, and 29 were assigned category 5. The sensitivity, specificity, PPV, NPV, and accuracy of BIRADS assessment were 96.5%, 9.5%, 59.5%, 66.6%, and 60%, respectively, with histopathology as the reference standard.

Qualitative SE using elasticity scores had a sensitivity of 100% and specificity of 76.1% in detecting malignancy. The PPV and NPV were 85.2% and 100%, respectively, with diagnostic accuracy of 90%. Higher elasticity score was significantly associated with malignant histopathology ($P < 0.00001$). The mean EI/B ratio for malignant lesions was 1.36 ± 0.24 while that of benign lesions was 1.03 ± 0.30 ($P = 0.000$). Table 2 shows the correlation between histopathology, BIRADS assessment, and elasticity scoring among the lesions.

Discussion

In this prospective study, we evaluated the diagnostic performance of SE in predicting malignancy in lesions of breast. Qualitative SE with elasticity scoring was found to have a superior sensitivity, specificity, and diagnostic accuracy compared to conventional BIRADS assessment.

USE estimates the stiffness of tissues based on the degree of deformation of a tissue in response to an externally applied force. SE is a qualitative technique that uses either manual compression or an acoustic radiation force impulse push pulse to deform tissues.

Several authors have reported the additional value of SE to improve the specificity of conventional US in the differentiation

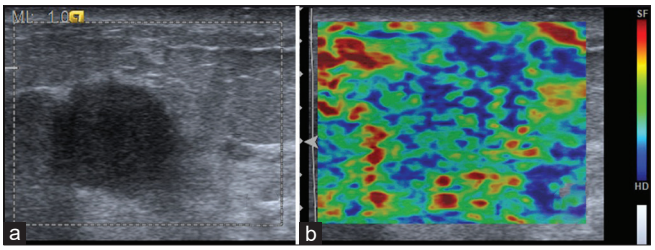

Figure 2: (a) B-mode ultrasound showing poorly marginated round hypoechoic lesion categorized as Breast Imaging Reporting and Data System category 3. (b) Strain elastographic image showing deformability of the peripheral portion of the lesion with stiff tissue in the center corresponding to elasticity score 3. Histopathology was suggestive of fibroadenoma

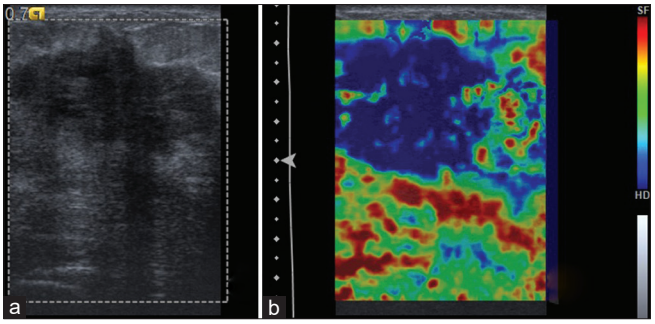

Figure 3: (a) B-mode ultrasound showing ill-defined hypoechoic lesion categorized as Breast Imaging Reporting and Data System 4. (b) With strain elastography, entire lesion is stiff, corresponding to elasticity score 4. Histopathology was suggestive of calcified fibroadenoma

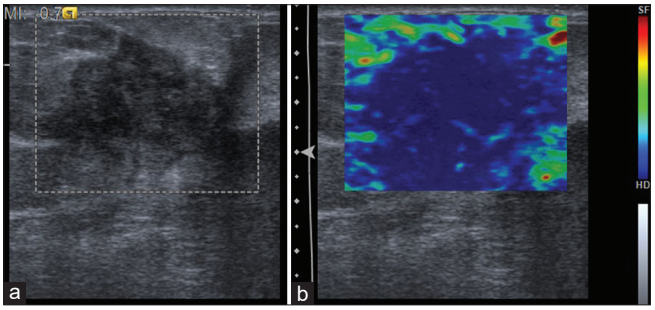

Figure 4: (a) B-mode ultrasound showing ill-defined hypoechoic lesion categorized as Breast Imaging Reporting and Data System 5. (b) With strain elastography, entire lesion and surrounding area are stiff, corresponding to elasticity score 5. Histopathology was suggestive of infiltrative ductal carcinoma

Table 2: Correlation between histopathology, Breast Imaging Reporting and Data System assessment and elasticity scoring among the lesions

Histopathology	BIRADS category	Elasticity score					Total (n=50)
		1	2	3	4	5	
Benign	3			2			2
	4	1	1	8	1	2	13
	5	1	1	2		2	6
Malignant	3					1	1
	4					5	5
	5					23	23

BIRADS: Breast Imaging Reporting and Data System

of benign and malignant breast masses and decrease the need for biopsies. While few have used EI/B ratio,[12] others have used five-point color scale and strain ratio[13,14] in the interpretation of SE images of the breast. However, the superior diagnostic performance of SE over B-mode US is controversial and factors such as operator experience, use of varied cutoffs, tumor size, and histologic subtype have been shown to influence the outcome.[15,16] Elasticity scoring had a sensitivity of 100% and specificity of 76.1%% in detecting malignancy among breast lesions in our study. The mean size of benign and malignant lesions was 17.06 ± 3.7 and 16.77 ± 3.1 mm, respectively. No significant difference in size was noted between benign and malignant lesions (P = 0.767). The superior diagnostic performance observed in our study can be attributed to the fact that most of the lesions (40/50) were smaller than 2 cm in size. Giuseppetti *et al*. have reported a better diagnostic performance of elastosonography in lesions smaller than 2 cm.[15] This is because a larger lesion has more chances of having hemorrhage or necrosis which might alter the tissue stiffness inside the lesion. Parajuly *et al*., based on their experience, have observed that lesions more than 5 cm should not be recruited in a study.[17]

Our results are comparable to that of Schaefer *et al*. and Atabey *et al*., who evaluated the performance of SE in breast lesions using a five-point scoring system.[18,19] With a cutoff between elasticity scores 3 and 4, elastography provided higher sensitivity and NPV. The authors have concluded that elastography can be an effective adjunct imaging modality in differential diagnosis of breast lesions, before the decision to biopsy a lesion in certain cases.[19]

In our study, 34 lesions were categorized as malignant on SE. Among these, 85% (29/34) were confirmed as malignancy on histopathology. Five benign lesions which had been categorized as malignant on SE were fibroadenoma (1), atypical ductal hyperplasia (3), and sclerosing adenosis (1) associated with calcification, which might have increased the stiffness of lesion. The false-positive rate was 23.8% in our study. In contrast, Zhi *et al*. have noted a false-positivity rate of 4.3% with SE in their study. Calcification and organized hemorrhage in benign lesions were responsible for false-positive diagnoses on SE.[3]

All the lesions with elasticity score less than or equal to 3 turned out to be negative for malignancy in our study. There were 13 benign lesions that presented as BIRADS category 4 necessitating biopsy. With a cutoff between 3 and 4 on SE, 10 of these 13 (76.9%) were true negatives on SE. Our observations are in line with recent literature, suggesting that SE can be useful in downgrading BIRADS category 4 lesions and reduce benign biopsy rates.[20]

Seven out of 18 BIRADS category 4 lesions and 25/29 BIRADS category 5 lesions had elasticity score 5. Among these, 87.8% turned out to be malignant, suggesting that elasticity scoring can be a useful predictor of malignancy. Satake *et al*. evaluated the ability of sonoelastography in predicting malignancy in breast masses classified as BIRADS category 4 or 5. Elasticity score was found to be a significant predictor of malignancy in BIRADS 4 masses (P = 0.002). However, elasticity score was not a significant predictor of malignancy in BIRADS category 5 lesions.[21]

A recent meta-analysis by Gong *et al*. on real-time elastography (RTE) in the differentiation of benign and malignant lesions of the breast that included 22 studies evaluating 4713 breast nodules reported an overall mean sensitivity and specificity of 0.834 and 0.842, respectively for elasticity scoring.[22] The authors have stated that RTE has high sensitivity and specificity in differentiating benign from malignant lesions and therefore can potentially reduce unnecessary breast biopsies. The mean EI/B ratio for malignant lesions was 1.36 ± 0.24 while that of benign lesions was 1.03 ± 0.30 (P = 0.000, P < 0.00001) in our study. Several studies have shown that tumors appear larger on elastography than on B-mode US.[23,24] A cutoff value of less than 1 for benign lesions and greater than or equal to 1 for malignant lesions has been shown to have high sensitivity and specificity for the characterization of lesions.[12] The variable dimension in elastography has been attributed to the desmoplastic reaction occurring in many cancers of the breast. Malignant lesions have been reported to appear significantly larger on strain imaging presumably because strain is uniquely sensitive to desmoplasia surrounding the lesion.[25]

Our study has few limitations. The sample size was limited and a single experienced radiologist performed all the examinations. SE is an operator-dependent technique and steady compression is needed for optimal images. However, in our study only images with optimal compression as displayed by the quality index were included. Intra- or inter-observer variability was not taken into account.

To the best of our knowledge, this is the first study on the utility of SE among the Indian population. The cancer projection data from India show that the number of breast cancer cases will become almost double by 2020.[26] Owing to the fact that the density of Indian breasts is different from that of the Western population[27] and density of breast parenchyma

can significantly influence the diagnostic performance of elastography, there is a need for more studies from this part of the world.

Conclusion

In this initial study from India, we conclude that real-time SE of the breast, with its superior sensitivity and specificity, could provide improved characterization of benign and malignant breast masses compared with mammography and conventional US. Due to greater diagnostic accuracy, SE can be an effective adjunctive tool to B-mode US in predicting malignancy of breast as well as decreasing unnecessary biopsies in clinical practice.

Abstract

Background: Resistive index (RI), derived from color Doppler imaging (CDI), is a marker of vascular resistance used widely in varied clinical settings. The aim of this study was to analyze the association between RIs of the orbital vessels in a pure cohort of type 2 diabetic patients with or without retinopathy using CDI. **Materials and Methods:** Fifty patients having type 2 diabetes and 50 age-matched controls were evaluated in this prospective study. Diabetic retinopathy (DR) was diagnosed based on seven-field stereo fundus photography and diabetic patients were divided into two. Patients with no DR ($n = 26$) were taken as Group 1, while patients with DR ($n = 24$) were taken as Group 2. CDI was performed and the RIs of the ophthalmic artery (OA), posterior ciliary artery (PCA), central retinal artery (CRA), and central retinal vein (CRV) were measured. **Results:** Significant differences were observed in the mean RI values of all orbital arteries between controls and patients with DR ($P < 0.05$). Comparison of RI values between controls and Group 1 showed no significant differences. Mean RI values of the PCA and CRA were found to be significantly higher in the patients in Group 2 than in Group 1 ($P = 0.03$ and $P < 0.001$, respectively). The duration of diabetes correlated with the mean RI of all the orbital vessels. RI of the CRA was a reliable predictive indicator for DR ($P = 0.001$). **Conclusion:** RIs of the orbital arteries are significantly higher in patients with DR. RI of the orbital vessels can be a potentially useful biomarker in the early diagnosis and follow-up of patients with DR.

Keywords: Color Doppler ultrasonography, diabetic retinopathy, vascular resistance

Introduction

Color Doppler imaging (CDI) is a convenient noninvasive method that gives information about the velocity of blood and vascular resistance at various sites of complex vasculature using simultaneous B mode ultrasound and Doppler images. The resistive index (RI), calculated from CDI, is a universally used measure of resistance to the arterial blood flow. In the recent past, RIs of the orbital arteries have been studied extensively to gain diagnostic and prognostic insight into a variety of clinical conditions, such as chronic obstructive pulmonary disease, hypertension, chronic kidney disease, and diabetes-related micro and macrovasculopathies.[1-5]

Usefulness of RI of the retrobulbar vessels in risk stratification and management of ophthalmic diseases such as diabetic retinopathy (DR), age-related macular degeneration, glaucoma, retinal vein occlusion, and thyroid-associated orbitopathy has been documented in the literature.[6,7]

Several studies have evaluated the RI of the retrobulbar vessels in diabetic patients with or without retinopathy and have shown inconsistent results. While few studies have shown significant correlation between RI of the orbital vessels and severity of DR,[8,9] few others suggest that the hemodynamic alterations observed in the orbital arteries reflect macrovascular changes and are not related to DR.[5,10] The observed inconsistencies can be attributed partly to the differences in sample sizes, patient characteristics, duration of diabetes, methods of assessment of DR, and probe positions used for color Doppler

measurement. Further, most of these studies included patients with comorbidities such as hypertension and coronary artery disease as well as those patients on cardiac or antihypertensive drugs, which might alter the vascular resistance.

The aim of this study was to analyze the association between RIs of the orbital vessels in a pure cohort of type 2 diabetic patients with or without retinopathy using CDI.

Materials and Methods

This prospective study was conducted between March 2017 and May 2019 from a tertiary care institution in South India. The institutional human ethical committee approval was obtained before the initiation of the study, and the principles of Declaration of Helsinki were adhered to. Informed, written consent was obtained from all the study participants. Fifty consecutive patients of type 2 diabetes (as per definition of the American Diabetes Association) were recruited for the study. Exclusion criteria were the presence of associated systemic hypertension, nephropathy, dyslipidemia, and cardiovascular diseases. Patients on medications known to affect systemic hemodynamics such as angiotensin-converting enzyme inhibitors, calcium channel blockers, and antimigraine drugs were excluded. Patients with a history of any ocular disease that might affect ocular blood flow such as retinal diseases, high myopia, glaucoma, previous ocular surgery, or panretinal photocoagulation were also excluded from the study. A control group of 50 age-matched subjects were included. None of the controls had any ocular or systemic disease.

Data regarding age, gender, body mass index (BMI), duration of diabetes and antidiabetic medications were obtained from all the study participants. Blood pressure and serum glycosylated hemoglobin (HbA1c) levels were determined.

All participants underwent a comprehensive eye examination and the presence/absence of retinopathy was diagnosed through dilated fundus examination and 30° stereoscopic fundus photograph of seven standard early treatment DR study fields using a digital fundus camera (TRC-50 DX Mydriatic Retinal Camera; Topcon Medical Systems, Oakland, NJ, USA). Diabetic patients were divided based on retinopathy into two groups. Group 1 contained patients with no DR; Group 2 included patients with DR. One eye (right eye, unless another ocular pathology was identified) was included from each study participant.

A masked expert radiologist performed CDI of the eye for all study participants using a color Doppler unit and a 12–5 MHZ linear-array transducer (Philips iU22 xMATRIX ultrasound system). The CDI was performed with patients lying in the supine position with a 30° head tilt and any undue pressure on the eye was avoided. Examiner's hand was rested on the orbital margin, and sterile coupling gel was applied over closed eyelids. Angle of the transducer was taken as 30°–60° during the examination. CDI was performed after exclusion of any other ocular or orbital pathologies by B mode, and optic nerve was considered as a reference for all further measurements. The velocity of blood flow in the ophthalmic artery (OA) was measured 20–30 mm behind the globe after crossing of the optic nerve in the nasal aspect. Blood flow velocity in the central retinal vein (CRV) and central retinal artery (CRA) was measured within the optic nerve around 5 mm behind the posterior margin of the eyeball. Blood flow velocity from the temporal branch of the short posterior ciliary artery (PCA) was determined approximately 5–10 mm posterior to the globe. The peak systolic velocity (PSV) and end diastolic velocity (EDV) measurements were taken for OA, CRA, PCA, and CRV. With the help of PSV and EDV, we calculated the vascular resistance based on the RI using Pourcelot's formula:

$$RI = (PSV - EDV)/PSV.$$

Statistical analysis

Statistical analysis was carried out using Statistical Package for the Social Sciences (SPSS, SPSS Inc., Chicago, IL, USA) Version 24. Data were reported as mean ± standard deviation. The normality of data distribution was assessed by Kolmogorov–Smirnov test. One-way analysis of variance with a *post hoc* Bonferroni was used for analysis of normally distributed continuous data. Kruskal–Wallis analysis was used for analyzing nonnormally distributed data. Bivariate analysis using Pearson's correlation coefficient was used to study the relationship of RIs with biochemical and demographic variables of patients with diabetes. Receiver operating characteristic (ROC) curve analysis was used to explore the predictive indicators of DR. A $P < 0.05$ (two-tailed) was considered statistically significant.

Results

The study consisted of 51 males and 49 females. The age of the participants ranged from 41 to 76 years. Duration of diabetes ranged between 6 months and 20 years. Among the diabetic patients studied, 26 had no DR and constituted Group 1. Group 2 consisted of 24 patients with DR. In Group 2, three patients had mild nonproliferative DR (NPDR) characterized by only few microaneurysms, seven had moderate NPDR (presence of more than just microaneurysms but less than severe NPDR), six had severe NPDR (presence of more than 20 intraretinal hemorrhages in each of four quadrants or definite venous beading in 2+ quadrants or prominent intraretinal microvascular abnormalities in 1+ quadrant), and eight had proliferative DR (presence of neovascularization of disc or elsewhere in the retina).

There were no statistically significant differences in the age, BMI, and blood pressure between controls and diabetic groups. Duration of diabetes and HbA1c levels were found to be significantly increased in Group 2 patients with DR ($P < 0.001$). Significant differences were observed in the RI values of all orbital arteries between controls and diabetic groups. Table 1 shows the demographic data and clinical attributes of controls and diabetic subjects.

Subgroup analysis with *post hoc* comparison revealed significantly higher RI values in OA, PCA, and CRA in Group 2 compared to controls ($P < 0.001$, $P < 0.001$, and $P = 0.03$, respectively). Comparison of RI values between Group 1 and controls showed no significant differences. When diabetic Groups 1 and 2 were compared, statistically significant differences were observed in the mean RI values of CRA and PCA ($P < 0.001$ and $P = 0.03$, respectively).

In bivariate analysis, the mean RI values of all orbital vessels, namely OA, CRA, PCA, and CRV, had a significant correlation with the duration of diabetes ($R = 0.396$, $P < 0.001$; $R = 0.282$, $P = 0.005$; $R = 0.334$, $P = 0.001$; and $R = 0.290$, $P = 0.003$, respectively) [Figure 1]. In addition, the mean RI of the OA correlated significantly with HbA1c levels ($R = 0.321$, $P = 0.001$) [Figure 2].

ROC analysis showed that the RI of CRA was a definitive predictive indicator for DR. RI of the CRA ≥ 0.79 indicated the existence of DR with a sensitivity of 75% and a specificity of 73% (area under the curve = 0.780 [95% confidence interval: 0.650–0.909]) [Figure 3].

Discussion

DR, a common microvascular complication of diabetes, is one of the leading causes for preventable blindness in people of the working age.[11] There has been conflicting evidence on the ocular hemodynamics as to whether blood flow is increased or decreased in diabetics. Curtis *et al*. have proposed a hemodynamic framework which states that there is an initial reduction in the perfusion of retina before the onset of DR which later increases as DR progresses.[12]

The various hematological changes observed in diabetes such as increased aggregation of erythrocytes and platelets, increased blood viscosity, and reduced deformability of

Table 1: Demographic and clinical characteristics of controls and diabetic subjects

Characteristic	Controls (n=50)	Group 1 (n=26)	Group 2 (n=24)	P

erythrocytes contribute to increased peripheral vascular resistance.[13] RI, an indirect measure of vascular resistance, can be useful to identify individuals at higher risk for developing DR. Further, RI, being independent of Doppler angle, has been shown to be reliable and reproducible with least coefficient of variation.[14]

Our study results demonstrate that significant changes occur in the RIs of the orbital vessels in patients with diabetes. The orbital vascular resistance (as reflected by RI) was found to be significantly increased in patients with DR as compared to controls and those in Group 1. Our observations are in agreement with certain other published studies.[15,16]

We observed no significant differences in the mean RI values between controls and those without DR. Our findings are similar to that of Basturk *et al*., who evaluated the RI of the orbital arteries in type 2 diabetics with microalbuminuria. No significant differences were observed in the mean RIs of OA, CRA, and PCA between controls and no DR group.[9]

In contrast, Dimitrova *et al*. have noted higher RI in the PCA in patients with no DR than controls.[17] However, their study included patients with hypertension and longer duration of diabetes than ours. In patients with hypertension, the RI of the PCA is reported to be high and correlates with duration of hypertension.[18] Moreover, CDI was performed in erect posture, which might have influenced the results. Few other investigators have noted increased RI values in the OA and CRA in patients with diabetes but without DR compared to that of controls, suggesting that even before the appearance of overt DR, there is increased resistance to blood flow in the peripheral vascular bed.[19,20]

We found significantly greater RI in the PCA and CRA ($P = 0.03$ and $P < 0.001$, respectively) in patients with DR compared to those without DR. While the inner layers of the retina are perfused by the CRA, the choroidal vasculature (derived from PCA) is responsible for the nourishment of outer retina. The various pathological changes observed in DR, such as loss of pericytes, thickening of the capillary basement membrane, and vascular smooth muscle cells, lead to compromised arteriolar integrity and autoregulation of blood flow. Loss of capillaries is critical to the pathogenesis of progressive retinal ischemia in DR and is a ubiquitous retinal finding from histopathological specimens.[21] Dropout of capillaries could be responsible for the increased vascular resistance observed in the RI of CRA and PCA in patients with DR. Further, the RI of the CRA was found to be a reliable predictive indicator of DR in our study. In this context, our findings are partly in agreement with that of Krasnicki *et al*., who have noted significant differences in the RI of CRA in subjects with DR and concomitant coronary artery disease.[5] The CRA, one of the major feeding vessels of the retina, reflects the identified vascular changes that have been associated with DR more sensitively. It has been suggested that hemodynamics in OA, a medium-sized muscular artery with many branches, is unlikely to be influenced by isolated alterations in blood flow in one of the branches.[22]

However, with progression of DR, the RI of the OA can eventually increase due to ensuing vascular changes related to diabetes in both retinal and choroidal vasculature.

Our finding of positive correlation between RI of all orbital vessels and the duration of diabetes is in concordance with that of Karami *et al*.[23] With prolonged duration of diabetes, alterations in blood vessel diameter and perfusion pressure occur due to disturbed autoregulatory mechanisms, subsequently leading to changes in the resistance of all retrobulbar vessels. We identified a statistically significant correlation between RI of the OA and the levels of HbA1c ($P = 0.001$). Clermont *et al*. have demonstrated reduction in the blood flow to retina with increasing HbA1c in subjects with type 1 diabetes without DR.[24]

Nagaoka *et al*. evaluated subjects with type 2 diabetes for changes in the retinal circulatory parameters using laser Doppler velocimetry and found significantly higher HbA1c in patients with the least retinal blood flow quartile, suggesting that poor glycemic control is associated with lowering of the retinal blood flow.[25]

Our study has several strengths. None of the patients had any associated vascular diseases such as hypertension. The presence of DR was assessed through seven-field stereo fundus photography for accuracy. A single experienced radiologist performed the CDI studies of the entire study participants, thereby eliminating interobserver variability. All examinations were performed with least pressure on the globe.

Limitations of our study include cross-sectional design and a small sample size. However, we intentionally excluded patients with other comorbid conditions to focus the effects of diabetes on retrobulbar circulation. Subgroup analysis of patients with different stages of retinopathy could not be performed because of limited sample size.

Conclusion

RIs of the orbital arteries are significantly higher in subjects with DR. RI of the orbital vessels can be a potentially useful biomarker in the early diagnosis and follow-up of patients with DR. This may be particularly helpful in patients with opacities in the ocular media.

Pseudotumor Cerebri Complicating Multisystem Inflammatory Syndrome in a Child

Karuppannasamy Divya[1], Chellappan Indumathi[2], Kanagaraju Vikrant[3], Sundaram Padmanaban[1]

[1]Department of Ophthalmology, PSG Institute of Medical Sciences and Research, Coimbatore, Tamil Nadu, India, [2]Department of Pediatrics, PSG Institute of Medical Sciences and Research, Coimbatore, Tamil Nadu, India, [3]Department of Radiology, PSG Institute of Medical Sciences and Research, Coimbatore, Tamil Nadu, India

Abstract

Purpose: To report a case of pseudotumor cerebri (PTC) in a child associated with multisystem inflammatory syndrome in children (MIS-C), associated with presumed coronavirus disease 2019.

Methods: A previously healthy 11-year-old female child presented with a 4-day history of fever, headache, vomiting, and loose stools. Laboratory investigations revealed neutrophilic leukocytosis, and markers of inflammation (C-reactive protein, ferritin, and interleukin-6) were significantly elevated. Pharyngeal swab for severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) by polymerase chain reaction was negative while anti-SARS-CoV-2 antibody was highly reactive. Ophthalmic evaluation for transient visual obscurations during hospital course revealed swelling of the optic disc in both eyes. Spectral-domain optical coherence tomography and ultrasonography confirmed the ophthalmoscopic findings. There was no neurologic deficit. Magnetic resonance imaging of the brain and magnetic resonance venogram revealed no structural lesion. The opening pressure of cerebrospinal fluid (CSF) was 336 mm of water, and CSF composition was normal.

Results: A diagnosis of PTC associated with MIS-C was made, and the child was treated with oral acetazolamide. Edema of the optic disc regressed following therapy, and the child is under follow-up.

Conclusions: PTC can occur in association with MIS-C. Clinicians need to be aware of this potential neuro-ophthalmic complication in MIS-C. Prompt diagnosis and treatment can prevent visual loss.

Introduction

Pseudotumor cerebri syndrome (PTCS) is a disorder characterized by increased intracranial pressure of unclear etiology that carries significant morbidity and limited therapeutic options. PTCS can be primary otherwise called idiopathic intracranial hypertension (IIH) or secondary, attributable to a number of medical conditions and drugs. This neurologic syndrome predominantly affects obese women of reproductive age group, and clinical features include symptoms and signs of raised intracranial pressure with normal cerebrospinal fluid (CSF) composition and no structural abnormality on brain imaging.[1] PTCS is relatively uncommon in children and is associated with variable risk factors and clinical presentation.[2] We report a case of PTCS in a child associated with multisystem inflammatory syndrome in children (MIS-C), temporally associated with coronavirus disease 2019 (COVID-19).

abdominal pain, and loose stools. There was associated lethargy but no history of seizures, altered sensorium, or respiratory symptoms. There were no sick contacts. At admission, the child had a temperature of 39°C, heart rate of 112 beats/min, and oxygen saturation of 100% on room air. Body mass index was 16 kg/m^2. Physical examination was unremarkable except for bilateral conjunctival congestion. Investigations revealed decreased hemoglobin, leukocytosis with neutrophilia, and elevated inflammatory markers including ferritin, interleukin-6 (IL-6), and C-reactive protein. Blood and urine cultures were negative, and liver function tests were found to be normal. Nasopharyngeal and oropharyngeal swabs for severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) by real-time polymerase chain reaction (RT-PCR) were negative. Serologic testing for SARS-CoV-2 antibodies by chemiluminescence immunoassay was highly reactive (observed titer – 212, ≥1 being labeled reactive) suggestive of SARS-CoV-2 infection. Table 1 shows the laboratory parameters. Echocardiogram was normal. On day 3 of admission, the child complained of transient obscurations of vision lasting for a few seconds associated with change in posture, and was referred for ophthalmic consultation.

On examination, uncorrected visual acuity was 20/20, and color vision was normal in both eyes. Anterior segment examination was unremarkable, and pupillary responses were normal. Extraocular movements were full. Fundus examination revealed optic disc swelling in both eyes [Figure 1a]. Neurologic examination was otherwise normal. Visual field evaluation by automated perimetry (Humphrey field analyzer) was found to be unreliable due to extensive fixation losses. Spectral-domain optical coherence tomography (OCT) showed increased thickness of peripapillary retinal nerve fiber layer (RNFL) in both eyes in all the four quadrants confirming edema of the optic disc [Figure 2a]. Magnetic resonance imaging of the brain and magnetic resonance venography (MRV) revealed normal ventricles, brain parenchyma, and venous sinuses. Transorbital ultrasound revealed bulging optic disc in both eyes. The optic nerve sheath diameter (ONSD) measurements obtained 3 mm posterior to the globe were found to be 5.6 mm in the right eye and 6 mm in the left eye [Figure 3a]. Lumbar puncture revealed a CSF opening pressure of 336 mm of water. CSF cultures were negative, and biochemistry was normal.

Since the child was hemodynamically stable and not hypoxic (SpO_2 100% on room air) at admission as well as during hospital course, she was managed with empiric broad-spectrum antibiotic therapy (intravenous ceftriaxone 2 g for 7 days) along with supportive care for fever (paracetamol) and loose stools (intravenous fluid replacement). As serial IL-6 and serum ferritin showed declining trend, the child was treated only with supportive measures. A diagnosis of pseudotumor cerebri (PTC) associated with MIS-C was made, and the child was started on oral acetazolamide 500 mg twice daily. By 4 weeks, headache and transient visual obscurations had subsided. Visual acuity remained 20/20, and fundus examination revealed resolving disc edema. The dose of oral acetazolamide was reduced to 250 mg thrice daily. At her last visit, 7 weeks since her initial presentation, she was found to have visual acuity of 20/20 and resolved disc edema in both eyes [Figure 1b]. Follow-up OCT revealed normalization of peripapillary RNFL thickness [Figure 2b]. The ONSD measurements were found to be 4 mm in both eyes at follow-up [Figure 3b]. The dose of acetazolamide has been tapered further, and she is under follow-up.

Table 1: Laboratory parameters of the patient and reference range

Parameter	Value	Reference range
Hemoglobin (g/dL)	10.5	11.5-15.5
White blood cell count (10^3/µL)	17	5-13
Neutrophil (%)	91.1	45-65
Lymphocyte (%)	7.5	32-52
Erythrocyte sedimentation rate (mm/h)	31	4-12
C-reactive protein (mg/dL)	39	<0.6
Serum ferritin (ng/mL)	352.4	7-140
IL-6 (pg/mL)	197.8	<7
NT-proBNP (pg/mL)	1163	<125
D-dimer (mg/L FEU)	1.48	<0.5
Anti-SARS-CoV-2 titer	212	<1

IL-6: Interleukin-6, NT-proBNP: N-terminal-pro-brain natriuretic peptide, Anti-SARS-CoV-2: Antibody against severe acute respiratory syndrome coronavirus 2

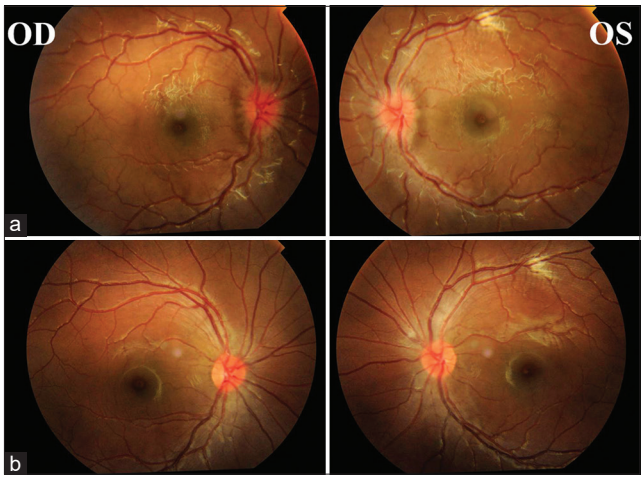

Figure 1: (a) Fundus photograph both eyes showing edema of optic disc. (b) Fundus photograph both eyes showing resolved disc edema at follow-up

Discussion

MIS-C, also called pediatric inflammatory multisystem syndrome temporally associated with SARS-CoV-2, is a life-threatening condition that can lead to multi-organ dysfunction and long-term sequelae. The clinical features of MIS-C include severe illness necessitating hospitalization, fever, and involvement of two or more organ systems, in combination with laboratory evidence of inflammation and laboratory or epidemiologic evidence of SARS-CoV-2 infection.[3] Our

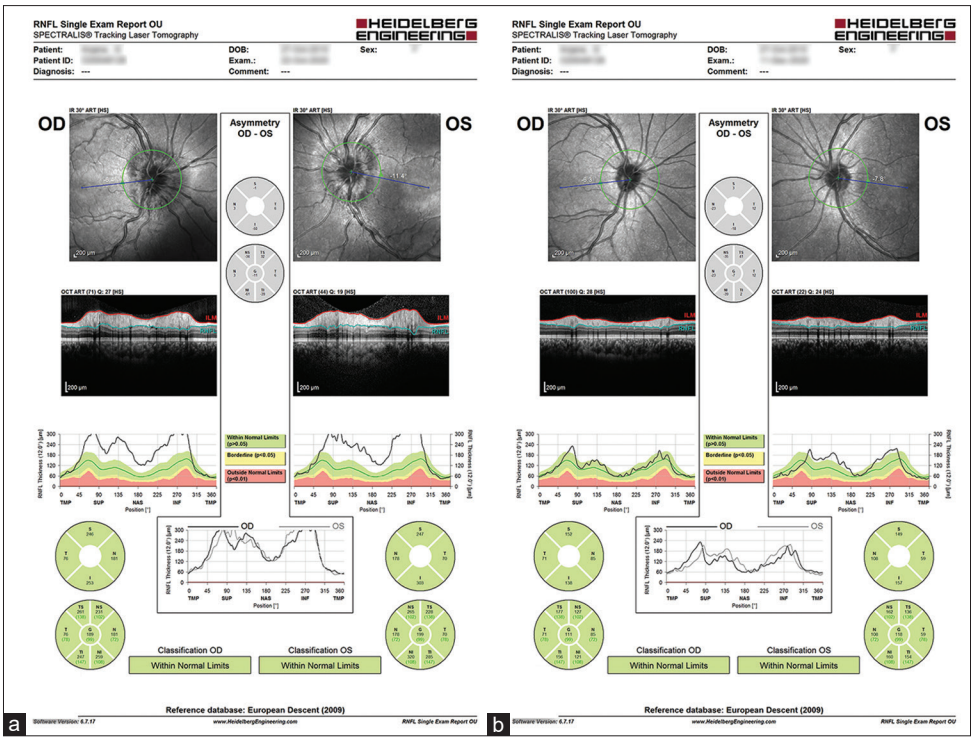

Figure 2: (a) Spectral-domain optical coherence tomography (SD-OCT) showing increased thickness of peripapillary retinal nerve fiber layer (RNFL) in both eyes. (b) SD-OCT both eyes at follow-up showing normalization of peripapillary RNFL thickness

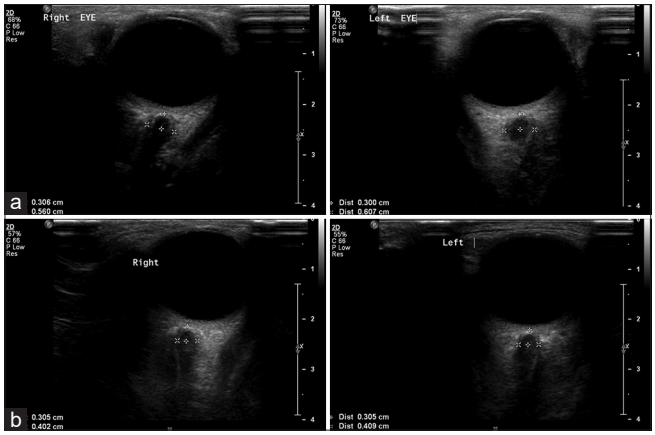

Figure 3: (a) Transorbital ultrasound showing increased optic nerve sheath diameter (ONSD) 3 mm posterior to inner scleral surface; 5.6 mm in the right eye and 6 mm in the left eye. (b) Transorbital ultrasound at follow-up showing normalization of ONSD; 4 mm in both eyes

patient was found to meet all the criteria specified in the Centers for Disease Control and Prevention and World Health Organization case definitions of MIS-C.[4,5]

The pathophysiology of MIS-C is unclear, and possible mechanisms include T-cell or antibody recognition of self-antigens resulting in autoantibodies, immune response against viral antigens expressed on infected cells and formation of immune complexes activating inflammation as well as viral superantigen sequences which activate host immune cells.[6] Dysregulated hyperinflammation is a critical event in the pathogenesis of MIS-C, and this condition is frequently associated with gastrointestinal symptoms and cardiovascular dysfunction.[7]

Although neurologic manifestations have been documented during acute phase of infection with SARS-CoV-2,[8,9] involvement of the central nervous system is uncommon in MIS-C. The neurologic features of MIS-C have been strongly suggested to represent a postinfectious immune response, and manifestations reported include headache, encephalopathy, and aseptic meningitis.[10]

We had not performed RT-PCR for SARS-CoV-2 on CSF since our patient showed evidence of previous infection with SARS-CoV-2 rather than current infection (pharyngeal swab was negative while antibodies to SARS-CoV-2 were present). Only one-third of cases of MIS-C have been reported to be positive by RT-PCR for SARS-CoV-2. The delayed presentation of MIS-C relative to the pandemic curve, a low proportion of cases who were SARS-CoV-2 positive by RT-PCR, and a high proportion who were antibody positive suggest that this inflammatory syndrome is not mediated by direct viral invasion but coincides with the development of acquired immune responses to SARS-CoV-2.[6] Previous studies have noted the absence of SARS-CoV-2 RNA in CSF analysis of COVID-19 patients with neurological symptoms suggesting that indirect mechanisms are responsible for neurologic manifestations in these patients.[11,12]

Although the symptoms of PTCS in children are similar to that of adults, the demographics vary, and children are reported to

have a higher incidence of secondary PTC. A distinct seasonal variation has been reported in the clinical presentation of IIH in prepubertal children, suggesting a possible association between IIH and concurrent infections in this age group.[13] Agraz *et al*. have noted a high incidence of atopy in their study cohort of children with PTC, suggesting that autoimmune component may play a role in pediatric population.[2]

To the best of our knowledge, four similar cases of PTCS associated with MIS-C (two case reports and a case series of two patients) have been reported in literature.[14-16] Although two patients had received therapy with doxycycline and steroids, the short course and recent initiation preclude the possibility of these medications contributing to increased intracranial pressure.

The mechanism behind the occurrence of PTCS in association with MIS-C is unclear. It has been postulated that increased intracranial pressure reflects systemic inflammation related to SARS-CoV-2 infection, resulting in central nervous system effects.[16] It is of interest to note that obesity, the most striking risk factor for PTCS, is associated with dysregulation of several inflammatory cytokines and aberrant glucocorticoid metabolism through manipulation of the enzyme 11-beta-hydroxysteroid dehydrogenase (11β-HSD).[17] 11β-HSD is a bidirectional enzyme that regulates prereceptor corticosteroid availability and glucocorticoid availability in the central nervous system that is one of the factors pivotal to intracranial pressure homeostasis. Among the two isoforms, 11β-HSD1 activates cortisol from cortisone while the isoform 11β-HSD2 inactivates cortisol. It is well established that several inflammatory cytokines such as tumor necrosis factor-α and ILs 1 and 6 are potent activators of 11β-HSD1.[18]

We speculate that PTC associated with MIS-C can be multifactorial, and one another possibility could be aberrant glucocorticoid metabolism as a result of cytokine storm and 11β-HSD1 activity. Increased 11β-HSD1 activity has been shown to influence the pathogenesis of PTC through manipulation of CSF dynamics at the level of choroidal plexus as well as arachnoidal granulations.[19] Further studies are warranted in this regard.

Few cases of isolated intracranial hypertension in association with active SARS-CoV-2 infection have been reported in adults. The proposed pathophysiologic mechanisms for intracranial hypertension include acute encephalitis, venous sinus thrombosis, intracranial venous congestion due to inflammation as a result of SARS-CoV-2 infection, and the associated coagulopathy as well as hyperviscosity state leading to impaired absorption of CSF.[20,21] The absence of clinical features such as altered sensorium/seizures and normal brain parenchyma evident on neuroimaging in our patient ruled out encephalitis. Normal MRV ruled out venous sinus thrombosis in our patient.

The other possible etiologies of swelling of optic disc in the setting of SARS-CoV-2 infection include optic neuritis, ischemic optic neuropathy, papillophlebitis, and retinal vein occlusion. The presence of normal visual acuity and color vision along with normal pupillary responses and the absence of associated retinal hemorrhages or venous tortuosity in our patient made us exclude these causes.

Prompt diagnosis and treatment of PTCS is essential since it can lead to irreversible visual loss. Although the pathophysiology remains unclear, clinicians should be aware of this potential complication with MIS-C. Fundus examination is valuable as part of a multidisciplinary approach toward management of MIS-C.

Declaration of patient consent

The authors certify that they have obtained all appropriate patient consent forms. In the form the patient(s) has/have given his/her/their consent for his/her/their images and other clinical information to be reported in the journal. The patients understand that their names and initials will not be published and due efforts will be made to conceal their identity, but anonymity cannot be guaranteed

ABSTRACT:

Background: Cervical spondylosis is a common degenerative disease of spine generally seen in old age, frequently causing compression of spinal cord and /or nerve roots by protruding disc or osteophytes. Magnetic Resonance Imaging (MRI) is the modality of choice for evaluation of patients with features of cervical spondylotic myelopathy. In addition to routine MRI sequences, advanced MR techniques like diffusion tensor imaging (DTI) can be used to obtain specific information about the spinal cord.

Materials and methods: It is a prospective observational study conducted in 30 patients who presented with clinical and neurological features of cervical spondylotic myelopathy, who had undergone MRI.

Result: All the patients had undergone routine MRI along with diffusion tensor imaging. The Apparent Diffusion Coefficient (ADC) and Fractional Anisotropy (FA) values of the spinal cord were measured at the level of normal spinal canal dimension and at the level where there is narrowing of the spinal canal. The ADC values were found to be high and the FA values were low at the level of the spinal canal stenosis in comparison with values measured at the level of normal spinal canal dimension, which were statistically significant.

Conclusion: DTI parameters showed significant correlation with the clinical parameters, suggesting that DTI can be used to detect microscopic changes related to compressive myelopathy, before changes are apparent in the routine MR sequences. This can enable us to intervene early to avoid irreversible damage to the spinal cord.

Key words: Cervical spondylotic myelopathy, Diffusion tensor imaging, Fractional anisotropy.

Introduction

Cervical spondylosis is a common degenerative disease of spine generally seen in old age, frequently causing compression of spinal cord and /or nerve roots by various pathological entities like protruding disc, osteophytes and thickening of ligamentous structures around the spinal cord.[1] Spondylotic myelopathy refers to compression of the spinal cord by the above mentioned structures leading to impairment of spinal cord function.[2] Cervical spondylotic myelopathy (CSM) is usually seen after the 5th decade. Patients with CSM usually present with symptoms of numbness and weakness in limbs, pain over shoulder and neck, incoordination. Magnetic Resonance Imaging (MRI) of cervical spine is non-invasive and accurate imaging tool in assessing the structural changes of spinal cord due to its high contrast and soft tissue resolution[3]. It helps to ascertain the site and the

severity of degenerative compressive myelopathy. It is also useful to exclude any other pathology, like neoplasm which can cause compressive myelopathy and mimic degenerative disc disease.

Classical MRI finding seen in compressive myelopathy is focal T2 hyperintensity in spinal cord at the level of a compressive lesion. This signal change is suggestive of either spinal cord oedema in acute cases, or gliosis and myelomalacia in chronic cases[4,5]. Oedema is associated with swelling of the spinal cord and chronic changes on the other hand show thinning of the spinal cord. Other imaging modalities like Computed Tomography (CT) and radiography play a complementary role in the evaluation of CSM. Due to its inherent high spatial resolution CT is better than MRI in the assessment of cortical bone, osteophytes and other calcified ligamentous structures. These structures can also cause spinal canal compromise. Plain radiography is still being used as an initial tool for evaluating degenerative disc changes[6]. The ultimate aim of doing imaging studies is to identify the spinal cord abnormalities early and take remedial measures to prevent further damage[7].

Aims:

1. To compare Fractional Anisotropy (FA) and Apparent Diffusion Coefficient (ADC) values of the spinal cord obtained at the level with above and below the level of spinal canal stenosis.
2. To compare the Diffusion Tensor Imaging (DTI) parameters with Nurick score and neurological examination findings.
3. To detect the early microscopic level structural abnormalities of spinal cord using DTI before overt, irreversible changes manifest in routine MR sequences.

Materials and methods:

It is a prospective observational study performed in 30 patients who were referred by the department of neurology. These patients presented with clinical symptoms and neurological findings suggestive of cervical myelopathy. The study period was from January 2018 to March 2019 at the department of Radiology and imaging sciences PSG Institute of Medical Sciences & Research. Prior to commencement of the study, clearance has been obtained from Institutional Human Ethical Committee and informed written consent has been taken from the participants. Patients with clinical and neurological features of CSM were included in the study. Patients with following abnormalities were excluded from the study: 1.focal or diffuse signal abnormality in the spinal cord. 2. History of cervical spine injury / surgery. 3. Focal lesions in the brain which may be the underlying pathology causing the neurological abnormality.

Prior to undergoing MRI all these patients were assessed symptom wise for the severity of CSM using Nurick score and neurological examination was performed to assess the power of lower and upper limbs. In Nurick score patients were categorized from grade 0 to 3, based on clinical history alone, where grade 0 represented mild form of disease with only symptoms suggestive of nerve root involvement (radiculopathy), grade 3 represents more severe neurological deficit where the patients are wheel chair bound with no independent mobility (myelopathy). On clinical examination muscle power of the limbs was assessed using standard grade 1 to grade 5.

All the patients underwent MRI in Siemens 1.5 Tesla 16 channel machine.

MRI protocol:

1. Routine non contrast T1 and T2 weighted images to look for overt signal changes in T2 Weighted Images.
2. DTI acquisition using EPI yielding the following set of images:

www.ijbamr.com P ISSN: 2250-284X , E ISSN : 2250-2858

1. Diffusion weighted imaging, 2.Trace weighted, 3.FA and ADC mapping 4.Tensor imaging.

DTI parameters:

Diffusion directions measured – 20.

The b factors – 0, 100 and 1000

TR/ TE - 3600 /94ms

Field of view - 230mm

Slice thickness - 5mm.

Images were analysed using Siemens Syngo via work station. Initially presence of any focal or diffuse spinal cord lesions was excluded. After that dimension of the spinal canal was measured at all the vertebral level. Subsequently DTI analysis was performed by drawing region of interest at the level of maximum spinal canal stenosis, one vertebral level above the spinal canal stenosis and one level below (Figure 1a). DTI Parameters assessed were FA and ADC, the values of which were displayed as a table in the system (Figure 1b) along with images of visual maps of ADC (Figure 2a) and FA (Figure 2b).

Statistical analysis:

The data has been analysed using SPSS 23.0 version. To describe the data descriptive statistics frequency analysis, percentage analysis were used for categorical variables and the mean & standard deviation (SD) were used for continuous variables. To find the significant difference in the multivariate analysis for repeated measures the repeated measures of ANOVA was used with Bonferroni correction to control the type I error on multiple comparison. To assess the relationship between the variables Pearson's Correlation was used. In all the above statistical tools the probability value .05 is considered as statistically significant.

Results:

A total of 30 patients were enrolled in our study of which 20 were men and 10 were women (Figure 3). Nurick Score distribution is given in the table 1.

All the patients had muscle power grade between III and V. (Figure 4). No patient in our study had muscle power less than 3.

Diffusion tensor parameters (ADC and FA) were measured at 3 levels of the spinal cord (Figure 1a). One measurement at the level of the spinal canal stenosis and 2 measurements (above and below the level of stenosis) at the level of normal canal dimension. The values of ADC and FA measured at different levels of the spinal cord are given in table 2.

Pairwise comparison of ADC and FA was performed and results are given in table 3 and table 4. Patients were found to have high ADC and low FA values at the level of stenosis when compared with ADC and FA values at the level of no stenosis. The differences were found to be statistically highly significant with a p value of 0.0005 (ANOVA test was used). There was negative correlation between the mean FA and ADC at the level of stenosis with r value of -0.424 and p value of 0.019. There was negative correlation between the mean FA and ADC at the level of no stenosis with r value of -0.0545 and p value of 0.002. There is negative correlation between Nurick score (clinical grading) and muscle power (neurological examination) r value of -0.07 and P value of 0.001.

www.ijbamr.com P ISSN: 2250-284X , E ISSN : 2250-2858

Correlation of FA and ADC with muscle power:

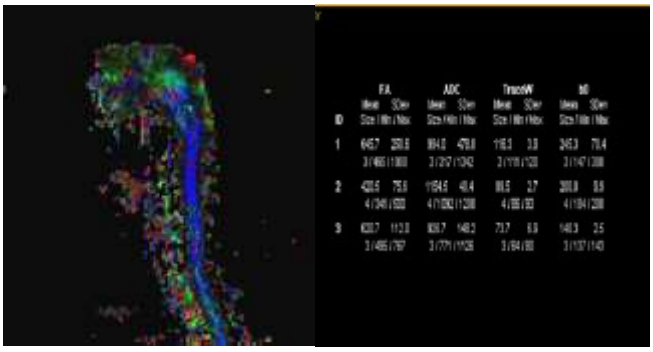
At the level of stenosis:

There was a positive correlation between muscle power and mean FA value with r value of 0.2 and p value 0.1. There is a negative correlation between muscle power and mean ADC value at the level of stenosis with r value of -0.1 and p value 0.1 and p value of 0.3.

At the level of no stenosis:

There is a positive correlation between muscle power grade and mean FA value at the non- stenosis level with r value of 0.18 and p value 0.32 and p value of 0.4. There is a negative correlation between muscle power grade and mean ADC value at the non-stenosis level upper with r value of -0.25 and p value 0.17.

Correlation of FA and ADC with Nurick score:



At the level of stenosis:

FA and Nurick score has negative correlation with r value of -0.4 and p value of .0005. ADC and Nurick score has a positive correlation with r value of -0.1 and p value of – 0.2

At the level of no stenosis:

FA and Nurick score had positive correlation with r value of 0.1 and p value of –0.4. ADC and Nurick score had negative correlation r value of -0.05 and p value of– 0.7

ROC analysis of FA in predicting microscopic level structural cord abnormality in the spinal cord at the level of the spinal canal stenosis. (Figure 5) was done. Subsequently test result variables (table 5) and sensitivity and specificity (table 6) were calculated. Likewise ROC analysis of ADC in predicting microscopic level structural cord abnormality was done (Figure 6). Test result variables (table 7) and sensitivity and specificity (table 8) were also calculated for ADC. Both FA and ADC showed good sensitivity and specificity in predicting the early microscopic level changes in the spinal cord caused by degenerative disease, ADC was slightly more specific than FA.

Discussion:

MRI has revolutionized the evaluation of pathology related to spinal cord. Exceptionally high contrast resolution and soft tissue resolution place MRI way above other imaging modalities in the evaluation of spinal cord.[2] Recent advances in respect to high field strength and fast and robust sequences have greatly contributed to the superior performance of MRI[8]. Very small yet important structures like the nerve roots and the thin ligaments need to be assessed in almost all patients which can harbour the pathology. However significant degree of anatomical and structures abnormalities need to be present before they are visible in routine MRI sequences, primarily in the spinal cord[6]. Hence the need for imaging technique which is similar to a biomarker to pick up early microscopic level changes in the neural structures, specially the spinal cord. Role of DTI in the evaluation of the brain pathologies has been proved and it is being used routinely, however its usage in the evaluation of spinal cord is still evolving.

The application of DTI in the evaluation of spinal cord is hindered by various factors. Spinal cord is a very narrow structure with a high elasticity and situated in anatomically complex location, which are the factors

www.ijbamr.com P ISSN: 2250-284X , E ISSN : 2250-2858

making evaluation difficult. Other factors like CSF pulsation, motion artefacts and breathing related artefacts make usage of DTI difficult as a routine sequence. Newer techniques like reduced field of view with oblique spin echo and OVS (outer volume suppression) have been used to overcome the limitations and better images can be obtained. All these improved techniques provide high resolution images not only in the cervical cord but also the entire spinal cord.

Budzik et al[9] studied the feasibility of DTI and fiber tracking in CSM. FA values showed correlation with the patients' clinical scores. High signal intensity of the spinal cord on T2WI did not correlated either with the DTI parameters or with the clinical symptoms, suggesting that FA is better in depicting the early structural abnormality of the spinal cord when compared with T2W imaging[10, 11]. But they did not study the relationship of DTI scalars with cervical canal width. In our study all the patients had spinal canal stenosis, in that about 73% of the patients had relative narrowing and 27% has absolute narrowing.

In our study degenerative changes like disc bulge, protrusion, osteophytes and ligament thickening led to spinal canal narrowing. These pathological changes caused disruption of the white matter tracts and other secondary changes in cervical cord. Secondary changes like cord edema and macrophage proliferation lead to increased diffusivity of water molecules with in the spinal cord parenchyma, especially in the white matter which can alter the FA and ADC values[12]. These changes were apparent much before macroscopic changes appear in routine T1 and T2W images.**UzeyirAhmadli et al**[13] investigated the utility of DTI sequence in patients with CSM symptoms for early detection of microscopic changes in the spinal cord at the level of narrowed spinal canal without any T2 signal alterations. FA values with in the cord were reduced and ADC increased at site of canal stenosis when compared with non-stenotic segments above the level of canal stenosis. However no significant difference was noted in FA and ADC values between stenotic segment and non-stenotic segment distal to the level of stenosis.

In our study there was statistically significant reduction in the FA values and increase in the ADC values at the site of stenosis when compared to the non-stenotic levels (upper and lower). There was no statistically significant reduction in FA value noted at the non-stenotic levels (upper and lower). The reduction in FA value at the stenotic level is presumably due to reduced neuronal fibers with increase in the extracellular space or due to extracellular edema which can result in increased diffusivity of water molecules and consequently facilitated diffusion.

Jones et al[14] reported a significant correlation between FA and modified Japanese orthopedic association score and Nurick score, and reported that patients who had a higher FA at the compressed level of spinal cord tended to have a better recovery of functionality after surgery when compared to patients undergoing surgery who had a lower FA value pre operatively. In our study there was significant correlation between the patient’s symptoms and the DTI parameters. We graded clinical symptoms using only Nurick score, modified Japanese orthopedic association score was not used.

FA and Nurick score had a negative correlation with r value of -0.4 and p value –0.0005, which implies that the FA values tend to be less when the Nurick score is on the higher side. ADC and Nurick score had a positive correlation with r value of-0.1 and p value of – 0.2, which is equal to higher ADC means higher Nurick score.There was also a significant correlation between the DTI parameters and muscle power. There was positive correlation between muscle power and mean FA value at the level of stenosis with r value of 0.2 and p

www.ijbamr.com P ISSN: 2250-284X , E ISSN : 2250-2858

value of 0.1. There is a negative correlation between muscle power and mean ADC value at the level of stenosis with r value of -0.1 and p value of 0.3. ROC was calculated between the stenotic and non stenotic level. The mean was calculated between the upper and lower non-stenotic level and it was compared with the stenotic level. FA showed a sensitivity of 86.7% and specificity was 86.7% when the cut was kept at 0.57 (Table 6). ADC showed a sensitivity of 86.7% and specificity was 90.0%, when the cut off is kept at 1.1. (Table 8).

Conclusion:

- Our study showed significant correlation between the patients' clinical symptoms and DTI parameters.
- DTI has the potential to detect microscopic structural changes in the spinal cord, before the T2 signal changes appear on conventional MRI.
- DTI can be used as a tool for detecting early changes in cervical spondylotic myelopathy, which would prognosticate the clinical and surgical outcome[14, 15].
- DTI technique should be routinely used on patients with clinical symptoms of cervical spondylotic myelopathy.

Limitations:

- The sample size of the study population was relatively small
- The long-term follow-up of the patients were not done
- It was impossible to determine the percentage of patients with early cervical spondylotic myelopathy who would have advanced to T2 hyperintensity changes in spinal cord, when left untreated.
- Cost and the availability of MRI.

Further studies have to be done on large group with long term follow up of those patients to determine the potential utility of quantitative diffusion tensor imaging.

Conflicts of interest:

There are no conflicts of interest to declare.

Technical Note

Assessment of Adult Diagnostic Reference Levels for Panoramic Radiography in Tamil Nadu Region

Amal Jose, A. Saravana Kumar, K. N. Govindarajan, B. Devanand[1], N. Elango[1]

Departments of Medical Physics and [1]Radiology, PSG Institute of Medical Sciences and Research, Coimbatore, Tamil Nadu, India

Abstract

Aim: The aim of this study was to calculate dose area product (DAP) and to determine diagnostic reference level (DRL) for adult panoramic procedures in Tamil Nadu. **Materials and Methods:** In this study, air kerma on the front side of the secondary collimator was measured with a Black Piranha, RTI Electronics, Sweden and multiplied with the corresponding exposed area to calculate DAP. The obtained DAP values were further analyzed, and DRL was calculated using the Microsoft Excel software. The study was carried out with regular adult exposure parameters. **Results:** The mean, range, and 3rd quartile values for 67 panoramic scanners in Tamil Nadu, India, were calculated as 94 mGycm^2, 41 mGycm^2–165 mGycm^2, and 114.3 mGycm^2, respectively. The results are comparable with other international studies. **Conclusion:** The present study suggests that further optimization can be achieved in many centers by the recruitment of professionally qualified radiographers and conducting periodic training programs on the optimization of exposure parameters. Considering this as the first study for the dental DRL assessment, further studies are suggested to establish national dental DRL in India.

Keywords: Dental radiography, diagnostic reference level, dose area product, radiation protection

Received on: 29-08-2019 **Review completed on: 13-10-2019** **Accepted on: 26-10-2019** **Published on: 11-12-2019**

Introduction

Dental radiographic examinations and their associated risks have long been neglected by the dental professionals and the institutions because of the relatively low levels of radiation doses involved,[1] compared to other diagnostic radiology disciplines. However, with the rapid increase in the number of dental facilities, in the last several years, across the country, especially in smaller towns, a huge number of children developing dental problems are undergoing dental X-ray imaging.[2] With the introduction of newer types of dental X-ray units such as the cone-beam (CB) dental computed tomography (CT) and increasing frequency of imaging with such advanced systems, the doses involved in dental imaging have gone up very steeply and are steadily bringing dental radiology into the renewed focus of the professional bodies and regulators. In the last decade, much stricter regulations have been introduced in the field of dental radiography, but not much attention has been given to this discipline, in India, so far. This work is an effort, in this direction, to assess doses in dental radiography facilities and their optimization, in the southern part of India, which can later be extended to other parts of India.

Diagnostic reference level (DRL) is a practical tool that can be used for the optimization of medical exposures.[3-6] A representative number of panoramic X-ray units in the region have to be selected for the establishment of regional DRL in panoramic dental radiography. By comparing the hospital dose with the regional DRL, any hospital in the region can assess whether the doses are consistently higher or lower compared to the regional DRL and then take corrective action. DRL along with the mean observed patient dose values would help to identify the good and bad panoramic practices in dental radiography. It can be used for the elimination of unnecessary radiation exposure that does not contribute to the clinical purpose of the image.[7] The measurement of patient radiation doses during diagnosis procedures is important[8,9] for the assessment of patient risk.

By establishing zone-wise DRL, in the South, North, East, West, and Central parts of the country and consolidating the data national level DRL can be set. Thus, the objective of the present study, initiated by PSG Institute of Medical Sciences and Research in consultation with and grant from the Atomic Energy Regulatory Board (AERB), is to establish DRL for adult panoramic radiography in the region of Tamil Nadu and compare them with the internationally recommended DRLs.

Materials and Methods

Panoramic scanners

Sixty-seven panoramic dental X-ray machines, including 22 different models were randomly selected based on workload from dental facilities in the Tamil Nadu region, and measurements were performed without the presence of the patient in place. Before commencing the measurements in the hospitals, a questionnaire was sent to collect the radiation safety status, detector type, quality assurance (QA) status, and exposure parameters used for the adult panoramic scans. Measurements were taken after doing the QA testing of the respective scanner. Mechanical, electrical, and radiation quality tests were done for the respective scanners as per the AERB to reconfirm the positional accuracy of the dosimeter. The beam area of the scanner was measured by using a computed radiography (CR) cassette and verified with the machine manual given by the manufacturer. Table 1 shows the average exposure parameters used with each model of panoramic scanners and their active detector beam area.

The CR cassette was kept in front of the secondary collimator and exposed for 1 s to measure the beam area. The procedure was repeated for all the selected machines involved in this study and confirmed the area of the detector.

Dosimeter

A solid-state dosimeter (RTI Black Piranha 557), from RTI electronics, Sweden, that has an active width of 3 mm, was used for the measurement of radiation dose.

Aligning Piranha dosimeter at the secondary collimator is a difficult task as it is heavy and single strap of Transpore tape may not be enough to hold it safely during the measurement. Since there is no laser light in some of the panoramic scanners to replicate the tube slit position at the detector side, positioning of solid-state dosimeter along the narrow tube slit is a tedious task. Thus, the initial positioning of dosimeter may not show an accurate result. Graphs shown in Ocean software helps to identify the inaccurate and accurate position of dosimeter after the radiation exposure [Figure 1]. Piranha holder, specifically configured to hold Piranha 557 dosimeter during the panoramic scan, helps to hold the dosimeter tightly during the scan time [Figure 2]. Minute positional alignment of dosimeter is also possible using piranha holder.

Experiment technique

The Piranha 557 dosimeter used in this study is more convenient to use as compared to the detector used by Lee *et al*.[5] in their study which had an active sensor width of 1.5 mm since its active sensor width is 3 mm. The "OCEAN 2014 connect" software enables the black Piranha to connect directly to the computer through bluetooth. During the measurement, the black Piranha solid-state dosimeter was attached in front of the secondary collimator with a Piranha holder [Figure 3].

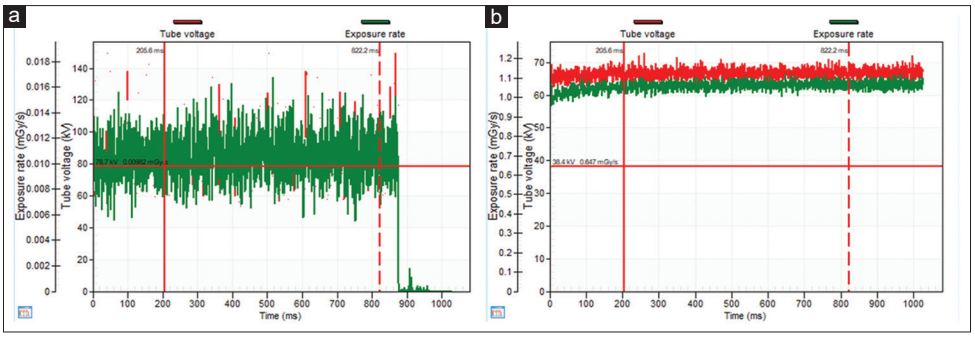

Figure 1: Graphical representation shown in Piranha Ocean software after inaccurate positioning (a) and accurate positioning (b) of dosimeter

Figure 2: Panoramic Piranha holder with Piranha dosimeter

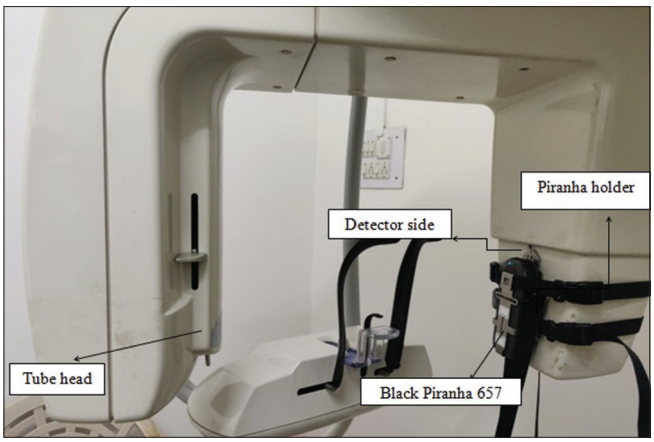

Figure 3: Pictorial representation of experimental procedure

Once the panoramic scanner passed AERB QA test, then that particular machine is included for the DRL study. The regular kVp, mA, and time used for the adult panoramic scan were loaded in the panoramic scanner. Measurements were taken for 20 patient protocols. Figure 4 shows the screenshot image of the reading shown in the software after the exposure. Exposures were repeated without the presence of patients, and radiation doses were noted.

The product of the measured dose with the measured area gives the dose area product (DAP) values. After calculating DAP from 67 panoramic dental scanners, statistical parameters such as average, 3rd quartile values were calculated using Microsoft Excel software. The 3rd quartile value can be suggested as DRL, according to Radiation Protection Document No. 109 of the European Commission.[10]

Results

Verification of DAP calculation was made by comparing the machine DAP and calculated DAP [Figure 5]. Of 38 displayed values from different panoramic scanners, the observed deviation from machine value was well within ± 18%. The maximum deviation observed between machine DAP and calculated DAP was −17.68%.

The assessed DRL value, along with the calculated DAP values, for 67 panoramic radiography units are given in Figure 6. The calculated DAP values ranged from 41 mGycm^2 to 165 mGycm^2. The lowest and highest DAP values for all procedures were calculated at scanners based on digital and analog type detectors, respectively. However, in many digital type scanners, high radiation doses were observed.

Mean exposure parameters, along with the mean, range, and the 3rd quartile of the DAP values for analog and digital mode of detectors are given in Table 2. There was nearly 3.6-fold difference between the highest (148 mGycm^2) and lowest (41 mGycm^2) DAP values for the digital detector units. Almost 2.5-fold difference was observed for analog type units between the lowest (65 mGycm^2) and highest (165 mGycm^2).

The DRL was calculated from DAP values using Microsoft Excel software by the formula "PERCENTILE, (array, k)," where array represents the DAP values and *k* represents the percentile value (in the present case *k* is 0.75).

From the findings of the present study, the suggested DRL for adult panoramic procedures in Tamil Nadu region was 114.3 mGycm^2.

Discussion

Unlike other dental X-ray units like intraoral and CBCT scanners, the panoramic unit produces a narrow slit beam and tracks a circular path around the patient's head to

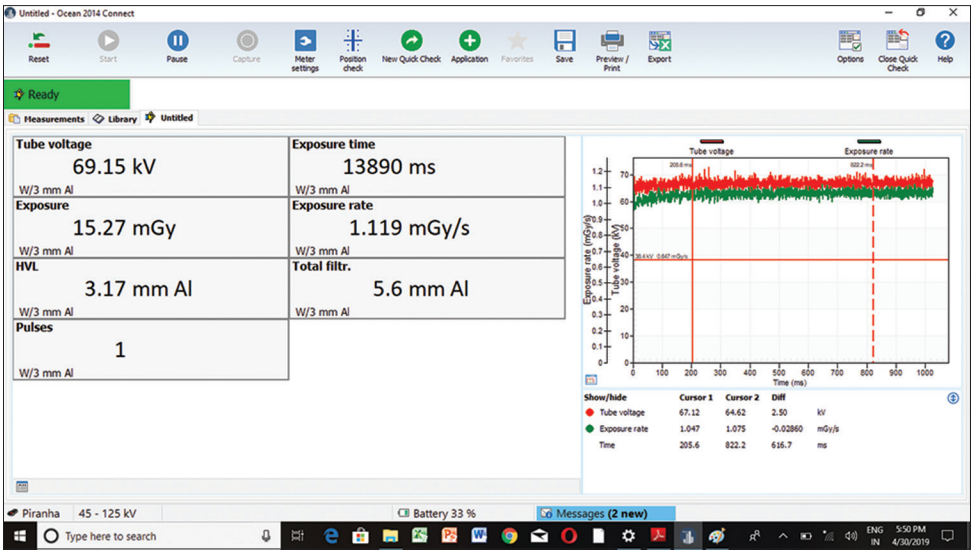

Figure 4: Screenshot of the reading obtained in Ocean 2014 Connect software for exposure parameters of 70 kVp, 10 mA and 13.9 s

Table 2: Mean exposure parameters along with range, mean and 3rd quartile of dose area product values for digital and analogue types of units

Type of unit	Exposure mean (kV)	Mean (mA)	Mean exposure time (s)	DAP range (mGycm²)	Mean DAP (mGycm²)	DRL (mGycm²)
Analogue	71.2	10.3	14.4	65-165	105.9	125.5
Digital	70.1	10.0	13.2	41-148	90.7	112.4
Total	70.3	10.0	13.5	41-165	93.6	114.3

DRL: Diagnostic reference level, DAP: Dose area product

obtain the dental X-ray image. For the accurate radiation dose measurement process during panoramic procedure, the dosimeter has to follow the narrow slit beam. Any misalignment of dosimeter may create a huge error. Moreover, the fact that the beam slit is broader at the detector side of the scanner makes it comparatively easy to align the dosimeter for radiation dose measurement. The agreement between the calculated DAP values and machine displayed DAP values further confirms the reasonable accuracy of the machine displayed values [Figure 5]. The observed deviation may be attributed to the difference in the type of dosimeter used, time slab of measurement and experimental technique. For better accuracy, the display values can be calibrated in terms of the measured values.

Figure 7 shows the comparison of other countries' dental panoramic DRL with the present study, the Tamil Nadu DRL. Similar results were published by different authors such as Tierris *et al*.[11] and Han *et al*.[12]

Tierris *et al*.[11] found 101 mGycm^2 and 117 mGycm^2, respectively, as their mean and 3rd quartile values. Careful analysis of the results published by them indicates that there are 18 units that have DAP > 100 mGycm^2 and in that, 8 units have DAP in between 200 mGycm^2 and 250 mGycm^2. Therefore, the DRL of their study was affected by the scanners with higher doses. The average exposure parameter (72.4 kVp, 10.5 mA, and 15.2 s) calculated by them was slightly higher than the average calculated values of the present study (70.3 kVp, 10.0 mA, and 13.5 s). The present study has 23 scanners which are having DAP >100 mGycm^2 and the highest DAP value calculated was 165 mGycm^2.

Han *et al*.[12] have measured DAP using DAP meter (VacuDAP-OEM, Vacutec, Germany) on 42 panoramic scanners. The maximum DAP observed from their study also crossed 200 mGycm^2 with an average of 98.2 mGycm^2 and a corresponding 3rd quartile value of 120.3 mGycm^2. Their average kVp and mAs calculated from different panoramic scanners ranged from 68–82.3 kVp and 110.7–211.2 mAs, respectively. The present study kVp and mAs ranged from 66–78 kVp and 46–204 mAs. Hence, the high DRL in Han *et al*.[12] is influenced by larger exposure parameters.

Williams and Montgomery[13] have assessed DRL from 16 panoramic X-ray units using thermoluminescence dosimeters. The mean DAP and corresponding 3rd quartile values for standard adult examination are 113 and 139 mGycm^2, respectively. The difference in the type of dosimeter and sample size may have influenced their DRL value. This may be the reason for variation in their DRL as compared with the present study.

The DRL assessed by Poppe *et al*.[14] and Hodolli *et al*.[15] are 101.4 and 93 mGycm^2, respectively. A close analysis of the results of their studies shows that the majority of their panoramic X-ray units have DAP lesser than 100 mGycm^2. Therefore, the DRLs of their studies are affected by the scanners with lower doses. The average exposure parameters calculated by Poppe *et al*.[14] and Hodolli *et al*.[15] are 73.1 kVp, 11.6 mA, and 15.3 s and 72.8 kVp, 12.8 mA, and 16.2 s, respectively. Although the exposure parameters are higher than the present study average values, their DAP values are lesser than the current study calculated values. The difference in tube inherent filtration and manufacturing date can result in lesser DAP readings for their studies.

In short DRL values obtained in the present study agree with the corresponding results reported by other countries. The difference in patient physical parameter, equipment exposure parameter, tube inherent filtration, type of dosimeter used for measurement were some of the reasons for slight variation between the DRLs as assessed by the present study and by other investigators referred to here. Although the method used in the present study produces comparable results, direct use of DAP meter is a much easier method.

In setting the DRL, special consideration has to be given for digital type detector scanners for further dose optimization. In the present study, almost 33% of digital detectors were having DAP >100 mGycm^2, whereas 38% analog-type detectors had DAP >100 mGycm^2. The current study also found that many clinics and hospitals were using higher exposure parameters while using digital type detectors and comparable or lesser parameters for analog type scanners. There is always a trend to increase the dose, as higher doses can reduce the image noise to an extent. Thus, high image quality can be obtained easily.[16] Periodic QA is suggested to assess the image quality and for the optimization of exposure parameters. Higher doses obtained from this study indicate that more attention is required toward the radiation protection aspects of digital radiography. While operating the panoramic X-ray units, the operators should ensure that the patient is not

exposed to a dose higher than necessary when using digital image receptors.

Table 3 shows the difference in exposure parameters and average DAP values between those panoramic scanners, which were operated by professionally qualified and not professionally qualified operators.

Conclusion

This paper shows dose measurements carried out in almost 50% of the panoramic scanners in the Tamil Nadu region of South India to establish adult panoramic DRL. Although the black Piranha dosimeter consumes time to position it along the narrow slit of the panoramic scanner, its active width of 3 mm enables in reducing the positioning error comparatively. The obtained results were shown to be comparable to another country DRLs. However, the calculated DAP of certain scanners is higher than the assessed DRL value indicating the fact that the exposure parameters used in those scanners are rather high and can be further optimized. Exposure parameters have suggested to further optimize the dose to prevent patient from receiving unnecessary radiation dose from these scanners. Further, it is suggested to conduct training programs for radiographers and dentists to follow the principle of as low as reasonably achievable (ALARA).

Role of Transrectal Ultrasound Elastography in the Diagnosis of Prostate Carcinoma

Vikrant Kanagaraju*, P. V. K. Ashlyin, N. Elango, B. Devanand

Department of Radiology, PSG Institute of Medical Sciences and Research, Coimbatore, Tamil Nadu, India

Abstract

Background: The purpose of this study was to evaluate the diagnostic value of transrectal real- time strain elastography (RTE) in identifying prostatic carcinoma (PCa). **Materials and Methods:** 60 patients suspected of having PCa based on abnormal digital rectal examination and raised prostate specific antigen levels underwent transrectal ultrasound (TRUS), color Doppler (CD) and RTE. Elastograms were scored on a five point scale based on distribution of strain in relation to hypoechoic area on TRUS. Twelve core systematic biopsy as well as targeted biopsy was performed from suspicious areas on TRUS and RTE. Diagnostic performance of sonoelastography was evaluated using histopathology as reference standard. **Results:** Histopathology revealed cancer in 28 out of 60 patients (47%) studied. Gleason score ranged from 6 to 9. The sensitivity, specificity, positive predictive value (PPV), and negative predictive value (NPV) of TRUS in detecting prostate cancer were 78.57%, 81.25%, 78.57%, and 81.25%, respectively. On CD evaluation 87.5% (n = 28) of benign lesions showed symmetric, radial flow compared to 14.3% (n = 4) of malignant lesions ($P < 0.0001$). The sensitivity and specificity of RTE was 89.29% and 56.25% with PPV and NPV being 58.13% and 82.35%, respectively. Higher elastography score was found to be significantly associated with malignant histopathology ($P = 0.004$). Cancer detection rate with RTE was greater for tumors with higher Gleason score. **Conclusion:** RTE was found to have better sensitivity than TRUS as well as combination of TRUS and CD. Although less specific, RTE can be an effective adjuvant tool to TRUS for guidance of biopsy and improve detection rate of PCa.

Keywords: Elastography, prostate cancer, ultrasonography

Introduction

Prostate carcinoma (PCa) is the second most frequently diagnosed cancer in males all over the world and is a major healthcare concern associated with significant morbidity and mortality. The burden of PCa is estimated to grow to 1.7 million new cases and 499000 new deaths by 2030 as a result of growth and aging of the global population.[1]

Digital rectal examination (DRE), screening for prostate specific antigen (PSA), and imaging techniques such as transrectal ultrasound (TRUS) and magnetic resonance imaging (MRI) are the methods commonly employed for detection of PCa. DRE is limited by its low sensitivity, subjective nature, and depends on the experience of the clinician. Although PSA testing has been widely used for screening of prostatic cancer, it is not disease specific and can be elevated in patients with prostatitis as well as benign prostatic hyperplasia.[2,3] In a patient with suspicion of prostatic cancer, current guidelines involve histopathologic examination of systematic biopsy cores to confirm or rule out cancer.[4] However, the conventional biopsy protocol misses significant cancer in a large proportion of patients.[5] Further many insignificant cancers that do not need immediate treatment are also detected leading to overdiagnosis and treatment.[6] Use of TRUS for detecting prostate cancer has limitations such as poor specificity of focal abnormalities, frequent multifocality of cancer within the prostate, and substantial percentage of isoechoic prostatic carcinoma (PCa).[7] Although MRI results are promising, it is expensive and not always available. In view of these limitations, improved noninvasive imaging modalities that

can provide better characterization of prostatic lesions and increase detection of prostatic cancer are needed.

Ultrasound elastography (USE) is a dynamic technique that uses ultrasound to estimate tissue stiffness by measuring the degree of distortion under application of an external force. As cancerous tissue has greater stiffness than a benign lesion USE has been used to differentiate malignant from benign lesions in breast, thyroid, liver, and cervix. Recent studies have demonstrated the utility of sonoelastography in detecting prostate cancer.[8-10]

Data on the usefulness of transrectal strain elastography (SE) in evaluation of prostatic cancer and its correlation with histopathology are relatively few, especially from India. The purpose of the present study was to evaluate the usefulness and diagnostic performance of transrectal SE in identifying prostatic cancer with histopathologic diagnosis obtained by needle biopsy of prostate as reference standard.

Materials and Methods

This prospective study was performed in a tertiary care center in South India between December 2014 and September 2016. 60 consecutive patients who were referred to the department of Radiology with suspicion of PCa based on abnormal DRE and elevated PSA levels (>4 ng/ml) were enrolled. The institutional review board approved the study protocol and the protocol was in compliance with tenets of the Declaration of Helsinki (IRB approval Number: 14/399). Informed consent was obtained from all participants. Exclusion criteria consisted of patients with bleeding disorders, inflammatory bowel disease and surgical absence of rectum or ileoanal pouch. All patients underwent TRUS (grey scale and Doppler) and SE as well as needle biopsy of prostate in the same session.

TRUS of prostate was done using an endocavitary transducer (Siemens Accuson S3000, Siemens Healthineers, Erlangen, Germany) with 9–4 MHz range and 174 degree field of vision, capable of user selectable multi hertz imaging. Xylocaine gel was applied over a probe cover applied onto the probe. All patients were examined in the left lateral decubitus position. Prostate was imaged in both axial and sagittal planes with assessment of volume, echogenicity, surface, calcification, vascularity, and the presence of nodules. Each nodule was assessed for size, margins, location in the gland, morphology, and echogenicity.

Glands with homogeneous echotexture or minimal heterogeneity on TRUS were labeled as benign while those with ill-defined echotexture abnormality, focal bulge or hypoechoic mass were categorized as malignant. For Color Doppler (CD) imaging, capsular/periurethral flow and symmetric radial flow from capsular branches were considered benign while asymmetric or increased flow with disorganized pattern was labeled malignant.[11]

Using the same probe transrectal real-time strain elastography (RTE) of prostate was done by a single experienced radiologist. The probe was placed over the region such that the lesion is in the center of the image. Elastograms were obtained by slight compression and decompression of the prostate. The appropriate frequency and pressure of the compression/decompression was optimized with the help of real time display of quality index. Elastograms obtained with quality index equal to or >60 were only included. At least a 5 mm thickness of normal adjacent tissue was included, to assess the lesion stiffness in relation with the average elasticity of the surrounding tissue. A standardized color coding system was used, where red indicated soft, more compliant areas and blue indicated stiff areas. Green color indicated average strain in the region of interest. The elastograms along with conventional B-mode images were displayed side by side on split screen mode. Multiple frames were acquired and the best fit B mode-elastography image pairs were selected for examination. The elasticity patterns were scored using a five point scale proposed by Kamoi *et al*.[10] [Table 1] The cut off for malignancy was set between scores of 2 and 3 [Figures 1-4].

Sampling of the prostate was performed either in the sagittal or in the axial plane. Biopsies were taken using an 18 G biopsy gun under strict aseptic precautions. Extended core biopsy protocol (12 cores) was used. Additional targeted biopsy was carried out on suspicious areas identified by B mode US and elastography. The grade (degree of aggressiveness) of prostate cancer was evaluated on the basis of the Gleason score. No major complications were encountered after the procedure.

The findings of TRUS, Doppler and RTE were interpreted by consensus by two experienced radiologists who were blinded to patients' clinical profile and biopsy results. The histopathologic results were considered as the reference standard, and utility of RTE was evaluated.

Statistical analysis

Data was entered in the Statistical Package for Social Sciences version 24 (SPSS Inc., Chicago, IL, USA). Descriptive statistics was presented as mean ± standard deviation. Qualitative variables were presented in the form of frequency and percentages. The diagnostic sensitivity, specificity, positive predictive value (PPV) and negative predictive value (NPV) were calculated with histopathologic analysis as reference standard. For analyzing the combined diagnostic performance of tests, the test was considered positive if either of them was

Table 1: Sonoelastography scoring system proposed by Kamoi *et al*.

Elastography score	Description
Score 1	Normal - homogeneous strain
Score 2	Probably normal - symmetric heterogeneous strain
Score 3	Indeterminate - asymmetric focal stiff lesion which is not related to any hypoechoic area
Score 4	Probably carcinoma (strain at the periphery of the hypoechoic lesion with sparing of the center
Score 5	Definitely carcinoma (no strain in the entire hypoechoic lesion or in the surrounding area)

suspicious for malignancy and negative if neither showed suspicious features. Pearson Chi-square test was used to study the association between categorical variables. $P < 0.05$ was considered as statistically significant.

Results

The age of the patients ranged from 53 to 88 years (Mean: 69.16 ± 9.40 years). Serum PSA levels ranged between 4.3 and 178.6 ng/ml (Mean 48.54 ± 56.69 ng/ml). No Significant difference in PSA levels were noted between patients with carcinoma and benign lesions of the prostate ($P = 0.083$). In 60 patients, 784 biopsy cores were harvested out of which 720 was according to the extended core biopsy protocol and 64 were targeted (36 and 28 targeted to areas found suspicious on B-mode US and RTE, respectively). Histopathology revealed cancerous focus in at least one biopsy core in 28/60 (47%) patients. Gleason score ranged from 6 to 9 (Mean: 7.42 ± 1.13). Among the 32 patients with benign histopathology results, 20 (62.5%) were found to have benign prostatic hyperplasia and 12 (37.5%) had prostatitis. The mean prostatic volume was 38.20 ± 18.25 cm^3 (range: 8–89 cm^3). The mean age of patients with benign and malignant lesions were 66.78 ± 9.56 years and 71.89 ± 8.59 years, respectively ($P = 0.035$).

Out of the 60 patients, 28 (47%) were suspected of having prostate cancer by TRUS. The sensitivity, specificity, PPV, and NPV of TRUS in detecting prostate cancer were 78.57%, 81.25%, 78.57%, and 81.25%, respectively, with histopathology as reference standard. On CD evaluation 87.5% ($n = 28$) of benign lesions showed symmetric, radial flow compared to 14.3% ($n = 4$) of malignant lesions ($P < 0.0001$).

Table 2 shows the correlation of elastography scores and histopathologic diagnoses of lesions. Out of the 32 patients

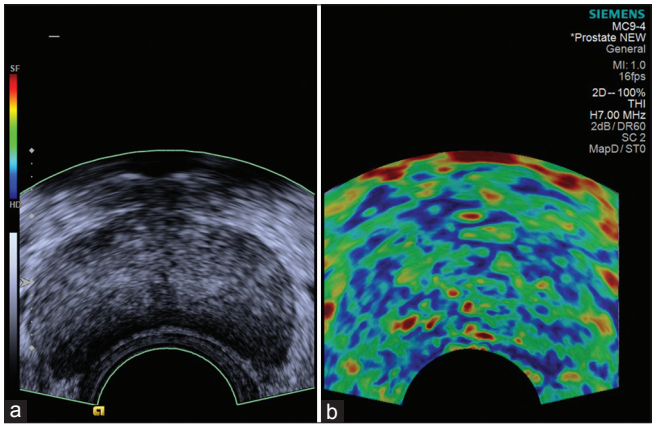

Figure 1: (a) Transrectal ultrasonography image showing mild enlargement of prostate. (b) Sonoelastography showing heterogeneous appearance with symmetrical mosaic pattern of green and blue (Score 2 – probably normal). Histopathology revealed hyperplasia of prostate with benign glandular pattern

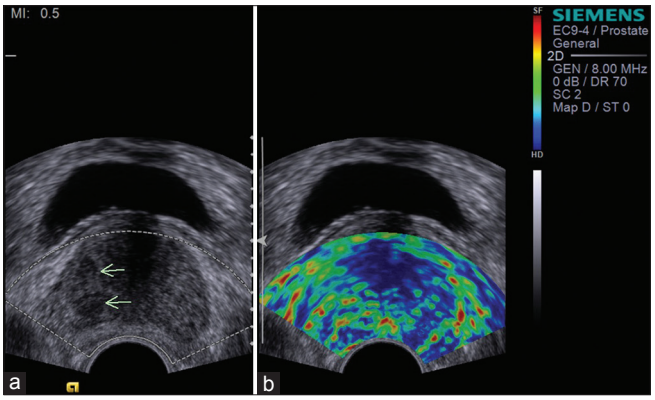

Figure 2: (a) Transrectal ultrasonography image showing hypoechoic lesion in the right peripheral zone (arrows) of prostate. (b) Sonoelastography showing focal asymmetric stiff lesion not related to hypoechoic area (score 3 – indeterminate). Histopathology was suggestive of adenocarcinoma prostate

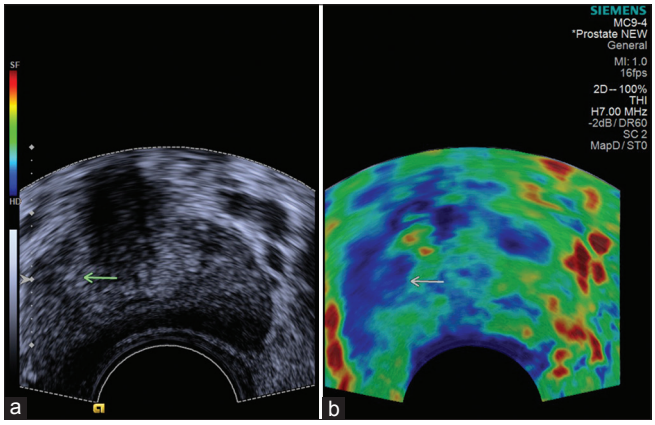

Figure 3: (a) Transrectal ultrasonography image showing hypoechoic lesion in the right peripheral zone (arrow) of prostate. (b) Sonoelastography showing stiffness in the center of the lesion and strain at the periphery; the peripheral part of lesion appears green and the central part appears blue (score 4 – probably carcinoma). Histopathology confirmed adenocarcinoma prostate

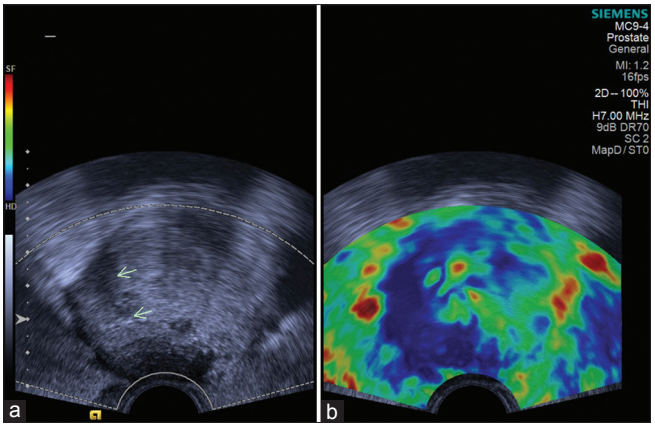

Figure 4: (a) Transrectal ultrasonography image showing hypoechoic lesion with irregular margin in the right peripheral zone (arrows) of prostate. (b) Sonoelastography showing stiffness in the entire hypoechoic lesion and in the surrounding area; the entire lesion appears blue (score 5 – definitely carcinoma). Histopathology confirmed adenocarcinoma prostate

with benign histopathology, 14 were judged as negative for malignancy at RTE. There were 3 false negative patients on elastography with score of 2. The sensitivity and specificity of RTE was 89.29% and 56.25% with positive and NPV of 58.13% and 82.35%, respectively. Higher elastography score was found to be significantly associated with malignant histopathology ($P = 0.004$).

Table 3 shows the relation between Gleason score and elastography scores. Approximately 84% of patients with a Gleason score ≤6 were detected by RTE whereas for scores 8–9, the detection rate was 100%.

The diagnostic performance of TRUS, combined modalities (TRUS and Doppler) and RTE are shown in Table 4.

Discussion

In this prospective study from South India, we evaluated the diagnostic performance of transrectal real-time elastography (RTE) in detection of prostatic cancer in patients with abnormal DRE and elevated PSA levels. RTE showed superior sensitivity of nearly 90% versus sensitivity of 79% by TRUS and 86% by a combination of TRUS and CD ultrasound.

Table 2: Correlation between elastography score and histopathologic diagnosis of lesions

Elastogram pattern	Benign ($n=32$)	Malignant ($n=28$)	Total ($n=60$)
1	0	0	0
2	14	3	17
3	18	4	22
4	0	9	9
5	0	12	12

Table 3: Relation between Gleason score and elastography scores

Gleason score	ES 1	ES 2	ES 3	ES 4	ES 5
≤6	0	1	0	2	3
7	0	2	2	6	2
8	0	0	0	1	1
9	0	0	2	0	6

ES: Elastography score

Table 4: Diagnostic performance of transrectal ultrasound, combined modalities (transrectal ultrasound and Doppler) and real-time strain elastography

Performance measure	TRUS	TRUS and doppler	RTE
Sensitivity (%)	78.57	85.71	89.29
Specificity (%)	81.25	75	56.25
Positive predictive value (%)	78.57	75	58.13
Negative predictive value (%)	81.25	85.71	82.35

TRUS: Transrectal ultrasound, RTE: Real-time strain elastography

Ever since the description of principles of elastography by Ophir *et al*., elasticity imaging has been applied to a wide variety of tissues such as breast, thyroid, liver, lymph nodes and prostate.[12]

The two US elastography techniques in clinical use are SE and shear wave elastography. Several studies have evaluated the utility of SE in diagnosing prostatic cancer and have shown varied results. While few have compared the diagnostic accuracy with needle biopsy of prostate,[13-15] others have used histopathologic examination of radical prostatectomy specimen as the reference standard.[8,9,16] The heterogeneous results can be attributed to the varied inclusion criteria, demographic characteristics of patients, serum PSA levels, location of tumors, reference standard, number of biopsy cores, systematic or targeted biopsies and Gleason score of the tumors examined.

The age of patients with malignancy of prostate was significantly higher compared to those with benign lesions in our study ($P = 0.035$). Age is considered to be an established risk factor for prostatic cancer and study of age-specific incidence curves have shown that risk of prostate cancer begins to rise sharply after 55 years of age and peaks at 70–74, declining slightly thereafter.[17]

In our study, TRUS revealed hypoechoic/focal lesions in 28 patients (47%). Out of these, 22 were confirmed as adenocarcinoma prostate while 6 turned out to be benign on histopathology. The results from our study in terms of specificity and PPV of TRUS in detecting prostatic cancer are similar to that of Ferrari *et al*. who had evaluated 84 patients suspected of prostatic cancer by TRUS, RTE and transperineal prostate biopsy.[18] B-mode US demonstrated 56% sensitivity, 80% specificity, 70% PPV and 67% NPV in diagnosing prostatic cancer. A hypoechoic lesion in the peripheral zone of prostate is suggested to be more likely malignant, the proposed cause being replacement of normal loose glandular tissue by a packed mass of tumor cells which results in fewer reflecting interfaces. Hyperplasia, prostatitis, fibrosis and cysts of prostate are other lesions that appear hypoechoic on TRUS.[19] Nearly 25%–40% of prostate cancers are isoechoic and missed by TRUS.[20]

CD and Power Doppler (PD) have been reported to be useful in detecting isoechoic tumors which may be missed by conventional ultrasound.[21,22] In 2 patients with prostatic cancer in our study, Doppler evaluation revealed asymmetric, increased flow while TRUS was not suspicious for malignancy. Few authors have shown that increased CD signal correlates positively with grading and staging of prostate cancer as well as risk of recurrence after treatment.[23,24]

On CD evaluation, 87.5% ($n = 28$) of benign lesions showed symmetric, radial flow compared to 14.3% ($n = 4$) of malignant lesions ($P < 0.0001$) in our study. A combination of TRUS and Doppler revealed superior diagnostic performance with sensitivity and NPV of nearly 86% compared to TRUS. However, benign lesions like prostatitis can also show

increased flow on CD and CD does not reveal microscopic vessels of prostatic cancer that do not possess enough flow to cause Doppler shift.[25,26] Despite these limitations, our findings indicate that CD imaging can be a useful adjunct to improve tumor detection by TRUS.

Prostatic cancer tends to be stiffer than benign lesions due to replacement of normal glandular tissue by neoplastic cells.[27] Stiffer tissues demonstrate less strain to deformation, and RTE helps in differentiation of benign and malignant tissues based on distribution of strain. Miyagawa *et al*. evaluated the usefulness of RTE in detecting prostatic cancer prior to systematic biopsy and have noted a diagnostic sensitivity of 72.6% for elastography and 89.5% for combination of TRUS and elastography.[14] Kamoi *et al*. used a five point subjective scale based on degree and distribution of strain in relation to hypoechoic area and found that RTE had 68% sensitivity and 81% specificity in detecting prostatic cancer. The combination of RTE with PD US further increased the sensitivity to 78%.[10]

Using the cutoff value of 3 (suggesting focal asymmetric lesion without strain unrelated to hypoechoic lesion) proposed by Kamoi *et al*., RTE was found to have sensitivity of 89.29% and specificity of 56.25% in our study. Of 43 patients with RTE findings suspicious for carcinoma, 25 were confirmed to be malignant on histopathology. Benign entities such as benign prostatic hyperplasia, adenomyomatosis, fibrosis and prostatitis can be associated with increased tissue stiffness and therefore may be difficult to distinguish from carcinoma prostate. This can be responsible for the relatively low specificity and PPV observed in our study. Because of the high frequency of false-positive results, RTE should be used in combination with TRUS to increase the detection rate.

In 5 of 28 patients with prostatic cancer (17.9%), B mode US was normal but RTE was suggestive of carcinoma. While systematic biopsy picked up malignancy in 3 patients, targeted biopsy based on RTE findings resulted in detection of cancer in 2 patients. The role of RTE targeted biopsy in detecting prostatic cancer has been reported by several authors. Pallwein *et al*. compared a 5-core RTE targeted biopsy with a 10-core systematic biopsy and concluded that cancer detection rate per patient was not significantly higher for targeted approach compared to systematic approach but an RTE targeted core was 2.9 fold more likely to be positive for cancer than a systematic core.[28] Salomon *et al*. analyzed the incremental detection rate of 4-core RTE targeted biopsy in addition to randomized 10-core in 1024 patients.[29] Additional use of RTE resulted in an incremental detection rate of 18.3%. 34 patients who harbored high-grade PCa (Gleason score ≥4) were diagnosed by RTE targeted biopsy only. A recent meta-analysis on the role of RTE targeted biopsy has shown that the detection rate of malignancy is enhanced when systematic biopsies are combined with RTE targeted biopsies.

Further RTE targeted biopsy can make a nearly equivalent diagnosis with fewer cores.[30]

In our study RTE detected 5 of 6 patients with prostatic cancer of Gleason score ≤6, 10 of 12 with score 7 and all with Gleason score 8 or 9. Our observations are similar to that of other authors who have noted that RTE detection rate of prostate cancer with higher Gleason score was greater than that of prostatic cancer with a lower Gleason score.[9,31] This might be explained by the greater cell density in high grade tumors resulting in stiffer tissue. In contrast, Tsutsumi *et al*. have noted a lower RTE detection rate for high grade tumors.[32]

Our study has few limitations. The sample size was small and no interobserver variability was studied since the RTE findings were interpreted by consensus. Another main limitation of RTE is that the degree of manual compression influences the elasticity image and may compromise diagnostic accuracy of RTE. However all examinations were performed by a single experienced radiologist and only images with optimal compression as displayed by the quality index were included in the study. Recent literature suggests that multiparametric MRI has greater sensitivity and specificity for detection of clinically significant prostate cancer.[33]

Although the incidence of prostatic cancer is low in Asian countries compared to the west, demographic and epidemiological transition in recent times have resulted in increase in the burden of various cancers including prostate in India. Prostate is reported to be the second leading site of cancer among males in several cities in India and cancer projection data estimate that the number of cases will become doubled by 2020.[34]

Conclusion

In this initial study from South India, RTE was found to have better sensitivity than TRUS as well as combination of TRUS and CD. With its greater sensitivity and NPV, RTE can be an effective adjuvant tool to guide biopsy and thereby increase the detection rate of prostatic cancer. Further prospective studies with larger sample size are needed before recommending RTE along with conventional TRUS for routine use in the evaluation of suspected prostatic malignancy in India.

Abstract

Background Acute ureteric colic is one of the most commonly encountered acute abdominal conditions. Diagnosis of obstruction caused by ureteric calculus occasionally becomes challenging if there is inadequate dilation of the urinary tract proximal to obstruction. In such a situation, intra-renal artery Doppler parameters can be used as a diagnostic tool. Our study compared intra-renal arterial Doppler in patients with obstructed and non-obstructed kidneys presenting within 24 h of onset of symptoms of unilateral acute renal colic.

Results The resistivity index (RI) in the segmental arteries of all 54 patients with obstructed kidneys was significantly higher than in those with non-obstructed kidney: 0.75 vs. 0.56, with a p value less than 0.001, a sensitivity of 85% and a specificity of 93%.

Conclusion Doppler ultrasound is a useful diagnostic tool in the evaluation of acute renal obstruction, thus enabling practitioners to avoid ordering unnecessary CT and exposing patients to ionizing radiation. An RI value > 0.7 has good sensitivity and specificity in our study. The results obtained in the study were comparable to those of pioneer studies conducted worldwide.

Keywords Acute renal colic · Renal artery Doppler · Resistive index

Abbreviations

ARC	Acute renal failure
ER	Emergency room
USG	Ultrasonography
US	Ultrasound
RI	Resistive index
CT	Computed tomography.
NSAID	Non-steroidal anti-inflammatory drugs
GFR	Glomerular filtration rate
eGFR	Estimated glomerular filtration rate.
Tc^{99m} DTPA	Technetium$^{-99\,m}$- Diethylene-triamine-penta-acetate
CDUS	Color Doppler Ultrasound
MPR	Multiplanar reconstruction
ROC	Receiver operating characteristic curve
PCS	Pelvicalyceal system

Background

Acute renal colic (ARC) is one of the common causes of patients presenting to the emergency room (ER). It accounts for 30–35% of urologic emergencies [1, 2]. The recurrence rate over a period of 5 years is 30–40% [2]. Ultrasonography (US) remains the most commonly used modality in the initial evaluation of patients presenting with acute abdomen, especially in children [3], and the utility of ultrasound in the diagnosis of ARC cannot be overstated in cases where ARC is one of the most common pathologies presenting as acute abdomen. Absence of significant dilatation of the pelvicalyceal system, in spite of severe obstruction being present, is a well-recognized finding in some patients. In some

studies, the absence of significant dilation in ARC has been reported in up to 30% [4] of patients. The dilated collecting system seen in US need not always be due to obstruction in the downstream urinary tract. These conditions include a baggy extra-renal type of pelvis, a compound upper pole calyx, due to over-distended urinary bladder, vesico-ureteric reflux, congenital type of mega calyces, infection and residual dilatation due to previous obstruction. Very rarely, pseudo-aneurysms of intra renal arteries can mimic renal pelvi-ectasis. This kind of vascular pathology can also be easily diagnosed with CDUS [5]. Acute complete ureteric obstruction is associated with changes in renal blood flow, as well as with an increase in renal pelvic pressure. In the first few hours, renal blood flow increases, and after 3 to 5 h, renal blood flow decreases, probably because of efferent arteriolar vasoconstriction produced by prostaglandins and other vasoactive substances [6, 7]. These changes can be effectively demonstrated by the RI of intra-renal arteries, as measured by Doppler ultrasound.

Methods

A prospective study was done on 54 patients who were referred to the department of radiology with clinical features of ARC for further evaluation with ultrasound or non-contrast CT. The study period is from January 2015 to December 2017. Prior to the commencement of the study, necessary clearance was obtained from the institutional ethics committee, and informed written consent was obtained from all the participating patients.

Inclusion criteria

All patients with symptoms of acute ureteric obstruction presenting to the emergency department within 24 h of onset of unilateral ARC were included.

Exclusion criteria

(a) Patients with history of renal parenchymal disease, chronic renal obstruction, renal trauma, or bilateral renal obstruction; (b) patients with a single kidney; and (c) patients in whom ureteric obstruction could not be confirmed either with USG or with CT were excluded.

All patients underwent gray-scale ultrasonography (US) and Doppler evaluation of intra-renal arteries. Computed tomography (CT) was done for those patients in whom US could not confirm the cause of obstruction.

Evaluation by ultrasound and Doppler study

The kidney on the side of obstruction was treated as the case kidney, and the contralateral normal (non-obstructed) kidney served as control. All patients underwent B-mode US and color doppler ultrasound (CDUS) with Philips iU22 using a C 1–5 transducer and Siemens Acuson S3000 using a 6C1 HD transducer. The presence or absence of pelvicalyceal system dilatation in each kidney was assessed using the gray-scale images. At least three Doppler spectra were obtained from inter-lobar arteries along the border of the medullary pyramids, and their mean was taken (Fig. 1).

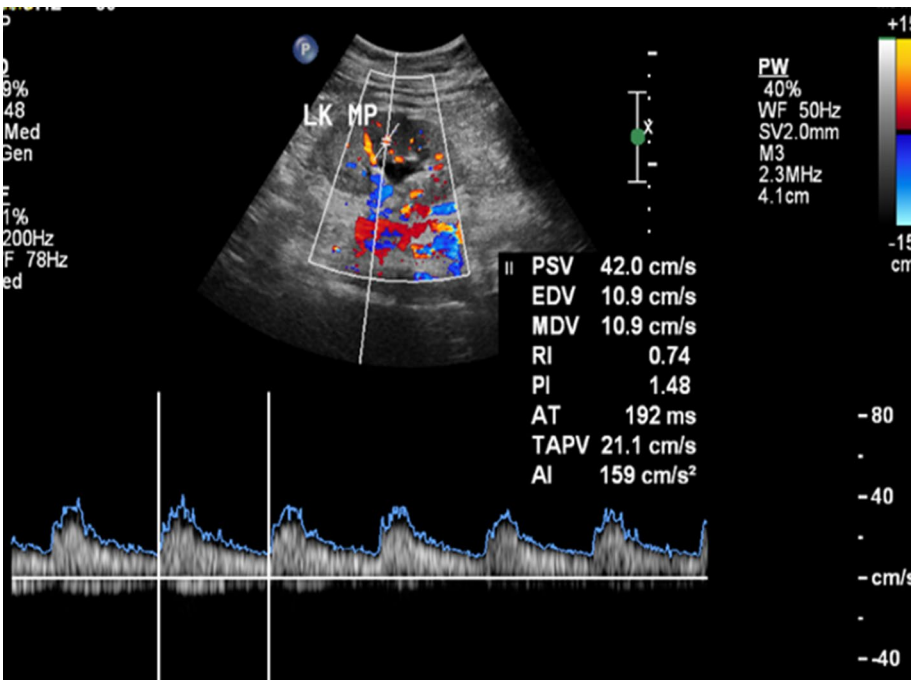

Fig. 1 Doppler US demonstrating an RI value of 0.74 in the mid pole of left kidney (obstructed kidney)

Author's personal copy

The Doppler waveforms were made using the lowest pulse repetition frequency possible without aliasing. This maximized the size of the Doppler spectrum and decreased the percentage error in the measurements. In addition, the lowest possible wall filter for each ultrasound scanner was used. The Doppler sample width was set at 2–3 mm. The renal RI was calculated using the standard formula. The mean RI value was calculated for each kidney.

Evaluation by computed tomography

Siemens SOMATOM Definition Edge 128 slice Computerized Tomography (CT) equipment was used for the study. Non-enhanced CT of the abdomen, extending from the dome of the diaphragm to the pubic symphysis, was performed in all patients in whom the site and cause of obstruction could not be confirmed with US. Raw data was acquired with 0.6 mm thickness and pitch of 0.8. Reconstruction from the raw data was done in 5 mm thickness for viewing purposes and in 1 mm thickness for coronal and sagittal multi-planar reconstruction (MPR) (Fig. 2). The sites of ureteric obstructions were identified. Those patients not confirmed to have obstructions by CT were excluded from the study.

Statistical methods

All data were systematically collected, tabulated and analyzed using Microsoft Excel and Strata 6 for Windows. The Student *t* test was used in univariate analysis for the continuous variables, and Chi square test was used for analysis of noncontiguous variables. A *p* value of less than 0.05 was considered to be statistically significant.

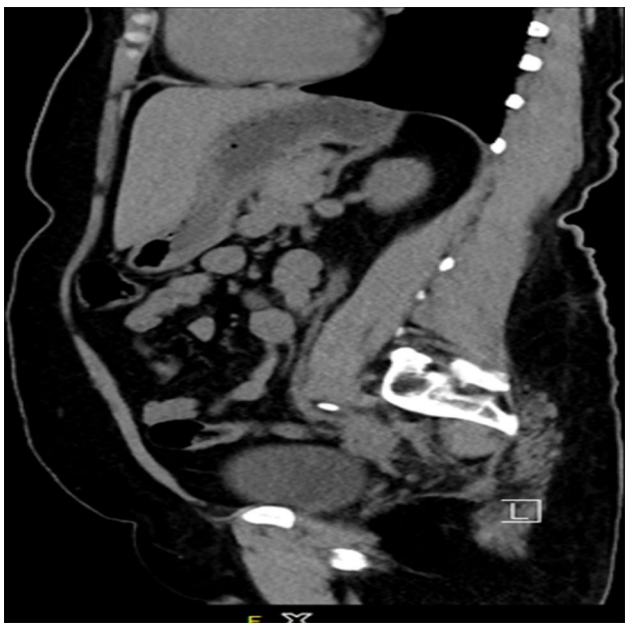

Fig. 2 Sagittal reconstruction of non-enhanced CT showing a calculus in the left distal ureter who presented with acute left renal colic

Results

This study evaluated 54 patients who had presented to the EMD with unilateral ARC within 24 h of the onset of symptoms. All the patients underwent B-mode US, CDUS and CT if the obstruction could not be confirmed in US. The presence or absence of PCS dilatation in each kidney was assessed using the grey-scale images. In this study population, 34 patients were males and 20 were females, as shown (Fig. 3). The mean age of the male patients was 46.8 years and that of the female patients was 38.5 years. The age range of the male patients was 19–79 years, and that of the female ones was 18–61 years.

The modalities used in the diagnosis and the site of obstruction are shown in Tables 1, 2.

Out of 54 patients, 26 cases proximal obstructions, while 28 had distal obstructions. The mean RI of the obstructed kidneys was higher in cases of distal obstruction (0.79 ± 0.004) than in those of proximal obstruction (0.76 ± 0.006).

Of the 54 patients, 45 patients had mild hydronephrosis, FIVE patients had moderate hydronephrosis and four patients did not have any dilatation of the collecting system despite the presence of ureteric obstruction (Fig. 4).

Of the 54 patients who were included in this study, 27 patients had elevated renal parameters, but did not have history of chronic renal impairment (Table 3).

In our study, we found that the RI in obstructed kidneys was significantly higher than in unobstructed kidneys (0.75 vs. 0.56; $p < 0.001$). The RI was higher in obstructed kidneys in all cases. The difference in RI between the obstructed and unobstructed kidneys (delta RI) ranged from 0.09 to 0.38, with a mean delta RI of 0.24 (Table 4).

The RI values in obstructed kidneys ranged from 0.68 to 0.84 (Fig. 5). The mean RI value in obstructed kidneys was 0.75, compared to 0.56 in unobstructed kidneys.

The group statistics of RI are shown in Tables 5, 6. The receiver operating characteristic curve (ROC) curve depicting the sensitivity of RI in ureteric obstruction is shown in Fig. 6.

By using a cut off RI value of > 0.70 in acute unilateral renal obstruction, the sensitivity obtained in the study was 85% and the specificity was 93% (Table 7).

Discussion

Grayscale ultrasound is the investigation method of choice in the initial evaluation of ARC, as it is easily available, portable and involves no ionizing radiation [8, 9]. However,

urinary system dilatation seen on conventional gray-scale USG has been shown to be sensitive (90%), but not specific (65–84%), in the diagnosis of renal obstruction.

The most sensitive, gold standard test for diagnosing obstructive uropathy is renal scintigraphy. However the availability of scintigraphy and radiation associated with it continue to be problematic [10]. Traditionally, the evidence of renal obstruction provided by US has been indirect and dependent on the anatomical criterion of dilatation of the pelvicalyceal system and ureter proximal to the level of obstruction. However, US fails to reveal hydronephrosis in acute obstruction of the kidney in up to 35% of cases [11]. More direct functional evidence of obstruction usually requires scintigraphy, but recently Doppler US techniques have been used to obtain functional information in suspected renal obstruction [11]. US imaging may miss (false negative) the diagnosis of obstruction in a variety of situations. Mild dilatation may be overlooked or considered clinically insignificant. Some patients with obstructive renal failure may show no pelvicalyceal system (PCS) dilatation. The reasons for this are unclear; in some patients, it may be related to dehydration or due to decompression of the pelvicalyceal system by rupture of a calyceal fornix [12]. It is commonly explained by urologists to be caused by the use of non-steroidal anti-inflammatory drugs (NSAIDs), by dehydration or by the renin angiotensin effect [13]. If that is true, such impairment will be detected through measurement of glomerular filtration rate (GFR). Measurement of GFR is commonly done using Technetium c-99 m diethylene-triamine-penta-acetate (DTPA), and does not require blood or urine sampling [14]. There is a growing evidence that renal impairment in acute unilateral ureteric obstruction is due to absorption of obstructed urine, with its high amount of creatinine, back into systemic circulation. This is considered false renal impairment with normal GFR [15]. In a study, El-Shazly et al. [16] measured renal function through measurement of estimated GFR (eGFR) usingTc-99 m DTPA. The authors showed that differences between eGFR on admission and after passage of stone or relieve of obstruction were non-significant. Their results support the hypothesis of false impairment in this clinical scenario. This tends to change the practice, as there is no need to embark on urgent intervention to relieve the ureteric obstruction, and conservative medical management is justifiable.

Routine B-mode US can be falsely positive or negative in acute ureteric obstruction [10]. PCS dilatation may be missed if the system is filled with blood clots, calculus, tumors or pus, in which case the usual anechoic appearance

of the PCS is lost. Intermittent ureteric obstruction, particularly that caused by ureteric calculi, may also lead to a failure to visualize dilatation of collecting system with US. On the other hand, in an attempt not to miss the diagnosis of obstruction in patients with only mild PCS dilatation, the false positive rate was found to be as high as 26% Causes of a false positive diagnosis include: (i) dilatation of non-obstructed PCS, when there are anatomical variants such as extra-renal pelvis; (ii) over-distended urinary bladder, with or without diuresis; (iii) vesico-ureteric reflux (VUR), (iv) residual dilatation of PCS due to previous obstruction or infection; (v) advanced pregnancy; and (vi) central renal fluid collections other than in the PCS, including in normal vessels, renal artery aneurysms and para-pelvic cysts.

Acute unilateral ureteric obstruction results in a complex sequence of changes in renal blood flow and ureteric

Author's personal copy

Cut off RI	Sensitivity	Specificity
> 0.70	85%	93%

pressure [17]. In the first two hours, the renal blood flow increases, because of afferent arteriole vasodilatation and the ureteric pressure increases. From two to six hours after obstruction, the renal blood flow decreases, secondary to vasoconstriction of the efferent arterioles, and the ureteric pressure remains elevated. Subsequently, at 6 to 18 hours, the renal blood flow remains reduced because of vasoconstriction of the afferent arterioles, and the ureteric pressure decreases.

The role of renal CDUS in the evaluation of ARC has been vigorously debated. Rodgers et al. [18] found an elevated RI in acutely obstructed kidneys, especially when compared with the RI in normal contralateral kidneys and with a control group of healthy subjects. Similar results were obtained by Platt et al. [19] in a study of 23 patients with acute unilateral ureteric obstruction. However, others have reported that Doppler ultrasound is highly insensitive for detecting ARC. Tublin et al. [20] correlated the results of Doppler USG with those of urography in 32 patients presenting with symptoms of renal colic. The RI value of normal kidneys is usually less than 0.7 [21, 22]. When the published discriminatory thresholds for obstruction (mean RI ≥ 0.70 and ΔRI ≥ 0.10) were applied, the sensitivity and specificity of Doppler USG were only 44% and 82%, respectively.

In our study of 54 patients, we found that the RI in obstructed kidneys was significantly higher than in the unobstructed kidneys (0.75 vs. 0.56; $p < 0.001$). The RI was higher in obstructed kidneys in all cases. The difference between the obstructed and unobstructed kidneys (delta RI) ranged from 0.09 to 0.38, with a mean delta RI of 0.24.

Saboo et al. [6] stated in their study that delta RI ≥ 0.006 was highly sensitive and specific, and with a higher delta RI specificity remained the same whereas the sensitivity fell rapidly. Our results correlate well with those reported in earlier studies by Badr et al. [23] and Miletic et al. [24].

We also studied the effect of the level of obstruction on RI values. When we compared levels of ureteric obstruction (proximal vs distal), distal obstructions had a higher mean RI value (0.79) than proximal obstructions (0.76), and the values were not statistically significant. However, the study done by de Toledo *et al.* [25] showed that patients with proximal ureteric obstructions have RIs higher than those with distal obstructions.

We also analyzed the utility of CDUS in patients who did not show dilatation of the PCS on ultrasound. Patients who did not have PCS dilatation on US were later confirmed to have obstruction on CT. RI values were higher in all these patients (0.71), with a delta RI of 0.24. Discriminatory RI ≥ 0.70, which is higher than the delta RI found in the study done by Platt JF et al. [26], was found to be highly sensitive (85%) and specific (93%) in this study.

Conclusion

Using the discriminatory threshold RI of ≥ 0.70, the overall sensitivity of CDUS in diagnosing acute ureteric obstruction is 85% and the specificity is 93%. CDUS is a useful tool for demonstrating altered renal perfusion in acute ureteric obstructions before pelvicalyceal system dilatation occurs, thus increasing the sensitivity and specificity. Gray-scale US should therefore, be complemented by CDUS as an adjunctive test in patients presenting with acute renal colic, as it is a very simple, noninvasive and easy-to-calculate parameter. The utility of this tool cannot be overemphasized in special cases like pregnant women and children, in whom a dilated pelvicalyceal system without acute obstruction is encountered more frequently. It is mandatory to differentiate obstructive and non-obstructive causes with US alone in this subset of patients, as further evaluation with CT is not desirable due to the hazard of ionizing radiation. Given the high propensity of any group of patients with urinary tract calculi to undergo frequent imaging studies due to recurrent ureteric colic and the presence of significant residual hydronephrosis, we should strive hard to minimize radiation dosage by avoiding frequent CT studies. At the same time, maintaining acceptable diagnostic accuracy is of paramount importance.

Author's personal copy

Limitations of the study: US is an operator-dependent examination and the results are affected by patients' body habitus and availability of good window. An increase in the RI of intra-renal vessels is also found in case of vascular or parenchymal diseases (renal vein thrombosis, acute renal insufficiency, etc.). The CDUS changes can return to normal after 48 h [27], after which its utility is doubtful with reduced sensitivity and specificity.

Abstract

Mass detection is a critical process in the examination of mammograms. The shape and texture of the mass are key parameters used in the diagnosis of breast cancer. To recover the shape of the mass, semantic segmentation is found to be more useful rather than mere object detection (or) localization. The main challenges involved in the mass segmentation include: (a) low signal to noise ratio (b) indiscernible mass boundaries, and (c) more false positives. These problems arise due to the significant overlap in the intensities of both the normal parenchymal region and the mass region. To address these challenges, deeply supervised U-Net model (DS U-Net) coupled with dense conditional random fields (CRFs) is proposed. Here, the input images are preprocessed using CLAHE and a modified encoder-decoder-based deep learning model is used for segmentation. In general, the encoder captures the textual information of various regions in an input image, whereas the decoder recovers the spatial location of the desired region of interest. The encoder-decoder-based models lack the ability to recover the non-conspicuous and spiculated mass boundaries. In the proposed work, deep supervision is integrated with a popular encoder-decoder model (U-Net) to improve the attention of the network toward the boundary of the suspicious regions. The final segmentation map is also created as a linear combination of the intermediate feature maps and the output feature map. The dense CRF is then used to fine-tune the segmentation map for the recovery of definite edges. The DS U-Net with dense CRF is evaluated on two publicly available benchmark datasets CBIS-DDSM and INBREAST. It provides a dice score of 82.9% for CBIS-DDSM and 79% for INBREAST.

conditional random fields, deep supervision, mammograms, mass segmentation

1 | INTRODUCTION

According to Global Cancer Observatory Database (GLOBOCAN) released in the year 2018, breast cancer is contributing to over 25.4% of all the new cases diagnosed.[1] Screening programs are organized by the government to aid in the early diagnosis of the disease. Mammograms are widely accepted as the primary screening tool for breast cancer. A mammogram is an X-ray image of the breast, which capture the changes in the breast tissue. Presence of mass and microcalcification in the mammograms characterize the disease.[2,3] The

detection of these regions is difficult as their pixel intensities often correlate with the normal tissue.

Computer-aided detection and computer-aided diagnosis tools[3] are used to lessen the burden of the radiologist in the process of diagnosis. They interpret digitally captured medical images and provide useful information about the suspicious regions. They employ artificial intelligence and image processing techniques for the task of detection and analysis. CAD systems are constantly evolving with the advent of new techniques in the domain to provide accurate results. This paper deals with mass segmentation: a key step in the diagnosis of breast cancer. Earlier studies on mass segmentation employ region growing[4] or contour-based techniques.[5] The shortcomings of the above-mentioned approaches are the initial seed selection and the initial contour selection.[2] With the recent success of the deep neural networks in most of the vision-oriented challenges, there has been a spurt of research into their applicability for medical diagnosis.[6-9] There are two different approaches applied for lesion identification: Object Detection and Semantic Segmentation. In object detection, mass locations are approximated by a bounding box and the network is trained to predict its coordinates. Cascade of belief networks[10] and region-based convolutional neural networks (CNNs)[11] have previously been explored for mass detection. The limitation of the object detection technique is that it requires additional processing to recover the object boundary. In the semantic segmentation, every pixel is classified either as a background or mass region. Fully CNN[12] is popularly used for the task wherein the fully connected layers of CNN are replaced with up sampling layers to restore the spatial context of the lesion. Though FCN flared well in most of the recognition tasks, it provides a coarser output. U-Net[13] employed a symmetrical encoder and decoder path with the concept of skip connections to recover the region of interest (ROI) context in the image. U-Net outperformed other models significantly when the image possess higher signal to noise ratio (SNR). The proposed work improves the U-Net model with deep supervision and channel attention to prevent the loss of information at the encoder.

The main contributions of the work include:

1. A lightweight U-Net architecture is proposed with improved attention to the boundaries of the suspicious regions. The output of the encoder layer is monitored for proper attention of the mass boundaries and the output of the decoder layer is monitored for proper attention of the mass regions. This leads to faster convergence and lesser false positives.
2. A learnable fusion layer is used to combine the output of the intermediate layers with output of the last layer. This prevents the loss of information at the encoder.
3. Exponential logarithm dice loss function is used to improve the segmentation of the smaller objects. It is an unbiased metric, which treat the objects equally irrespective of their size.
4. Unlike other works, the proposed model uses dedicated preprocessing and post processing modules to improve the segmentation result. CLAHE is used to enhance the contrast of the input image and dense conditional random field (CRF) is used to recover the boundary of the detected regions from the final segmentation map of deeply supervised U-Net model (DS U-Net).

2 | METHOD

2.1 | Overview

The proposed model employs an end-to-end architecture for mass segmentation in mammograms. The model is trained over the images from CBIS-DDSM and INBREAST dataset (Figure 1). It starts with preprocessing the images using CLAHE to improve SNR. Then, it segments the mass regions in the preprocessed image using DS U-Net. Finally, it applies dense CRF to recover the shape of the mass. Figure 2 shows the various components involved in the proposed architecture.

2.2 | Preprocessing

Preprocessing is often neglected when the deep neural networks perform the task of segmentation. Since mammogram images exhibit low SNR, the detection becomes infeasible without proper preprocessing. From the literature, it is found that the histogram equalization

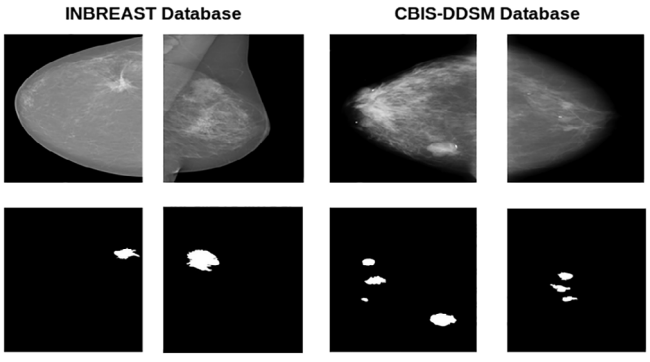

FIGURE 1 Mammogram images with ground truth indicating mass. First row: full field of view mammogram images in INBREAST and CBIS-DDSM dataset. Second row: manually segmented mass regions

technique and its variants are beneficial for the mammogram images.[14,15]

In the proposed work, CLAHE is used to improve the contrast in the mammogram image.[11] It splits the image into nonoverlapping blocks of size N * N and computes the transformation function for each of these blocks separately using histogram equalization. Then, for every pixel in the image, four nearest blocks are considered and their respective transformation mapping is used to find the resultant pixel intensity. Applying histogram equalization to homogenous regions can introduce noise in the resultant image. To remove the noise, Intensity values with frequency count greater than clip limit (threshold) are redistributed across other bins with lesser frequency count. This technique is found to improve the edges in the image. Figure 3 shows the sample images from INBREAST and CBIS-DDSM which are enhanced using CLAHE.

2.3 | Deeply supervised U-net

Deep supervision[16-18] brings in transparency to the intermediate hidden layers of deep neural networks. It uses the error factor of intermediate feature maps with respect to the ground truth in the training objective criterion. This improves the robustness of the neural network in both the segmentation and the classification tasks.[16] In the segmentation network, the output of intermediate layers is up-sampled and compared with ground truth to quantize their error margin.

U-Net[13] has become the de-facto standard for biomedical image segmentation. It employs an encoder decoder-based architecture. Encoder consists of convolution layers for retrieving contextual information and pooling layers for down-sampling the images. Downsampling aids in the retrieval of higher-level contextual information and also offers translational invariance. U-Net has a symmetrical decoder path which up-samples the feature map so as to recover the spatial context of the detections. Skip connections are pathways which carry the spatial information from the encoder to the decoder. The proposed work has extended over the idea of Chen et al[19] and Mishra et al[13] to use the intermediate layers of the encoder and the decoder to focus on the boundaries and regions simultaneously. In addition, the proposed model utilizes Squeeze Excitation blocks[12,20] to reinforce the channels of higher importance before combining the feature maps from the skip connection and the decoder. Figure 4 shows the complete architecture of proposed model. The DS U-Net is used to improve the recovery of the object boundary and significantly reduce the number of false positives.

The encoder block applies repeated 3*3 convolution on the input tensor as shown in Figure 5A. After every convolution, batch normalization is applied followed by ReLU activation. The decoder block (Figure 5C) up-samples the high-level features from the previous layer using bilinear interpolation and combines it with spatial context (low level features) from the encoder block. Subsequently, 3*3 convolution is applied before passing the tensor to the next layer. After every stage of the decoder,

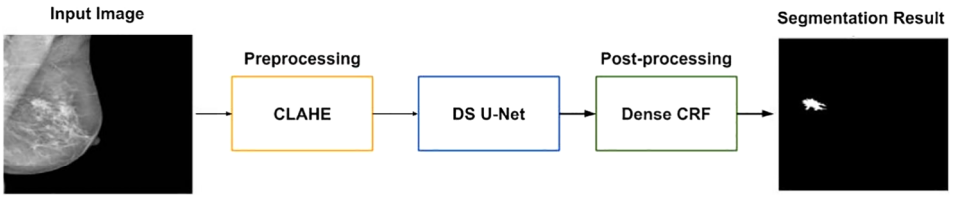

FIGURE 2 Proposed architecture for mass segmentation in mammograms [Color figure can be viewed at wileyonlinelibrary.com]

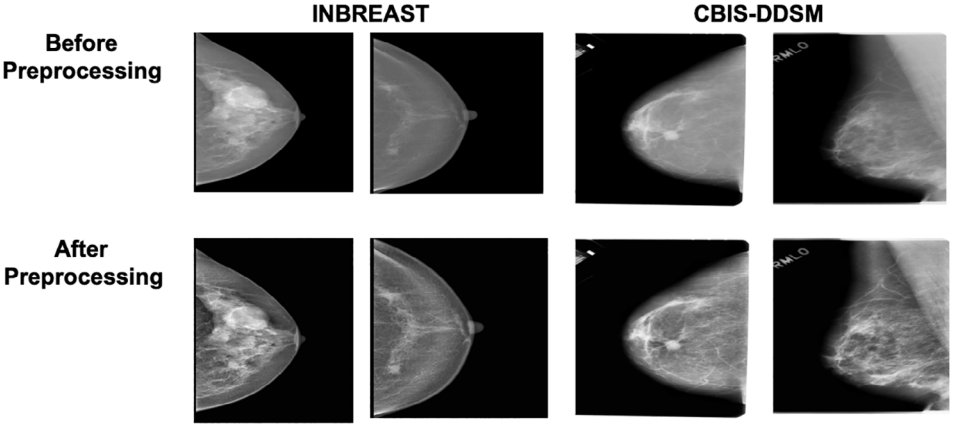

FIGURE 3 Preprocessed mammogram images using CLAHE

a drop out layer with the probability of 0.5 is used to avoid overfitting. The high-level features and the low-level features are subjected to channel attention before being fed as the input to the decoder block. Channel attention reinforces the feature maps with salient features using two-layered network. The first layer contains nodes equal to 1/16th of the number of input feature maps and the second layer contains nodes equal to the number of input feature maps. The network operates over the average intensity value of the input channels as shown in Figure 5B. Blocks A1 to A6 are attention blocks, which supervises the encoder and decoder layers as shown in Figure 4. It applies 1*1 convolution to reduce the dimensions and bilinear upsampling to enlarge the size of the intermediate tensor to match the output dimensions (Figure 5B). Fusion layer produces the end segmentation result as the linear combination of the outputs from the attention blocks and the output from the final decoder layer (D_4) as shown in Equation (1).

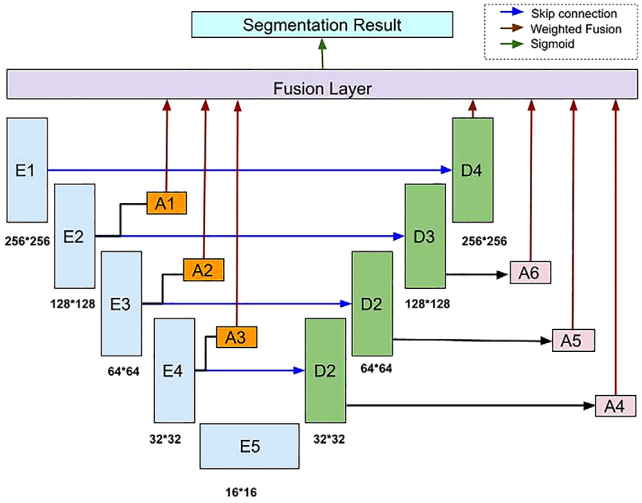

FIGURE 4 Deeply supervised U-Net: auxiliary blocks A1, A2, and A3 are providing attention to the boundaries, and auxiliary blocks A4, A5, and A6 are used to discriminate the entire mass region from the background [Color figure can be viewed at wileyonlinelibrary.com]

$$\hat{y} = \text{sigmoid}\left(\sum_{i=1}^{6} h_i O(A_i) + h_D O(D_4)\right) \quad (1)$$

Here, $\hat{y}$ represents the final segmentation result, O(.) represents the output of the block provided in the parenthesis and h $\{h_D, h_1, h_2 \ldots . h_6\}$ represents the weights associated with the output of final decoder block and the attention blocks. The objective criterion is modified as in Equation (2) so that the attention blocks A1 to A3 can steer the network toward boundary identification and blocks A4 to A6 can steer the network toward region identification.

$$L(\hat{y}, y_B, y_M; \theta) = L_f(\hat{y}, y_M) + \text{Auxiliaryloss} \quad (2)$$

$$\text{Auxiliary loss} = \left(1 - \frac{t}{T}\right)^d \left(\sum_{i=1}^{3} L_{A_i}(O(A_i), y_B) + \sum_{i=4}^{6} L_{A_i}(O(A_i), y_M) + L_{D_4}(O(D_4), y_M)\right) \quad (3)$$

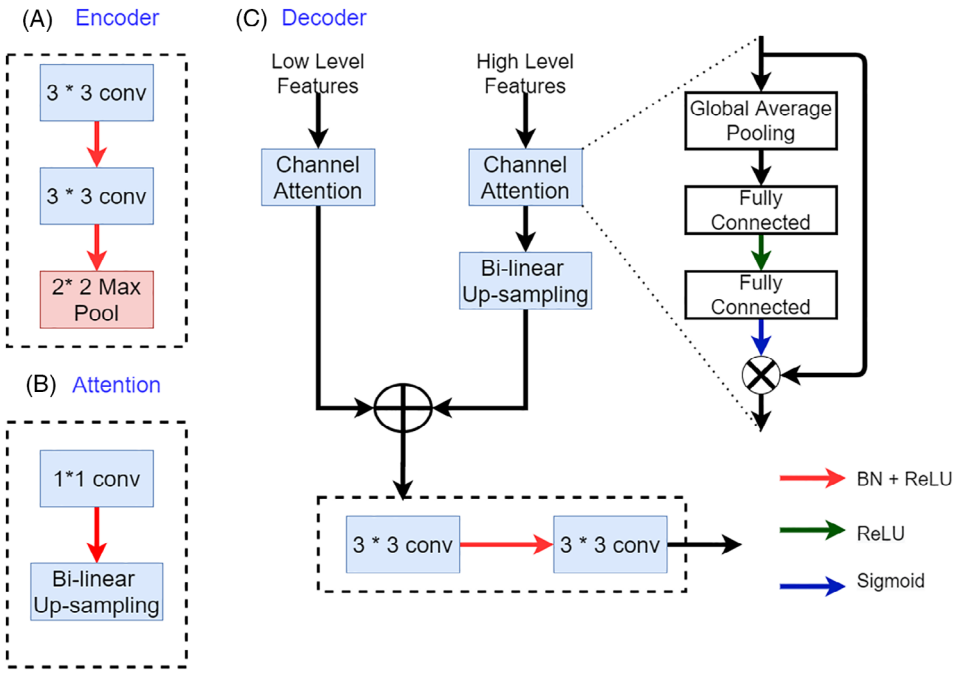

FIGURE 5 Various blocks of DS U-Net architecture, A, encoder, B, attention, and, C, decoder [Color figure can be viewed at wileyonlinelibrary.com]

Here, L represents the loss function which is discussed in section D, θ represents the parameters of the network which include (W_{encoder},W_{decoder}, $W_{\text{attention}}$,h), Y_B represents the ground truth labeled with only the boundary pixels of the suspicious mass and Y_M represents the ground truth labeled for the entire region of the suspicious mass.

A factor of $\left(1-\frac{t}{T}\right)^d$ is used for auxiliary loss to reduce the impact of attention layers as the number of iterations (t) approach the total number of epochs T.[17] It ensures that the intermediate activations are not modified to a larger extent at the later stage of the training process. d is a constant which is set to a value of 2. The boundary pixels are extracted by performing morphological erosion on the region mask with disk shaped structuring element (value of radius is set to 3) and subtracting the resultant from the original image. The boundary mask obtained after the morphological operation is shown in Figure 6.

2.4 | Loss function

Sorensen dice coefficient is the popularly used metric to measure the similarity between two images. To gauge the differences between the prediction and ground truth, error value of (1-Dice coefficient) is used. The size of the object can influence this value as it just takes into account the percentage of misclassified pixels. In particular, this error function results in higher value even with fewer number of misclassifications for smaller objects. Thus, the network may be biased toward the object of larger sizes upon using this loss function. To achieve a balanced loss whereby the network focuses on both the objects with low and high prediction accuracy equally, exponential logarithm dice loss is used.[21]

Let y_i represents the ground truth of i^{th} pixel which takes either a value of 0 (or) 1. A value of 0 indicates the background (normal region) and a value of 1 indicates the mass (abnormal region). Let p_i represents the prediction probability of i^{th} pixel belonging to mass. The exponential logarithm dice loss is computed as in Equation (4), where M denotes the total number of training samples in the mini-batch.

$$\mathcal{L}=\frac{\sum_{k=1}^{M}\left(-\ln(\text{Dice}_k)\right)^{\gamma}}{M} \tag{4}$$

The dice score for image k is calculated as $\text{Dice}_k=\frac{\sum_{i=1}^{N}2y_i*p_i+\varepsilon}{\sum_{i=1}^{N}y_i+\sum_{i=1}^{N}p_i+\varepsilon}$. ε(epsilon) value of 1e-6 is used for numerical stability. γ value in the loss is used to adjust the non-linearity between the dice score value and the error. In the experiments, γ value of 0.3 is used[21] as it offers a decreasing gradient with dice score values less than 0.5 and an increasing gradient with dice score greater than 0.5. This helps the loss function to behave differently for objects of varying sizes.

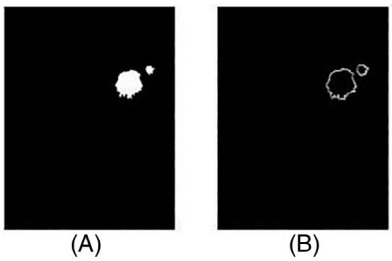

FIGURE 6 Segmentation masks. A, Region mask. B, Boundary mask

2.5 | Post-processing

DS U-Net precisely identifies the location of the mass in a given mammogram image. As the shape of the detected lesions can aid in the diagnosis of the disease, post-processing is applied to recover the entire context of the detected lesions. Probabilistic graphical models have proven to be effective in modeling the neighborhood dependencies. Therefore, it possesses higher discriminatory power to differentiate the foreground pixels from the background pixels. Hence, CRFs is used to fine-tune the resulting segmentation map of Deep Supervised U-Net model. Works by Chen et al[22] and Zheng et al[23] showed that state of the art segmentation results can be obtained by incorporating the dense CRF model. The model accepts the raw intensity values of input image and the unary potentials (sigmoid probabilities of DS U-Net) to generate the final probability map as shown in Figure 7.

CRF model treats the individual pixels X_u as random variables which can take values from the set $L = 0, 1$ where 0 indicate background and 1 indicate foreground (suspicious mass region). CRF inference assigns a configuration $X=X_1,X_2,X_3.....X_{N^2}$ for every random variable in the image I such that the energy given in Equation (5) is minimized.

$$\begin{aligned}E(X,I)&=\sum\nolimits_{uV}\Phi_u(X_u=x\,|\,I)\\&+\sum\nolimits_{\{u,v\}\xi}\Psi_{u,v}(X_u=x,X_v=y|I)\end{aligned} \tag{5}$$

The term $\Phi_u$denotes the unary cost associated with assigning label x for the variable X_u. This cost is usually obtained from the classifier. The interdependencies

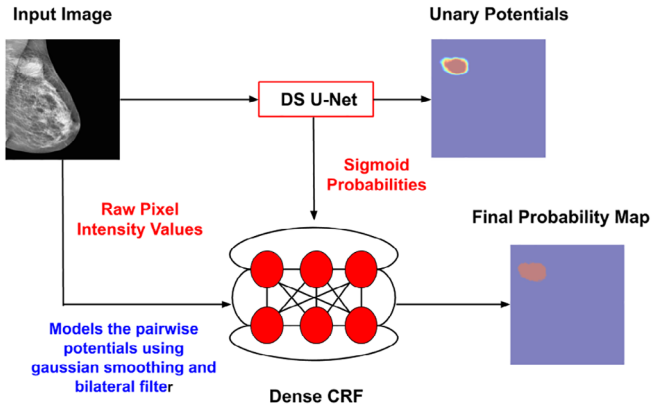

FIGURE 7 Dense CRF model process flow [Color figure can be viewed at wileyonlinelibrary.com]

between the pixels are modeled using pairwise cost $\Psi_{u,\,v}$ which accounts for the cost of assigning labels x and y for the pixels X_u and X_v, respectively. The common pairwise cost used is Pott's model which provides a cost of 0 when the neighboring pixels are assigned with same label and a value of 1 otherwise. Further, certain assumptions should also be made on how the pixels connect with each other. There are two popular configurations used: Grid CRF and fully connected CRF. Fully connected CRF assume that every pixel in the image is connected with every other pixel whereas Grid CRF assumes that every pixel is connected only to its adjacent pixels. Dense CRF leverages on fully connected CRF to model the neighborhood dependencies. CRF has been formulated on the basis of the Gibbs distribution as given in Equation (6).

$$P(X\,|\,I) = \frac{1}{Z(I)}\exp(-E(X,I)) \tag{6}$$

The learning phase of CRF is defined as the computation of marginal probabilities for every random variable X_u and for every pair of random variables (X_u, X_v) which are connected by edges, that is, all pixels except itself $u \neq v$ in a fully connected graph. Detection of true distribution for the unary Φ and pairwise potentials Ψ are infeasible. Mean field inference approximates the p(X|I) using a simpler distribution Q(X|I) and iteratively reduces the Kullback Leibler divergence between Q(X|I) and p(X|I). In the proposed model, unary potentials Φ are obtained from DS U-Net and the pairwise potentials Ψ are modeled using the sum of two Gaussian kernels as suggested in Reference 24: Gaussian smoothing kernel $\exp\left(-\frac{||p_u-p_v||^2}{2\sigma_\alpha^2}\right)$ and Gaussian preserved bilateral filtering kernel $\exp\left(-\frac{||p_u-p_v||^2}{2\sigma_\alpha^2}-\frac{||I_u-I_v||^2}{2\sigma_\beta^2}\right)$. Here, $p_u$and p_V denote the position of the pixels. I_u and I_v denote the intensity of the pixels. Weights are associated with the kernels to control the significance of the filters.

Thus, the pairwise potentials in CRF is formulated as $\Psi_{u,\,v}(X_u, X_v) = \mu(X_u, X_v)k(f_u, f_v)$ where μ denotes the label similarity using common Pott's model and k denotes the sum of Gaussian kernels. Mean Field updates for assigning a label l for the random variable X_u is provided in Equation (7).

$$Q_u(X_u = l\,|\,I) = \frac{1}{Z_u}\exp -\Phi_u(I) - \sum\nolimits_{l'L}\mu(l,l') \sum\nolimits_{m=1}^{2} w^{(m)} \sum\nolimits_{v\neq u} k^{(m)}(f_u,f_v)Q_u(l') \tag{7}$$

Here, $w^{(m)}$ indicate the strength of the filter m. In the experiments, weights for Gaussian smoothing and bilateral filters are considered as 1 and 5, respectively. Number of iterations T_0 for convergence is set as 50.

III Experiment

2.6 | Datasets

The model is evaluated on two popularly available benchmark datasets: INbreast[25] and CBIS-DDSM.[26] INbreast contains 107 full field digital mammography (FFDM) images with mass findings. These images are available in DICOM format and are of size 3328 * 4084 (or) 2560 * 3328 with 14-bit resolution. The boundary pixels of the mass are manually annotated and provided in XML format. Because of the smaller size of the dataset, a 5-fold cross-validation is performed on the dataset to gauge the model's performance.

CBIS-DDSM dataset contains curated mammogram images from DDSM, a largest available mammogram database. They provide separate training and test set for mass detection and microcalcification detection. The dataset comprises of FFDM images along with the segmentation mask and the cropped ROI for every suspicious finding in DICOM format. For the experiments, a curated set of 689 images is used for training and a set of 168 images is used for testing.[27] There are multiple ROI detections in an image which are provided as separate masks in the dataset. They are merged into a single mask before training. Both the datasets contain significant amount of benign cases[27] and they also include masses of varying sizes as shown in Figure 1.

2.7 | Experimental framework

All the experiments are carried out using NVIDIA GTX 1080 Ti GPU and the models are implemented in keras. Adam[28] optimizer with warm restart is used for the training

Algorithm 1

end while

process with the batch size as 4. The models are trained for about 200 epochs with 0.001 as the initial learning rate. Here, the learning rate is decreased using cosine annealing for a defined number of iterations known as a cycle and it is reinitialized to a maximum value after every cycle. The parameters of the model are randomly assigned as the other initializers failed to converge. The intensity values in the image are scaled to a fixed range between 0 and 1 before being fed as the input to the network.

2.8 | Metrics

To measure the correctness of the prediction, two types of metrics are used: pixel level metrics and region level metrics. Pixel level metrics include accuracy, sensitivity, and specificity. The **Accuracy** measures overall pixel accuracy, that is, percentage of correctly classified pixels, **Sensitivity** measures the percentage of correct predictions corresponding to pixels constituting the mass region in the ground truth, **Specificity** measures the percentage of correct predictions corresponding to pixels constituting the normal region in the prediction map.

$$\text{Sensitivity} = \frac{\text{TP}}{\text{TP} + \text{FN}} \tag{8}$$

$$\text{Specificity} = \frac{\text{TN}}{\text{TN} + \text{FP}}. \tag{9}$$

Here, true positive (TP) denotes the count of pixels which are classified correctly as belonging to mass. False positive (FP) denotes the count of normal pixels classified as mass and false negative (FN) denotes the count of pixels which are incorrectly classified as normal pixels. Sensitivity will be low when there are more FN. It happens due to under-segmentation wherein the mass occupies a very small region that cannot be properly captured by the model. Specificity is affected when there are large number of FP. False positives are the consequence of over-segmentation wherein the normal parenchymal regions are detected as mass.

Object level metrics use the size and the boundary of positive predictions for evaluation. Jaccard coefficient, dice score, relative area difference (ΔA), and Hausdorff distance are used for evaluating the regions in the resulting prediction map.

$$\text{Jaccard} = \frac{\text{TP}}{\text{TP} + \text{FP} + \text{FN}} \tag{10}$$

$$\text{Dice score} = \frac{2\text{TP}}{2\text{TP} + \text{FP} + \text{FN}} \tag{11}$$

$$\Delta A = \frac{|(TP + FP) - (TP + FN)|}{(TP + FN)}. \quad (12)$$

Jaccard and **dice score** measure the amount of overlap between ground truth (GT) and prediction map. A value of 0 indicates that there is no overlap between prediction and GT. A value of 1 indicates an exact match between GT and prediction. Jaccard is an estimate of average performance of the model and Dice score is an estimate of worst-case performance of the model. **Relative area difference** is used to measure the differences in the size of prediction against the ground truth. To measure the maximum deviation along the boundary between GT and predictions, **Hausdorff distance** metric is used. It measures the longest distance between any two closest points that lie in the boundary of ground truth and prediction.

$$H = \max(h(\mathrm{GT}, \mathrm{pred}), h(\mathrm{pred}, \mathrm{GT})) \quad (13)$$

Here, $h(\mathrm{A}, \mathrm{B}) = \max(\min(\|a - b\|))a \in A, \quad b \in B$ where A and B represent the set of boundary pixels. The lower values of H indicate accurate segmentation.

2.9 | Experimental results

The proposed work is aimed at improving the segmentation of lesions in whole mammograms. An ablation study is conducted to determine the effectiveness of pre-processing and post-processing techniques. To measure the performance of the model, experiments are repeated thrice and the average value of the metrics are considered.

2.9.1 | Impact of preprocessing

Mammograms exhibit low contrast when compared with other medical images. To improve the contrast in the mammograms, CLAHE is used. Since the images in CBIS-DDSM are obtained from four different scanners, they exhibit varying contrast. Hence, selective preprocessing is used, that is, CLAHE is applied only to those images which exhibit poor global contrast. The global contrast in an image is estimated using root mean square (RMS) metric. RMS measures the variance of the normalized gray level values in an image as specified in Equation (14).

$$\mathrm{RMS} = \sqrt{\frac{1}{n-1}\sum_{i=1}^{n}(x_i - \bar{x})^2} \quad (14)$$

where x_i is a normalized gray level value $0 \le x_i \le 1$, $\bar{x}$ is the mean normalized gray level and n denotes the total number of pixels in an image. The block size and the clip limit for CLAHE are considered as (128128) and 0.01, respectively.

Table 1 depicts the performance of DS U-Net for both the datasets w/ & w/o preprocessing. There is a significant improvement in all the metrics for both the datasets when preprocessed images are used in the model construction. In particular, the dice score is increased by a factor of 4% and 1.6% for CBIS-DDSM and INbreast, respectively.

2.9.2 | Impact of postprocessing

Postprocessing is applied on the prediction maps obtained from the DS U-Net model using dense CRF. It is used to recover the boundary of the abnormal region. This stage is critical as the region boundary can offer crucial information about the malignancy of the region. Dense CRF uses the probability of pixels from DS U-Net as unary potential and models the pairwise potential as the sum of Gaussian smoothing and bilateral filters. After a grid search over different kernel sizes and filter strength, ideal values are determined. The kernel size of (7,7) for Gaussian smoothing filter and (3,3) for bilateral filter provided the optimal performance.

Table 2 depicts the performance of DS U-Net after postprocessing. Hausdorff distance is the only metric which accounts for the shape of the object out of all the considered metrics. A significant reduction of 0.05 is observed for Hausdorff distance metric after applying dense CRF over the prediction maps of DS U-Net. As the

technique only changes the class label for a smaller percentage of pixels which lie along the boundary of the detected regions, it does not affect the value of other metrics as reported in the table.

2.9.3 | Comparison with other state-of-art models

In order to compare the effectiveness of the proposed model, AU-Net[27] and U-Net[13] models are considered. The U-Net model uses skip connections to carry information from the encoder stage to the decoder stage for recovering the spatial context. This information is then combined with the feature maps of the decoder through concatenation. But it is found to be ineffective and also attributes to certain information loss.[27] This problem is addressed in AU-Net by utilizing an asymmetrical network backbone and attention guided dense up-sampling. AU-Net offers better accuracy than the U-Net model at the cost of increased computational complexity. DS U-Net addresses the loss of information by employing deep supervision over the intermediate activations. It also uses channel attention to retrieve important information from the feature maps. The computational complexity of DS U-Net is reduced by employing feature addition instead of concatenation. Table 3 depicts the performance of all the three models. It clearly shows that the DS U-Net provides substantial improvement in all the key metrics when compared with other models. In particular, the dice score of DS U-Net shows an improvement of 1.8% in comparison with the AU-Net model for the CBIS-DDSM dataset. There is also a huge reduction in the Hausdorff distance and ΔA by 0.54 and 7.2, respectively, for the CBIS-DDSM dataset when compared with the AU-Net model. Dice score values of all the models are inspected further using CDF (Figure 8).

The qualitative improvement of the proposed model over the others is shown in Figures 9 and 10. The

AU-Net[27]	Complex up-sampling with asymmetrical encoder and decoder blocks	CBIS-DDSM	857	80.9	84.5

prediction result of all the models for sample images from both the datasets are depicted. The boundary of the ground truth is delineated using lines in green color and the boundary of the predicted regions are delineated using lines in red color. From the figures, it is apparent that the U-Net model fails to detect lesions of smaller size.

To better understand the overlap of predictions and ground truth across the entire set of images in CBIS-DDSM dataset, empirical cumulative difference of dice score is plotted (Figure 8). It shows the frequency count of every possible dice score in the obtained predictions. The DS U-Net locates lesion in the images quite comfortably as the graph starts with dice score of 0.4, that is, the model does not have any predictions with a dice score less than 0.4. The graph of the DS U-Net also shows a steeper increase after the dice score 0.8. This is indicative of the fact that most of the model predictions are precise.

Table 4 specifies the number of trainable parameters of the considered models. The DS U-Net uses a smaller number of convolution layers in the encoder and the decoder blocks compared with AU-Net. This subsequently reduces the training and inference time. It also performs better than AU-Net with half the number of parameters involved in it.

Table 5 provides an overview of other popular semantic segmentation architectures that are used for mass segmentation in the digital mammograms. Most of the works were carried out on a dataset with not more than 400 images. This work uses 857 images from the CBIS-DDSM dataset.

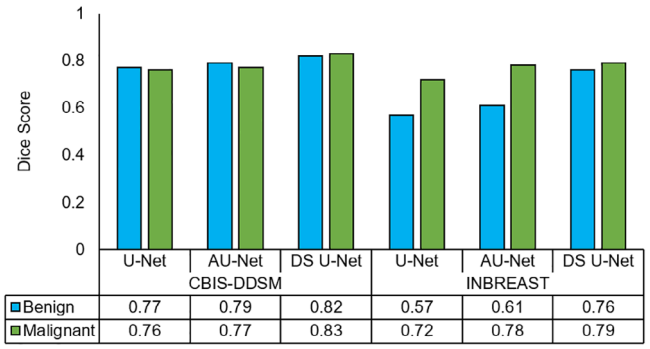

FIGURE 11 Average dice score of different models with respect to lesion type [Color figure can be viewed at wileyonlinelibrary.com]

Effectiveness of the model in the segmentation of benign lesions

The existing CAD system fails to detect lesions at benign stage, as the lesions are more subtle in nature. To assess the effectiveness of the model in detecting the lesions at benign stage, the model's average dice score for benign and malignant lesions are determined. Figure 11 depicts the performance of AU-Net, U-Net and DS U-Net model for both the datasets. The DS U-

Net provides a similar dice score for both the lesion categories. There is also a significant improvement in the average dice score of DS U-Net for benign lesions when compared with AU-Net. This strengthens the inference that DS U-Net works better for mammograms when compared to other models.

3 | CONCLUSION

In this work, an end-to-end framework is created for the mass segmentation in digital mammograms. It uses CLAHE to improve the contrast of the input mammogram, deep supervised U-Net to segment the lesions and dense CRF to recover the entire context of the lesions. The DS U-Net has improved the U-Net model with channel attention and deep supervision for faster convergence and increased performance. Several pixel level and region level metrics are used to evaluate the performance of the model. The proposed architecture is found to perform better when compared with AU-Net and U-Net. In future, this model can also be explored for the segmentation of other medical images.

ACKNOWLEDGMENTS

Research was conducted as part of the study (Ref:19/359) approved by Institutional Human Ethics Committee of PSG Institute of Medical Sciences and Research. We appreciate Cheng Li, Shenzhen Institutes of Advanced Technology, Chinese Academy of Science, for sharing the representative set of images from CBIS-DDSM to enable validation of the model.

Qualitative and Quantitative Assessment of Enhancement and Washout Characteristics of HCC and non HCC Hypervascular Liver Tumours

PRERNA GARG[1], SALIL PANDEY[2], MUTHUSUBRAMANIAN[3], CINDREL[4], B DEVANAND[5], V MAHESHWARAN[6], R RAJAKUMAR[7]

Introduction: The image based diagnosis of Hepatocellular Carcinoma (HCC) relies on assessment of arterial enhancement and venous or delayed phase washout. This assessment is based on visual analysis; however, studies quantifying such enhancement and washout are lacking.

Aim: To qualitative assessment of the imaging characteristics of HCC and non HCC hypervascular liver tumours followed by quantitative assessment of the enhancement and washout kinetics, and also to derive objective values that may help in differentiating HCC from non HCC on Computed Tomography (CT).

Materials and Methods: The present study was carried out in PSG hospitals, Coimbatore, Tamil Nadu, India. Retrospective analysis of hypervascular liver lesions was performed over a study period of four years (January 2012 to February 2016). These lesions were divided into two groups namely; HCC and non HCC. All non HCCs were pathologically proven, while HCC cases included those diagnosed on histopathology or typical imaging findings based on American Association for the Study of Liver Diseases (AASLD) (2010) and Liver Imaging Reporting and Data Systems (LIRADS) (2014) diagnostic criteria along with an elevated Alpha Fetoprotein (AFP) of more than 400 IU/mL.

A qualitative analysis of the enhancement and washout patterns was done followed by quantitative analysis using Regions of Interest (ROI) measurement of attenuation in Hounsfield units (HU). The quantitative parameters assessed were; Mean Attenuation (MA) of lesions in different phases, Attenuation Gain Percentage (AGP) on arterial phase, Arterial Phase Attenuation Change (AAC), Attenuation Loss Percentage in venous and delayed phases (ALP-V, ALP-D), Percentage Attenuation Ratio in venous and delayed phases (PAR-V, PAR-D) and Relative Washout Ratios from arterial to venous/delayed (RWR A-V, RWR A-D) and from venous to delayed phases (RWR V-D). Sensitivity and specificity were calculated for qualitative washout.

For quantitative variables comparative analysis between HCCs and non HCCs was done using Student's t-test. ANOVA was used to compare different categories. ROC curves were drawn for values that were significantly different to establish a cutoff value.

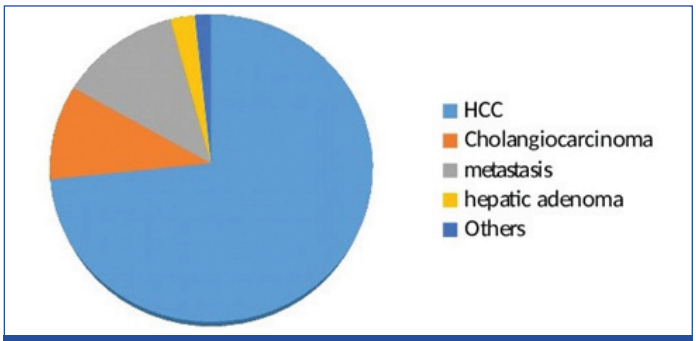
Results: A total of 120 lesions were evaluated consisting of HCCs (n=88) and non HCCs (n=32). Qualitatively majority (81) of HCCs demonstrated arterial enhancement and washout with eight cases of these demonstrating subtle washout requiring settlement by consensus. Washout were absent in seven cases. True mimics of HCC on qualitative analysis were hepatic adenomas, few cases of metastasis and hepatoblastoma were also there. The overall sensitivity of the washout appearance for predicting HCC was 92% while specificity was 78%. On quantitative analysis a PAR-V≥106 has sensitivity of 70% and specificity of 75%, RWR-V-D≥41.79 has sensitivity of 75% and specificity of 70% for HCC detection. Additionally significant difference was seen between RWR V-D of HCC when compared to cholangiocarcinomas (p-value 0.035) and metastasis (p-value 0.026) and also between PAR-V of HCC and metastasis (p-value 0.033).

Conclusion: The qualitative analysis combined with quantitative assessment of washout using percentage attenuation ratio in venous phase and relative washout ratio from venous to delayed phase offers good sensitivity and specificity in image based diagnosis of HCC.

Keywords: Hepatocellular carcinoma, Percentage attenuation ratio, Relative washout ratio

INTRODUCTION

The diagnosis of HCC on imaging relies on subjective assessment of arterial enhancement and venous or delayed phase washout. The arterial phase enhancement is attributed to an increase in intralesional flow with relative reduction in portal flow which occurs as the lesion progresses from dysplastic nodule to HCC [1,2]. Venous or delayed phase washout is decrease in attenuation of the lesion relative to background liver. Factors attributed to washout include early drainage of contrast material as compared to parenchyma and retention of contrast by surrounding fibrotic parenchyma [1-3]. There is ample literature on arterial enhancing mimics of HCC [1,3-7]. Arterial enhancing metastases, cholangiocarcinomas are known, similarly washout, a hallmark of HCC has been described in other tumours [5-7]. According to some studies Intrahepatic Mass-forming Cholangiocarcinoma (IMCC) showing arterial enhancement, was the most common lesion misinterpreted as HCC in preliver transplant imaging work up in recipients [5,9]. In cirrhotic livers lesions like regenerative nodules, dysplastic nodules, arterioportal or venous shunts and confluent fibrosis may also mimic this appearance [2,5-9]. Owing to typical enhancement characteristics of HCC, radiological imaging plays a crucial role in diagnosis and this combined with certain clinical and biochemical characteristics have been adopted as practice guideline for diagnosing HCC over the world. Differentiating HCC from other hypervascular tumours is important since HCC has therapeutic implications and prognostic factors which are very different from other lesions [2,8,10].



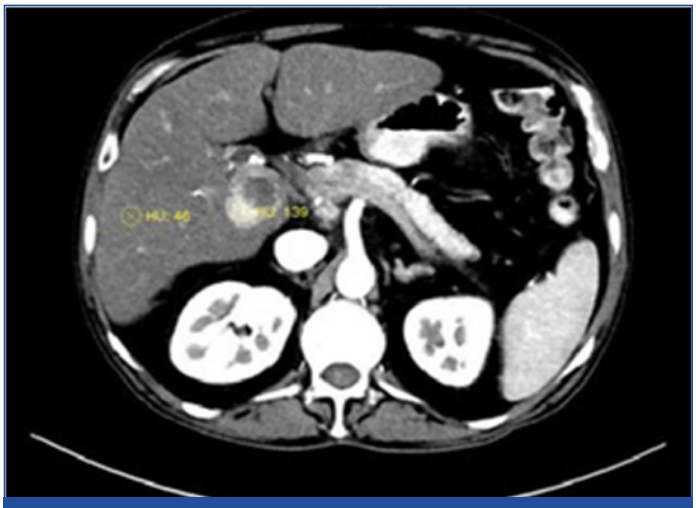
The assessment for hypervascularity of tumours and washout or persistent enhancement relies heavily on radiologist's subjective visual assessment. Only few studies have attempted to quantitate these variables and define the washout phenomenon [2,10]. In one

study, parameters such as relative contrast washout ratio between the arterial phase and delayed phase and attenuation ratio of the lesion to the background liver were studied and the attenuation ratio of the lesion to the background liver in the delayed phase was found to have excellent sensitivity and specificity for HCC detection and good correlation with subjective assessment [2]. In yet another study, an attenuation difference of greater than 10 HU between the arterial and delayed phase yielded optimal sensitivity and specificity for detecting HCC [10]. Certain studies have also quantitatively assessed the washout pattern on Magnetic Resonance Imaging (MRI), with a study evaluating the signal to noise ratio and liver to lesion contrast [11]. Overall the available literature is limited in this aspect with variable results. In present study, we analysed a large retrospective cohort of hypervascular liver tumours which were consecutively diagnosed over a period of four years in our hospital. We performed a qualitative assessment of the imaging characteristics of HCC and non HCC hypervascular liver tumours followed by quantitative assessment of the enhancement, washout kinetics and derived objective values that help in differentiating HCC from non HCC on CT. To the best of our knowledge this is the first such Indian cohort of hypervascular liver tumours being subjected to such qualitative and quantitative assessment.

MATERIALS AND METHODS

Institutional Ethics Committee approval was obtained and requirement for informed consent was waived after considering the retrospective nature of study. An extensive search of our Hospital Information System/Picture Archiving And Communication System (HIS/PACS-Vepro Medical Systems) for liver lesions on CT using keywords Hepatic, liver lesion, hepatic lesion, space occupying lesion, mass, HCC, Hepatocellular carcinoma and each of the individual common malignant and benign liver lesions revealed a total of 389 patients from January 2012 to February 2016 (four years duration). All Multidetector Computed Tomography (MDCT) examinations were performed on 64 slice MDCT (Somatom 64, Seimens healthcare) or 128 slice (Somatom Definition edge, Siemens healthcare) helical scanners. All studies were carried out in craniocaudal direction with patient supine with average 120 KV and 250-450 mA, values varying depending on patients build. Unenhanced images were obtained followed by administration of IV contrast (Iopromide 350-370 mg/mL), power injector was used for injection of contrast at a rate of 4 mL/sec. Automated bolus tracking was used. Images were obtained in arterial, venous and delayed phases, typically at 18-28 seconds, 55-65 seconds and 300 seconds after initiation of contrast administration.

Hypervascular tumours on arterial phase were studied; thus, all hypo or avascular lesions were excluded. Hypodense lesions with thin peripheral enhancement, the pattern which is most common in metastatic lesions, were also excluded. The other exclusion criteria were: i) HCCs without histopathology and not meeting the criteria mentioned below in confirmation of tumor subtype, ii) Diffusely infiltrative HCCs as enhancement pattern and washout characteristics are difficult to assess in them, iii) HCCs with changes related to treatments like thermal ablation or transarterial chemoembolisation, iv) Non HCCs without definitive histological diagnosis, v) Very small tumours less than one cm in size as placing ROI for measurements is difficult in them, vi) Benign lesions like hemangiomas, abscess and cysts were also excluded as they show fairly typical enhancement patterns and in most no histopathological confirmation is done. Histopathological confirmation was available for all non HCCs and HCC (35 cases). 53 HCCs, all in at risk population having underlying cirrhosis were diagnosed based on AASLD guidelines (2010) and LI-RADS (version 2014). First AASLD criteria was applied (a lesion of more than 2 cm showing arterial phase hyperenhancement and subsequent washout, in presence of cirrhosis and elevated AFP levels, we used AFP cutoff of >400 IU/mL to enhance specificity), tumours meeting these criteria are virtually diagnostic of HCC [13]. All of these 53 cases were LI-RADS 5 category (indicating 100% certainty of HCC), with 34 cases being LR-5, 17 cases LR-5V with macrovascular invasion and two cases being LR-5us (being 1-2 cm in size and being visible as discrete nodules on ultrasound) [14]. Two HCCs were histological variants, one a fibrolamellar HCC and another cholangiocellular variant. After application of exclusion and inclusion criteria we arrived at a study population of 120 patients (86 males and 34 females) mean age 58.5 years, range (3-78 years). There were 88 (73%) HCCs, 12 (10%) mass forming cholangiocarcinomas, 15 (12.5%) metastasis, 3 (2%) adenomas, 1 (0.08%) hepatoblastoma and 1 (0.08%) angiosarcoma [Table/Fig-1]. For purpose of comparability the tumours were divided in two broad groups of HCC and non HCC.



[Table/Fig-1]: Distribution of tumours.

A subjective or qualitative assessment was performed by two radiologists; having nine and five years of experience in abdominal imaging. After confirming the hypervascular nature of the tumour on the arterial phase assessment of subjective washout was done and presence or absence of washout on venous or delayed phases was noted. Presence of any delayed hyperenhancing central stroma was also noted. The examining radiologists were blinded to the results of histopathology and final diagnosis. Discrepancies if any were settled by consensus.

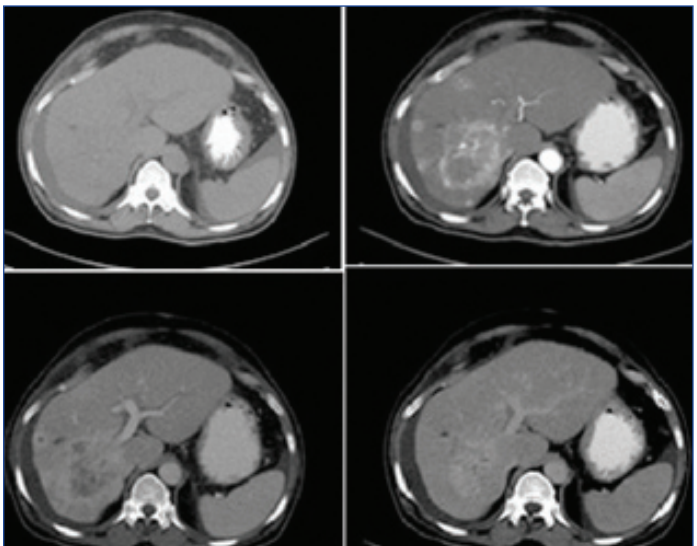
The quantitative analysis was done by one radiologist. The attenuation were measured in HU by drawing circular or oval ROI over the lesion. The ROIs were drawn to include maximally enhancing areas on arterial phase and ranged from 10 to 20 mm with similar ROI drawn on corresponding venous and delayed phase images. The necrotic areas of the tumour, major intratumoral feeding vessels or intratumoral arterioportal shunts were excluded [Table/Fig-2]. In case of large tumours with variable areas of enhancement, multiple ROIs were drawn in the enhancing regions of the tumour and averaged. Two ROIs were also obtained in the adjacent normal background liver in all the phases, taking care to avoid blood vessels. In case of multiple lesions, largest lesion was selected.

The following quantitative indices were calculated 1) Mean attenuation(MA) of lesions in different phases 2) Attenuation gain

[Table/Fig-2]: Hepatocellular carcinoma in caudate lobe with an eccentric necrotic component, ROI placement was done in the enhancing tumour component .

percentage on arterial phase (AGP): SOL a-BL a / BL a x100), Arterial phase attenuation change (AAC): SOL a –BL a (these indices assess the arterial enhancement of the lesions). 3) Attenuation loss percentage in venous and delayed phases (ALP-V, ALP-D): BL v/d-SOL v/d/ BL v/d x100; Percentage attenuation ratio in venous and delayed phases (PAR-V, PAR-D): 100x BL v/d/SOL v/d; Relative wash out ratio (RWR A-V, RWR A-D) from arterial to venous and delayed phases: 100x (SOL a-SOL v/d)/SOL a and from venous to delayed phases(RWR V-D): 100 x (SOLv-SOL d)/ SOL v.(these variables define the washout characteristics). (SOL a and BL a were attenuation of space occupying lesion and background liver attenuation on arterial phase respectively, SOL v/d and BL v/d were lesion and background liver attenuation on venous and delayed phases).

STATISTICAL ANALYSIS



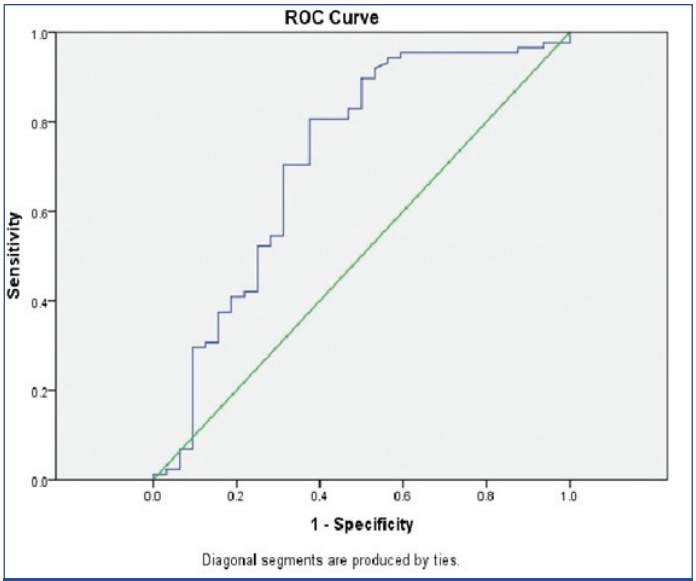
Statistical analysis was performed using IBM SPSS Statistics for Windows, version 20.0 (IBM Corp., Armonk, N.Y., USA). Sensitivity and specificity for washout appearance were calculated. For quantitative variables comparative analysis between HCCs and non HCCs was done using Student's t-test. ANOVA analysis was used for comparison between HCC and individual categories in Non HCC (cholangiocarcinomas, metastasis and others). ROC curves were drawn for values that were significantly different to establish a cutoff value.

RESULTS

The demographic and qualitative characteristics of the HCC and non HCC are as in [Table/Fig-3]. On qualitative analysis all HCCs showed homogenous or patchy enhancement on arterial phase. There was excellent interobserver agreement between the two radiologists for hypervascularity (Kappa value of 0.91) and presence of washout (Kappa value of 0.86) and discrepancies if any, were settled by consensus. Washout was noted on venous phase in 62/88 (69.3%) patients while on delayed phase additional 19 patients showed washout (81/88,92%). Overall 92% HCCs demonstrated washout in either venous or delayed phase. There was lack of subjective washout as perceived by both radiologists in 7/88 (8%) tumours [Table/Fig-4]. Of these however, two tumours did demonstrate a difference in quantitative washout if absolute values of HU obtained from ROI between the lesion and background liver were considered (though the difference was less than 10 HU). In addition in 8 (9%) tumours the washout was perceived as subtle and required either extensive window setting adjustments (in five cases) or settlement by consensus (three cases). The confounding factors encountered affecting visual assessment were presence of 1) steatosis in the background liver with lesion appearing hyperdense relative to the surrounding fatty liver in two cases, 2) presence of enhancing peripheral pseudocapusle in five cases and a delayed enhancing central fibrous stroma (noted in one case of fibrolamellar HCC). The metastases were the commonest non HCC lesion. Most of the hypervascular metastases were from adenocarcinomas with known or unknown primary sites. A qualitative washout appearance similar to HCC was noted in three cases (20%). Amongst the carcinoid metastasis or neuroendocrine tumours in present study sparing one which washed out the other two were hyper or isodense to parenchyma. Both cases of sarcoma metastasis (n=2) had peripheral enhancement, while washout was seen in one, the other was seen filling in from periphery to the centre. Thus, most of metastatic lesions showed no washout in the venous or delayed phase except one case of transitional cell carcinoma, one of neuroendocrine tumour and one sarcoma. Most of the adenocarcinoma metastases were isodense to parenchyma on delayed phase. The metastasis from gastrointestinal stromal tumour had peripheral fill in pattern.

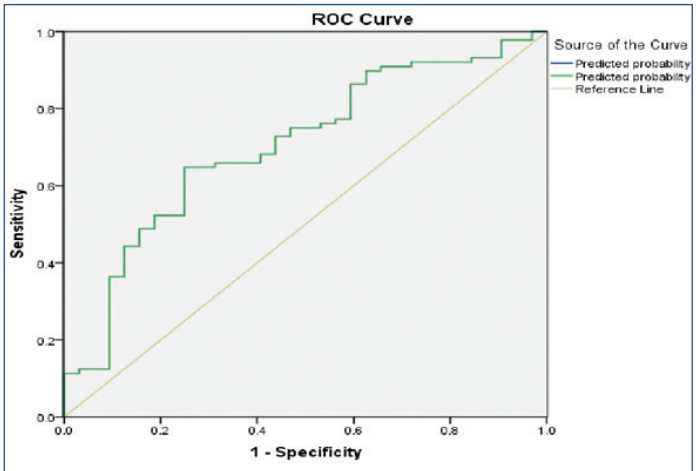
	HCC	Non HCC	p-value
Females	21	13	0.107
Mean age (years)	63.8	54.03	0.000
Size <3 cm	18 (20.45%)	3 (9.37%)	0.1868
Mean size (cm)	6.55±4.17	7.00±3.7	0.5916
Washout present (%)	81 (92%)	7 (21.8%)	0.001

[Table/Fig-3]: Demographic and qualitative parameters of HCC and Non HCC. The difference is significant at p<0.05
HCC*- Hepatocellular carcinoma



[Table/Fig-4]: Histopathologically proven hepatocelluar carcinoma, multinodular in alcohol related cirrhosis, showing progressive enhancement pattern with lack of subjective or quantitative washout.

Amongst cholangiocarcinomas, none demonstrated washout on delayed phase, all the lesions appeared isodense, hyperdense or showed central enhancing stroma in the delayed phase. The true HCC mimics on qualitative analysis were the three cases of hepatic adenomas and one case of hepatoblastoma which had an enhancement and washout appearance similar to HCC. The only case of angiosarcoma showed hyperdense appearance on delayed phase. Thus, hepatic adenomas, few hypervascular non adenocarcinoma metastasis and hepatoblastoma showed washout appearance in venous or delayed phase; thus, mimicking HCC. The overall sensitivity of the qualitative washout appearance for predicting HCC was 92% while specificity was 78%.



The difference between the mean attenuation of the HCCs and non HCCs was significant in noncontrast (p-value 0.01), arterial (p-value 0.002) and delayed phases (p-value 0.013), while the difference was not significant in the venous phase (p-value 0.614). The quantitative indices are as listed in [Table/Fig-5]. There was no significant difference between the two groups in attenuation change in arterial phase (AAC), while AGP was significant (p-value 0.018). Of the washout parameters, in venous phase significant difference (p-value 0.002) was found in PAR-V in venous phases with no significant difference seen between the two groups in PAR-D. The washout parameters assessed were relative washout from arterial to venous or delayed phase (RWR A-V, A-D) and from venous to delayed phase (RWR-V-D). The relative washout from arterial to venous or delayed phases was (RWR A-V,A-D) was found to be significant (p-value 0.022, 0.004). Washout from venous to delayed phase (RWR-V-D) was also significant between the two groups (p-value 0.000). ALP-V that is attenuation loss percentage in venous phase was also significant (p-value 0.001). However, area under curve was significant for RWR V-D and PAR-V only (r-value >0.7) and analysis of ROC curves for PAR-V and RWR-V-D revealed good sensitivity and specificity for detection of HCC [Table/Fig-6,7].

	HCC (Mean)	Non HCC (Mean)	p-value
MA-NCCT	66.31	52.71	0.01
MA-Arterial	105.96	89.8	0.002
MA-Venous	89.34	91.73	0.614
MA-Delayed	51.75	63.09	0.013
AAC	13.5	2.46	0.070
AGP	27.9	7.17	0.018
PAR-V	116.29	101.89	0.002
PAR-D	117.33	116.09	0.810
RWR A-V	9.3	-6.6	0.022
RWR A-D	45.05	25.6	0.004
RWR V-D	43.27	31.38	<0.001
ALP-V	10.83	-1.16	0.001
ALP-D	12.01	9.73	0.487

[Table/Fig-5]: Details of quantitative variables assessed.
MA-NCCT*-Mean Attenuation Non Contrast CT
AAC*- Arterial phase attenuation change, AGP*- Attenuation gain percentage, PAR-V*- Percentage attenuation ratio-venous phase, PAR-D*- Percentage attenuation ratio-delayed phase, RWR A-V*- Relative washout ratios arterial-ratio, RWR A-D*- Relative washout ratios arterial-delayed, RWR V-D*- Relative washout ratios venous-phase, PLP-V*- Attenuation loss percentage-venous phase, ALP-D*- Attenuation loss percentage-delayed phase

[Table/Fig-6]: Receiver operating curve (ROC) for RWR-V-D, area under curve >0.7

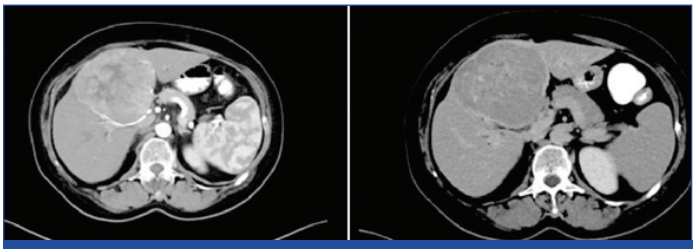
[Table/Fig-7]: Receiver operating curve (ROC) for PAR-V, area under curve >0.7

On individual comparison of HCC with metastasis, cholangiocarcinoma and others category, significant difference was seen between RWR V-D of HCC (mean 43.27) when compared to cholangiocarcinomas (mean 31.2, p value 0.035) and metastasis (mean 33.63, p value 0.026).

DISCUSSION

Studies show that combination of arterial hypervascularity and washout appearance of HCC on MDCT offers a specificity approaching 100% for HCC >20 mm in at risk populations. According to the AASLD guidelines (2010) a lesion of more than 10 mm showing arterial phase hyperenhancement and subsequent washout, in presence of cirrhosis can be considered as HCC and treated as such. Similar guidelines have been proposed by European Association for the Study of the Liver (EASL) in 2012 [13-15]. More recently LIRADS (2014) has been developed for categorising liver lesions in at risk population; this classification aims to facilitate clear communication between different personnel involved in care of these patients. The lesions falling in LR-5 category are nearly certain to be HCCs and consists of hypervascular lesions of more than 2 cm with one or more combinations of washout, capsule, threshold growth. In addition macrovascular mainly portal vein invasion constitutes LR-5V category [14].

A comprehensive quantitative analysis may help in providing further parameters that assists differentiation between HCC and non HCC. A quantitative assessment may also reduce interobserver variability and lay foundation for development of diagnostic algorithms and computed aided detection parameters. To the best of our knowledge, this is also the first study of this kind in India with no previous Indian cohort of hypervascular liver tumours having being subjected to this kind of qualitative and quantitative assessment.



HCCs showed uniform or nonuniform enhancement with most showing washout appearance. The overall sensitivity of the qualitative washout appearance for predicting HCC was 92% while specificity was 78%. The venous phase washout was seen in 69.3% patients while in delayed phase this number increased to 92%. About 8% of HCC did not washout at all while another 9% had a subtle washout. Latter could be resolved subjectively itself and washout even though subtle could be resolved qualitatively with a consensus agreement of two experienced radiologists. Thus, a qualitative washout assessment in a tertiary level setup with high volumes and experienced radiological staff does hold an excellent sensitivity and a reasonable specificity for HCC detection. The specificity may approach 100% if additionally presence of imaging features of cirrhosis is taken into account since none of the non HCCs had underlying cirrhosis. The overall sensitivity of the qualitative washout appearance for predicting HCC was 92% while specificity was 78%.

On quantitative evaluation there was significant difference in the attenuation between the two groups on noncontrast, arterial and delayed phases. Of the arterial parameters the AAC was found to be significantly different between the HCCs and non HCCs. However, when comparing the HCCs with individual subgroups of non HCCs the significance could not be elicited. The AGP was found to be significantly different between the two groups however, it merely represents arterial hypervascularity and doesn't quantitate washout. The PAR as suggested by Liu Y et al., is a measurement of washout appearance of HCC, measured as a ratio of liver and lesion attenuation [2]. The values for PAR in venous phase showed significant difference between the HCC and non HCC while in delayed phase the difference was not statistically significant. The mean PAR-V of HCC was higher than Non HCC. The absence of difference of PAR in delayed phase is probably because there were lesions like adenoma and certain metastases that washed out significantly more than HCC from venous to delayed phase as compared to HCC resulting in almost similar values of PAR-D. A cutoff of PAR-V of 106 provided 70% sensitivity in diagnosing HCC. Relative Washout Ratio (RWR) from arterial to delayed and venous phase was significantly different between the two groups but seems irrelevant as many of the values were negative, since maximum enhancement was obtained in venous phase in many tumours. Considering the fact that attenuation of the lesion was maximum in

venous phase, the calculated RWR from venous to delayed phase (RWR-V-D) showed that the HCC washout significantly more than non HCC and this temporal parameter of washout from venous to delayed phase seems more relevant than ascertaining washout from arterial to venous or arterial to delayed phase. As discussed earlier the washout phenomena is an appearance based on a lot of factors and RWR from venous to delayed phase seems to be one of the parameters that may differentiate the HCC and non HCC negating the effect of liver parenchymal attenuation. It is likely that gradient of loss of attenuation of lesion from venous to delayed phase is much more significant. The mean values of RWR-V-D of HCC (43.27) and non HCC (31.38) were significantly different and a cutoff of 41.79 offered a sensitivity of 75%.

When comparing individual groups there was a significant difference between the mean RWR-V-D values of HCC (mean 43.27) versus hypervascular IMCC (mean 31.2) and metastasis (mean 33.63). Loyer EM et al., compared the kinetics of HCC versus IMCC and found that HCC loose enhancement from venous to delayed phase while IMCC gain enhancement from the corresponding phases, however they included all cases of cholangiocarcinomas and not just the hypervascular variants [16]. Liu Y et al., used PAR ratio as a simple tool to measure the washout appearance [2]. In present study it is apparent that there are some arterial phase enhancing mimics showing the washout appearance complicating the oversimplified guidelines. We also had a much larger study population. In present study PAR-V was significant offering good sensitivity and specificity. This is in contradistinction to the study by Liu Y et al., which found PAR-D to be significant [2]. RWR-V-D was also significantly different between two groups and this gradient may actually help in cases that are not so straight forward.

In present study we found some true HCC mimics; however, which have similar qualitative appearance and quantitative indices like HCC, something which has not been highlighted in the other studies. These mimics were hepatocellular adenomas, hepatoblastoma and certain hypervascular metastasis [Table/Fig-8]. Hypervascular liver metastases from neuroendocrine tumours mimicking hepatocellular carcinoma in enhancement and washout pattern has been described in literature [16,17]. These mimics should be considered as differentials for HCC arising in noncirrhotic liver. The value of quantitative indices also appears to be doubtful for these mimics and appeared to be similar in both subgroups. Although, proving this statistically was difficult in present study due to the small sample size of the mimics. Thus, while a qualitative assessment combined with some useful quantitative parameters, can provide a noninvasive image based diagnosis in majority of cases in the settings of cirrhosis, the same may not hold true for HCC in noncirrhotic livers. A thorough clinicoradiological assessment can however, point to correct diagnosis with hepatocellular adenoma having distinct age group and predispositions, hepatoblastoma usually arising in pediatric age groups and metastatic lesions usually being accompanied by their primary known tumours, though biopsy may be needed for confirmation. Nevertheless a thorough qualitative assessment combined with assessment of certain useful quantitative indices mentioned above, can permit confident noninvasive image based diagnosis for a majority of HCCs in most radiological setup.

[Table/Fig-8]: Neuroendocrine tumour metastatic to liver, showing arterial phase enhancement and delayed phase washout, a pattern indistinguishable from HCC.

LIMITATION

There were some limitations of present study, firstly the lack of histopathology for all HCCs and the use of AASLD guidelines and LIRADS classification with AFP levels for identifying the same (partly because obtaining a biopsy is now almost unethical in patients with cirrhosis meeting the classic imaging diagnostic criteria), but we were stringent in including patients with image based diagnosis, only cirrhotic patients with AFP of more than 400 IU/mL with washout were included. The incidence of cholangiocarcinomas which is known to be the most common mimic would be very low in this group and is unlikely to alter the results. The other limitations included, HCCs less than 1 cm which were not included in our data set. Thus, their behavior was not assessed, heterogeneity within the non HCC group and the sample size of the non HCC group was small compared to HCC. Retrospective nature of analysis also limits the evaluation.

CONCLUSION

While there are number of guidelines which include the more popular likes of AASLD and LI-RADS for diagnosis of HCCs and categorising liver lesions; yet, most of these continue to be subjective in nature with lack of quantification of hypervascularity or washout. A quantitative analysis defining the washout is useful additional determinant adding objectivity to image based diagnosis. Quantitative variables like PAR-V (threshold value 106), RWR-V-D (threshold of 41.79) complement the qualitative analysis, for diagnosis of HCC and have future implications like incorporation into guidelines and development of diagnostic algorithms for computed aided detection software packages.

Abstract:

Background: Variceal bleed the major cause of mortality in cirrhosis. Upper gastrointestinal (GI) endoscopy remains the main stay of diagnosis and treatment in variceal bleed. Splenic elastography using Acoustic Radiation Force Impulse (ARFI) technique can be used to non-invasively predict presence and severity of esophageal varices.

Material and methods: It is a hospital based prospective case control study, done in 100 patients with chronic liver parenchymal disease, who had undergone upper GI endoscopy. Fifty consecutive patients with esophageal varies and 50 consecutive patients without esophageal varices were included in the study and subjected to splenic ARFI. Data was analyzed with SPSS version 20.0 software using chi-square test or Fischer exact test, independent sample-t test. The receiver operating characteristics (ROC) curve was plotted and the area under the curve was used to determine the cut off points for statistically significant variables.

Results: Spleen ARFI showed significant correlation between cirrhotics with esophageal varices and without varices groups. The cut off of ≥ 3.16 m/s (AUROC: 0.906) precisely detects varices with sensitivity of 94% and specificity of 92%. Spleen ARFI also correlates with severity of varices. Cut off of ≥ 3.29 m/s (AUROC: 0.874) can confidentially differentiate low grade from high grade varices in cirrhotics with sensitivity of 85% and specificity of 100%.

Conclusions: Amongst the noninvasive parameters analyzed in this study, spleenic ARFI exclusively showed highest sensitivity and specificity in the detection of varices and differentiation of high grade varices from low grade varices.

Key words: Splenic ARFI, cirrhosis, Endoscopy, Esophageal varices.

Introduction:

Diverse insults on the liver lead to a common endpoint as cirrhosis. Cirrhosis is pathologically characterized by extensive fibrosis, regenerative nodules and distortion of hepatic parenchymal architecture [1]. Alcoholism and viral hepatitis have been the most common etiologies leading to cirrhosis, however nonalcoholic fatty liver disease is emerging as an important underlying pathology.

Complications of cirrhosis can be categorized as portal hypertension related and portal hypertension unrelated complications. Most common portal hypertension related complications is development of esophageal varices and variceal bleeding [2]. Till date, invasive upper gastrointestinal endoscopy (UGI scopy) remains the mainstay

www.ijbamr.com P ISSN: 2250-284X , E ISSN : 2250-2858

for the detection and grading of esophageal varices [3]. In addition to diagnostic advantage, UGI scopy plays a major role in treatment such as band ligation and sclerotherapy. Despite its diagnostic and therapeutic utility, UGI scopy is an invasive procedure, has its inherent complications such as bleeding, perforation, infection and cardio-respiratory complications related to sedation [4].

With current advances in the field of Ultrasonography, estimation of elasticity of the tissue has been made possible with Elastography. It is analogous to manual palpation and in fact offers better information, based on the principle that pathology changes the stiffness of the tissue. Shear Wave Elastography (SWE) is a technique of elastography that uses "shear wave" generated within tissue secondary to the acoustic push, the so called Acoustic Radiation Force Impulse (ARFI). In this technique as no external compression is required and a push impulse can be directed anywhere, it is possible to attain a fine elastogram of entire organ. Additionally, quantification of elasticity of particular region of interest based on shear wave velocity (SWV) is possible [5].

Elasticity of the spleen will be decreased in cirrhosis due to portal venous congestion and hyperplasia of splenic tissue; hence the splenic stiffness will be increased. Portal venous congestion results in esophageal varices. Screening UGI scopy is recommended in all cirrhotic patients in accordance with recent guidelines as primary prophylaxis against variceal hemorrhage[6]. Implementing these guidelines is confronted with cost, complications and invasiveness of UGI scopy. Hence, it necessitates accurate and noninvasive methods for detecting and grading the severity of esophageal varices.

Aim:

To evaluate splenic ARFI as a noninvasive tool for detection of esophageal varices and grading of varices as to high and low grades in chronic liver parenchymal disease.

Materials and methods:

It is a prospective case control study done on 100 patients over a period of 14 months, who were referred to the department of radiology with a diagnosis of chronic liver parenchymal disease. Subsequently all these patients underwent UGI scopy and were divided into two groups. Consecutive 50 patients without esophageal varices comprised the first group and 50 patients with esophageal varices comprised second group. Study was undertaken after obtaining necessary clearance from the institutional human ethics committee. Patients who are of less than 18 years of age and who did not undergo UGI scopy were excluded from the study. All the patients were subjected to splenic ARFI and UGI scopy.

Splenic ARFI protocol:

Splenic ARFI was performed with Siemens Acuson S2000^{TM} / Siemens Acuson S3000 ^{TM} ultrasound systems with ARFI enabled 6C1 / 4C1 curvilinear transducers. Patient was made to lie in right lateral decubitus position and assessment was done by intercostal approach. In order to cover uniformly the spleen, we adopted the stratified random sampling method used in the previous studies [7] (Figure 1). Spleen will be subdivided into cranial external(1), cranial central(2), cranial internal(1), intermediate external(1), intermediate central(1), intermediate internal(1), caudal external(1), caudal central(1) and caudal internal(1) segments. Numbers in the parenthesis represents the number of ARFI values obtained in each segment. In breath hold position, region of interest measuring 10mm in depth and 5mm in width was placed in parenchyma devoid of visible blood vessels and >1 cm below the level of spleen capsule and ARFI evaluation was done (Figure 2). Total of 10 successful measurements were obtained for each patient. Mean ARFI values were automatically calculated and expressed

www.ijbamr.com P ISSN: 2250-284X , E ISSN : 2250-2858

in meters per second (m/s).

The data obtained was coded and entered in Microsoft Excel Spreadsheet. Data was analyzed using SPSS version 20.0 statistical software. Categorical variables were expressed as percentages and the comparative analysis was done using chisquare test or Fischer exact test. Continuous variables were expressed as mean ±standard deviation (SD) and the comparative analysis was done by independentsample 't' test. The receiver operating characteristics (ROC) curve was plotted and the area under the curve was determined to the cut off points for statistically significant variables. A probability value (p value) of less than or equal to 0.05 at 95% confidence interval was considered as statistically significant.

Various radilogical parameters like liver size, portal vein diamater, portal vein flow velocity, spleen size, liver ARFI and splenic ARFI were analysed for their value as predictors of presence or absence of esophageal varices, if present, to differentiate high grade varices from low grade varices using various statistical methods as mentioned above.

Discussion:

Recent guidelines endorse that endoscopic screening should be done for all cirrhotic patients at the time of diagnosis to recognize those at high risk of bleeding and possibly to benefit from primary prophylaxis [6]. Implementation of these guidelines imposes huge burden on UGI scopy units and frequent testing over time can decrease the compliance of patient. By noninvasive prediction of the presence of EVs, one can recommend the appropriate category of patients to undergo invasive UGI scopy, thereby reducing unnecessary endoscopic examinations and burden on endoscopy units.

Previous studies have correlated various radiological and laboratory parameters either alone or in combination with the presence or absence of EVs in cirrhotics. Although, the efficiency of parameters or combination of parameters reported in each study differ amongst them, due to the heterogeneous nature of the studies. Good predictive value of several non-endoscopic variables for the presence or absence of EVs have been documented

www.ijbamr.com P ISSN: 2250-284X , E ISSN : 2250-2858

by many previous studies, but the data is limited from our part of the country. This study was performed to assess the effectiveness of various clinical, laboratory and radiological parameters, in reliably detecting the existence of EVs and high grade EVs in cirrhotic patients.

In the present study, there is no significant association of demographic parameters between the two study groups. Previous studies by Zaman et al [8] and Cherian et al [9], showed that Child Pugh class B or C cirrhotic patients, as compared to class A cirrhotics, have high propensity towards the detection of EVs on UGI scopy. In contrary, our study inferred no significant association between Child Pugh class and the presence of EVs (p = 0.799). In addition, we assessed MELD scores and found significant affiliation with presence of EVs, in congruence to the results of previous studies by De Mattos et al [10] , Tafarel et al [11] and Chandail VS et al [12].

Our study showed no significant variation in either portal vein diameter or portal vein flow velocity between cirrhotic patients with EVs and without EVs. Our study in contradiction to previous studies inferred that there is no significant difference in liver stiffness measured by elastography between cirrhotics with EVs and cirrhotics without EVs (p= 0.458).

In agreement with previous studies, our study also showed significant difference in the values of spleen stiffness measured by ARFI between cirrhotics with EVs and without EVs (p= 0.000). We acquired the optimal cutoff of ≥ 3.16m/s (AUROC: 0.906) with sensitivity of 94% and specificity of 92%, thereby validating spleen ARFI as a non-invasive radiological marker for the presence of EVs in cirrhotics.

In the present study, we furthermore evaluated the utility of the above discussed noninvasive clinical, laboratory and radiological parameters in the detection of high grade EVs in cirrhotics. Of all the noninvasive parameters analyzed, spleen ARFI exclusively showed significant difference between the two subgroups (p= 0.001). We derived the optimal cutoff of ≥ 3.29m/s (AUROC: 0.874) with sensitivity of 85% and specificity of 100%, which is in very close approximation with spleen ARFI cutoff of ≥ 3.30m/s obtained by Takuma et al[13]. Thereby substantiating spleen ARFI as a non-invasive radiological marker for the presence of high grade EVs in cirrhotics. In other words, the presence of high grade EVs can be reliably ruled out with the spleen ARFI cutoff of < 3.29m/s in patients with chronic liver parenchymal disease. Our study was limited by only few patients with grade IV EVs being included in this study. It is due to the lower prevalence of grade IV EVs, as in part by the practice of generous prophylactic and therapeutic measures which delays or eliminates progression of low grade EVs to high grade EVs. Inter observer variability is not assessed in this study. Future studies on this context should focus on multicenter design with evaluation of equipment of various manufacturers and assessment of inter observer variability.

Conclusions:

Amongst the noninvasive parameters analyzed in this study, spleenic ARFI exclusively showed highest sensitivity and specificity in the detection of varices and differentiation of high grade varices from low grade varices.

Department of Radiology, PSG Institute of Medical Sciences and Research, Coimbatore, Tamil Nadu, India

Abstract

Background: The purpose of this study was to evaluate the usefulness of strain elastography and acoustic radiation force impulse (ARFI) imaging in the differentiation of benign and malignant cervical lymph nodes (LNs). **Materials and Methods:** In this prospective study, 50 enlarged cervical LNs (33 benign and 17 malignant) were examined by B-mode ultrasound (US), color Doppler, and strain elastography. Elastographic patterns (1–5) were categorized based on distribution of hard area within LN. The shear wave velocity (SWV) of LNs was evaluated by ARFI imaging. Diagnostic performance of sonoelastographic parameters was compared taking histopathology of LN as a reference standard. Optimal cutoff value of the mean SWV values for predicting malignancy was determined using receiver operating characteristic curve analysis. **Results:** Among US parameters, borders of LN had the highest diagnostic accuracy (80%), while echogenicity had the least (48%). Majority of benign LNs ($n = 31$) had elastography patterns 1 and 2, while majority of malignant LNs ($n = 16$) had patterns 3–5 ($P = 0.000$). The sensitivity, specificity, and accuracy of elastography were 94.1%, 93.9%, and 94%, respectively. The mean SWV of benign LNs (1.670 ± 0.367 m/s) differed significantly from malignant LNs (2.965 ± 0.826 m/s; $P = 0.000$). A cutoff value of 2.05 m/s predicted malignancy with 88.2% sensitivity and 84.8% specificity and gave an area under the curve of 0.949 (95% confidence interval: 0.70–1.20). **Conclusion:** Elastography has high diagnostic accuracy in differentiating benign and malignant cervical LNs and can be potentially useful in selecting the LN with high probability of malignancy, on which fine-needle aspiration cytology/biopsy can be performed.

Keywords: Acoustic radiation force impulse imaging, elastography, lymph nodes, ultrasound

Introduction

Cervical lymphadenopathy, a common condition encountered by physicians in clinical practice, could be caused by a variety of pathologic processes such as infections, vasculitis, and malignancies such as lymphoma and metastases. Metastatic cervical lymphadenopathy is a common problem in head and neck oncology. Depending on the primary site, up to 80% of patients with upper aerodigestive mucosal malignancy have been reported to have cervical nodal metastasis at presentation.[1] The differentiation of malignant from benign lymph nodes (LNs) is essential because it predicts the patient prognosis and helps in decision-making and planning of management.[2]

High-resolution ultrasound (US) is the extensively used imaging technique for evaluating the morphology and internal architecture of cervical LNs. Color Doppler sonography is used to assess the pattern of intranodal vessels, blood flow velocity, and vascular resistance.[3] Although Gray-scale sonography in combination with Doppler has been suggested to be useful in differentiating metastatic LNs from reactive ones based on various criteria, there is no single US criterion for diagnosing malignant LNs with satisfactory sensitivity and specificity.[4,5]

Real-time elastography (RTE) is a novel, noninvasive imaging modality that assesses tissue elasticity by comparing local tissue displacement from US signals before and after the application of a compressive force.[6] Stiff tissues show less deformation (strain) than soft tissues under the compression of a transducer. Since malignant tissues are stiffer than their benign counterparts at many

sites, several reports have documented the utility of US elastography in differentiating malignant from benign lesions in the breast, prostate, liver, thyroid, and cervix.[7-11] There are two types of elastography techniques, namely strain elastography and shear wave-based elastography. Recent studies have shown the usefulness of strain elastography in differential diagnosis of benign and malignant cervical LNs.[12-14] However, some authors have questioned its additional value over conventional US in predicting malignancy and decision-making in terms of selection of LNs for biopsy.[15-17] Shear wave elastography with acoustic radiation force impulse (ARFI) imaging is an emerging sonographic technique in the assessment of malignant cervical nodes.[18,19]

Data on the utility of elastography in the evaluation of cervical LNs are relatively few, especially from India. The purpose of the present study was to evaluate the utility and diagnostic performance of strain elastography compared to conventional B-mode US and color Doppler in the differentiation of benign and malignant cervical LNs. We also investigated the usefulness of ARFI imaging in differentiating benign and malignant LNs.

Materials and Methods

This prospective study was performed at a tertiary care center in South India between August 2016 and February 2018. Fifty LNs of 50 consecutive patients who were referred for ultrasonogram of enlarged cervical LNs were enrolled. The Institutional review board (IRB) approved the study protocol, and the protocol complied with the tenets of the Declaration of Helsinki (IRB Approval No. 16/334). Informed consent was obtained from all participants. Patients with suboptimal image quality and those with completely necrotic nodes without solid component were not included. Patients who had received specific treatment (chemotherapy/radiotherapy) were also excluded from the study.

High-resolution US imaging was performed in the supine position with a high-frequency linear probe 9 L4 (Siemens Accuson S3000, Siemens Healthineers, Erlangen, Germany) by a single expert radiologist, blinded to patient's clinical profile. In gray-scale US, the LNs were evaluated for short-axis diameter and short-to-long axis diameter ratio (S/L ratio) in the longitudinal plane, borders (regular or irregular), echogenicity (homogeneous/heterogeneous), and hilum (present or absent). Intranodal vascular pattern was evaluated using color Doppler imaging. Absent flow signals or blood flow limited to the hilum was categorized as benign. Nonhilar blood flow with spotted, peripheral, or mixed types of vascularization was categorized as malignant. RTE was performed for the targeted node using the same probe. Manual light compression and decompression of the target LN by the transducer were performed to achieve an optimal image. Patients were asked to hold their breath and avoid swallowing during the examination to minimize motion of LNs. The elastographic box contained the LN and adjacent sternocleidomastoid muscle for each patient. Elastograms obtained with quality factor score ≥60 were included in the study. Color map settings with red coded as hard area and blue coded as soft area were used. The images were displayed on split screen mode with US gray-scale images on the left and elastogram images on the right. The best-fit B-mode US elastogram image pairs were selected for analysis. The elasticity patterns were categorized on a 5-point scale described by Alam *et al*.[12] [Table 1]. LNs showing type 1 and 2 elastography patterns were considered benign, while those with types 3, 4, and 5 were categorized as malignant.

For ARFI imaging, the targeted LN on B-mode image was identified using a region of interest, characterized by a fixed box [Figures 1-5]. Three measurements of shear wave velocity (SWV) were performed, and the average was calculated. SWV was expressed in meter/second.

Table 1: Elastographic patterns of lymph nodes

Patterns	Description
1	Absent or very small hard area
2	Small, scattered hard areas, hard area <45% of LN
3	Hard area ≥45% of LN
4	Peripheral hard area and central soft area
5	Hard area occupying entire LN

LN: Lymph node

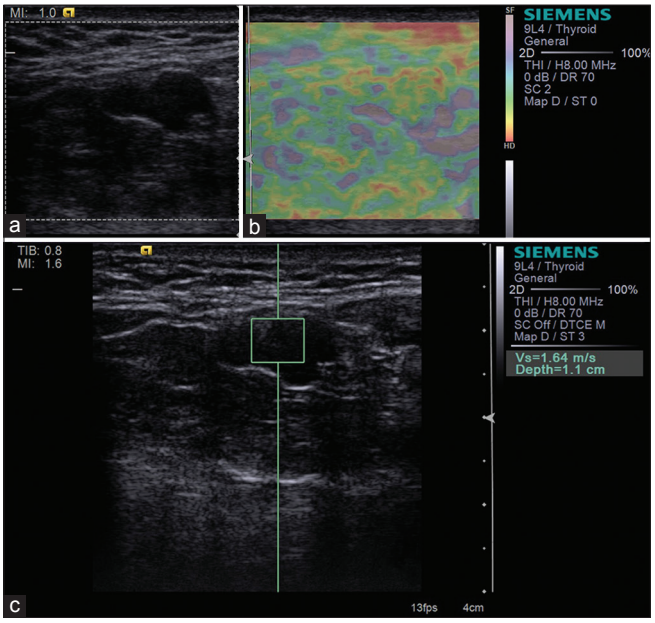

Figure 1: (a) B-mode ultrasound showing oval hypoechoic lymph node with irregular margins and absent hilum, (b) elastography image showing absent or very small hard area corresponding to pattern 1, and (c) acoustic radiation force impulse imaging shows a shear wave velocity of 1.64 m/s in the boxed area. Histopathology was suggestive of tuberculous lymphadenitis

[Downloaded free from http://www.jmuonline.org on Tuesday, December 17, 2019, IP: 10.232.74.23]

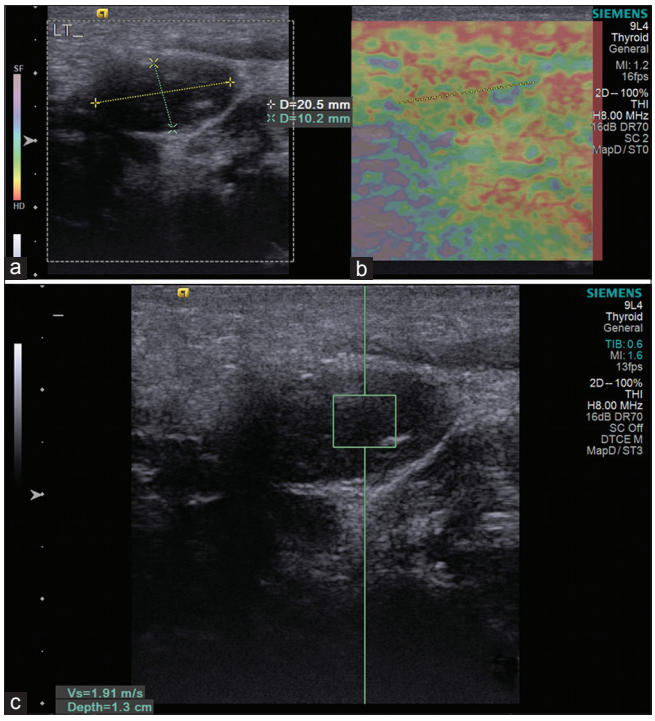

Figure 2: (a) B-mode ultrasound showing oval hypoechoic lymph node, (b) elastography image showing small, scattered hard areas corresponding to pattern 2, and (c) acoustic radiation force impulse imaging shows a shear wave velocity of 1.91 m/s in the boxed area. Histopathology was suggestive of reactive lymphadenitis

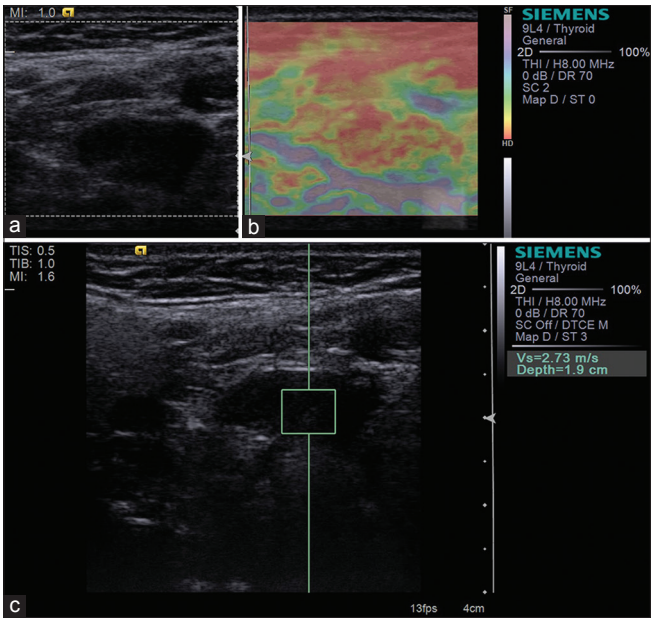

Figure 3: (a) B-mode ultrasound showing oval hypoechoic lymph node with loss of fatty hilum, (b) elastography image showing hard area ≥45% of lymph node corresponding to pattern 3, and (c) acoustic radiation force impulse imaging shows a shear wave velocity of 2.73 m/s in the boxed area. Histopathology revealed metastatic lymph node from carcinoma breast

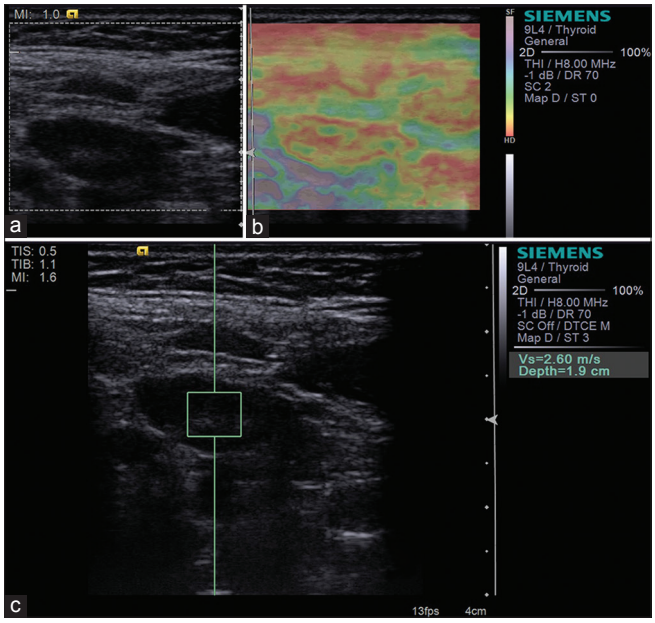

Figure 4: (a) B-mode ultrasound showing oval hypoechoic lymph node with loss of fatty hilum, (b) elastography image showing peripheral hard area and central soft area corresponding to pattern 4, and (c) acoustic radiation force impulse imaging shows a shear wave velocity of 2.60 m/s in the boxed area. Histopathology revealed metastatic lymph node from mucoepidermoid carcinoma parotid

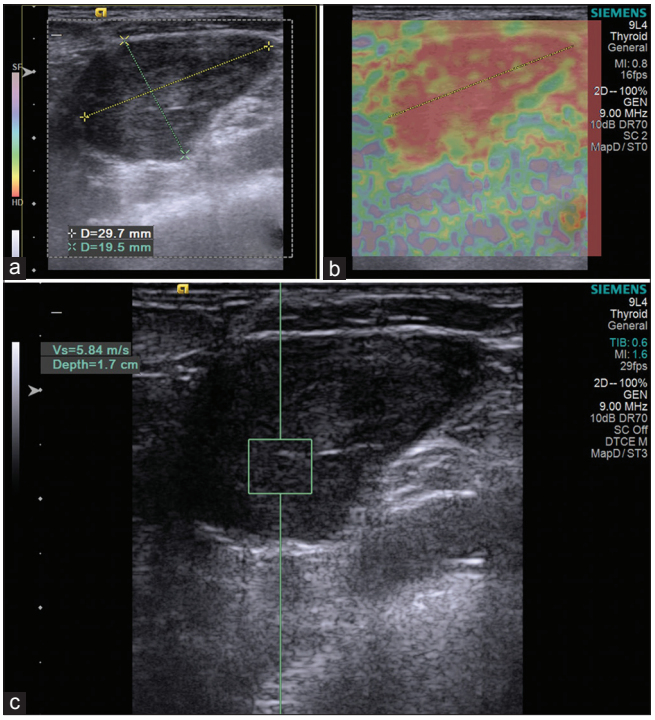

Figure 5: (a) B-mode ultrasound showing hypoechoic lymph node with irregular margins and absent hilum, (b) elastography image showing hard area occupying entire lymph node corresponding to pattern 5, and (c) acoustic radiation force impulse imaging shows a shear wave velocity of 5.84 m/s in the boxed area. Histopathology revealed metastatic lymph node from small cell carcinoma lung

Following elastography, all patients underwent surgical excision of the LN after cutaneous marking under US guidance. Histopathologic analysis of the LN was taken as the diagnostic standard of reference.

Statistical analysis

Statistical analysis was performed using the Statistical Package for Social Sciences version 24 (SPSS Inc., Chicago, IL, USA). Descriptive statistics was presented as mean ± standard deviation. Qualitative variables were presented in the form of frequency and percentages. Chi-square test was used to know the association between categorical variables. The diagnostic sensitivity, specificity, positive predictive value (PPV), negative predictive value (NPV), and accuracy were calculated with histopathologic analysis as reference standard. For analyzing the combined diagnostic performance of B-mode and Doppler, scores were assigned for five criteria: S/L ratio (ratio ≤0.5, score of 1: >0.5, 2), hilum (present, 1; absent, 2), borders (regular, 1; irregular, 2), echogenicity (homogenous, 1; heterogeneous, 2), and blood flow (hilar, 1; nonhilar, 2). The score for each LN was determined by adding the individual scores. A statistically supported cutoff line was set between scores 6 and 7. LNs with score <6 were categorized as benign, and 7–10 were categorized as malignant. Student *t*-test was performed to evaluate for significant difference in SWV values between benign and malignant LNs. A receiver operating characteristic (ROC) curve analysis was applied to obtain the optimal cutoff value for SWV to differentiate between benign and malignant LNs. Statistical significance was set at $P < 0.05$.

Results

The age of the patients ranged from 12 to 75 years (mean: 45.4 ± 16.9 years). About 52% (n = 26) were female and 48% (n = 24) were male. Of the 50 LNs examined, 33 (66%) were benign and 17 (34%) were malignant on histopathology. Of the 33 benign LNs, 27 had been reported as reactive and six as tuberculous lymphadenitis. Among the 17 malignant nodes, 15 were metastatic and two were due to lymphoma. Metastatic nodes were secondary to carcinoma lung, 4; parotid, 2; thyroid, 1; stomach, 1; breast, 1; poorly differentiated carcinoma from occult primary, 1; and head-and-neck squamous cell carcinoma, 5.

The US characteristics of the LNs and their diagnostic sensitivity, specificity, PPVs and NPV s, and accuracy are shown in Table 2. There were no significant differences between the benign and malignant LNs with respect to S/L ratio and echogenicity ($P = 0.273$ and $P = 0.623$, respectively). Hilum was found to be abnormal in all the 17 malignant LNs studied. Almost 81.8% of benign LNs (n = 27) had regular borders, whereas only 23.5% (n = 4) of malignant LNs had regular borders (P = 0.000). Among all B-mode parameters, borders of LN had the highest diagnostic accuracy (80%), while echogenicity was found to have the least accuracy (48%). On color Doppler evaluation, nearly 72% (n = 24) of benign nodes showed hilar flow compared to 35% (n = 6) of malignant nodes (P = 0.010).

Table 3 shows the correlation of elastographic pattern and histopathologic diagnosis of LNs. Majority of benign LNs (n = 31) had elastography patterns 1 and 2, while majority of malignant LNs (n = 16) had patterns 3–5. Higher elastographic pattern was significantly associated with malignant histopathology (P = 0.000).

The diagnostic performance of combined modalities (B-mode and color Doppler) and elastography is shown in Table 4.

The mean SWV of benign LNs was 1.670 ± 0.367 m/s. Metastatic LNs were significantly stiffer with mean SWV of 2.965 ± 0.826 m/s (P = 0.000). Figure 6 shows the ROC curve for SWVs measured using ARFI imaging in the differentiation of benign and malignant LNs. The best cutoff value for differentiating benign from malignant LNs was estimated to be 2.05 m/s with sensitivity of 88.2%, specificity of 84.8%, and area under the curve equal to 0.949 (95% confidence interval [CI]: 0.70–1.20).

Table 2: Ultrasound characteristics of lymph nodes and their diagnostic performance

US criteria	Benign LNs (n=33)	Malignant LNs (n=17)	Sensitivity (%)	Specificity (%)	PPV (%)	NPV (%)	Accuracy (%)
S/L ratio							
≤0.5	15 (45.4)	5 (29.4)	70.5	45.4	40	75	54
>0.5	18 (54.6)	12 (70.6)					
Hilum							
Present	22 (66.7)	0	100	66.6	60	100	78
Absent	11 (33.3)	17 (100)					
Borders							
Regular	27 (81.8)	4 (23.5)	68.4	87.1	76.4	81.8	80
Irregular	6 (18.2)	13 (76.5)					
Echogenicity							
Homogeneous	16 (48.5)	7 (41.2)	41.1	51.5	30.4	62.9	48
Heterogeneous	17 (51.5)	10 (58.8)					
Color Doppler							
Hilar	24 (72.8)	6 (35.3)	64.7	72.7	55	80	70
Nonhilar	9 (27.2)	11 (64.7)

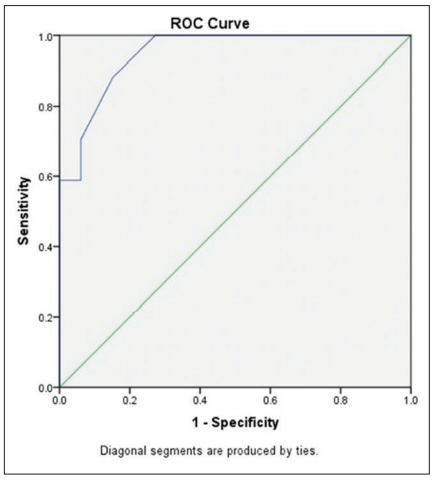

Figure 6: Receiver operating characteristic curve for shear wave velocities measured using acoustic radiation force impulse imaging in the differentiation of benign and malignant lymph nodes. The area under the curve was 0.949

Discussion

In this prospective study from India, we evaluated the performance of RTE in classification of benign and malignant cervical LNs. Our results indicate that RTE has a high specificity and diagnostic accuracy for identification of malignant LNs.

Although B-mode US is the most extensively used method for classification of cervical LNs because of its noninvasiveness and easy accessibility, specific criteria for distinguishing benign and malignant LNs are yet unclear. The association of signs often produces a highly suggestive appearance in most cases. In our study, the accuracy rate in distinguishing benign and malignant LNs was greatest for borders of LN (80%) and least for echogenicity (48%).

There were no significant differences between the benign and malignant LNs with respect to S/L ratio in our study. In contrast, several studies have noted S/L ratio >0.5 or a rounded shape to be associated with malignancy.[12,20] However, shape of LN can be misleading as nodes in nonmalignant conditions such as tuberculosis and Rosai–Dorfman disease have also been described as round.[21]

Our criterion of regular versus irregular borders revealed a diagnostic accuracy of 80%. Some other studies have categorized the LN borders as sharp and unsharp.[22,23] In a study by Khanna *et al*. from India, irregular margins were found in 7% of reactive LNs versus 55% of metastatic and 66% of tubercular nodes.[24] The absence of visible hilum due to replacement or effacement is considered as an important criterion for malignant LNs and has been reported by several authors.[12,13,25] In our study, all the 17 malignant LNs had no visible hilum, thus showing 100% sensitivity and NPV.

We observed a statistically significant difference in the vascular patterns between benign and malignant LNs ($P = 0.010$). Our observations can be comparable to that of Misra *et al*. and several other authors who have noted significant difference in vascularity between benign and malignant LNs.[13,26] In our study, the accuracy of vascularity of LN in predicting malignancy was 70%.

Table 3: Correlation of elastographic pattern and histopathologic diagnosis of lymph nodes

Elastogram pattern	Benign ($n=33$)	Malignant ($n=17$)	Total ($n=50$)
1	5	0	5
2	26	1	27
3	1	2	3
4	1	4	5
5	0	10	10

Table 4: Diagnostic performance of elastography and combined evaluation (B-mode and color Doppler)

Performance measure	Elastography	Combined B-mode and Doppler
Sensitivity (%)	94.1	94.1
Specificity (%)	93.9	81.2
PPV (%)	88.9	72.7
NPV (%)	96.9	96.4
Accuracy (%)	94	86

PPV: Positive predictive value, NPV: Negative predictive value

Even though combined B-mode US and Doppler could be potentially useful in differentiating reactive from malignant LNs, this modality may not have definite diagnostic value because of some overlapping sonographic appearances of benign and malignant nodes. Fine-needle aspiration cytology (FNAC) in the evaluation of cervical LNs has been reported to have a sensitivity of 82% and specificity of 97%.[27] However, FNAC is invasive and does not always provide a conclusive diagnostic result. Core needle biopsy from cervical LNs is also difficult owing to their relatively small size and potential injury to adjacent vascular structures.

RTE being noninvasive, has been suggested to be an adjunctive imaging tool to conventional US and could potentially reduce unnecessary biopsies.[28] Few prospective and retrospective studies concerning strain elastography of cervical LNs have been published in the literature.[29] While some have performed the measurement of elasticity scores (ES), some have measured both ES and strain ratio.

In our study, we used a 5-point scale described by Alam *et al*. to categorize the elasticity patterns. Accordingly, LNs showing types 1 and 2 elastography pattern were considered benign, while those with types 3, 4, and 5 were categorized as malignant. Nearly, 93.9% of benign LNs ($n = 31$) had a score of 1 or 2, while 94.1% of malignant LNs ($n = 16$) had a score of 3–5. The sensitivity, specificity, and accuracy of elastography were 94.1%, 93.9%, and 94%, respectively.

[Downloaded free from http://www.jmuonline.org on Tuesday, December 17, 2019, IP: 10.232.74.23]

Alam *et al*. evaluated 85 cervical LNs (53 metastatic and 32 reactive) using 5-point elasticity scale and documented 83% sensitivity, 100% specificity, and 89% accuracy in differentiating metastatic from reactive LNs.[12] Bhatia *et al*. evaluated 74 cervical LNs (37 malignant and 37 benign) using RTE.[17] Dynamic cine loops of elasticity imaging were qualitatively scored on a 4-point elasticity scale by three independent observers. Median ES for benign and malignant nodes was 2 and 3, respectively. A cutoff ES score of ≥2 achieved only 62.2% sensitivity, 83.8% specificity, and 73% accuracy for malignancy. Fair to good interobserver agreement was noted in their study.

Higher accuracy rates observed in our study can be attributed to the fact that there were very few cases of lymphoma ($n = 2$) and tuberculous adenitis ($n = 6$) in our study. Lymphomas have been reported to show low stiffness from an elastographic point of view because of the large size and homogeneous structure of LNs which can produce false-negative results for malignancy.[30] Granulomatous lymphadenitis associated with tuberculosis may demonstrate calcification, scarring, or necrosis and therefore show areas of greater stiffness (false positive).[14]

Ying *et al*. performed a meta-analysis to evaluate the performance of RTE for diagnosis of malignant LNs.[29] Nine studies including 835 LNs were analyzed. The pooled sensitivity and specificity for ES in diagnosing malignant LNs were 74% (95% CI: 66%–81%) and 90% (95% CI: 82%–94%), respectively.

In the present study, we were able to obtain greater specificity, PPV, and accuracy with RTE than conventional US and Doppler for detecting malignant LNs from diverse primary sites. Hence, RTE with its fairly high specificity and diagnostic accuracy can reduce unnecessary invasive procedures for diagnosis of malignant LNs. However, it cannot replace the conventional B-mode US and Doppler because it is dependent on the machine as well as operator's expertise since excessive compression can cause nonaxial displacement and change the tissue stiffness. This in turn can affect the accuracy of the software's correlation algorithms. Furthermore, elastography is not useful for calcified LNs and those with cystic degeneration.

Relatively, few clinical studies have evaluated ARFI in the assessment of malignant cervical LNs.

In our study, ARFI imaging revealed higher SWV for malignant LNs than benign ones. The cutoff value of 2.05 m/s had sensitivity of 88.2% and specificity of 84.8% in identifying malignant LNs. Our results are comparable to that of Fujiwara *et al*. who evaluated SWVs of 42 cervical LNs using ARFI.[31] Of the numerous cutoff values tested, a SWV cutoff value of 1.9 m/s best distinguished between reactive and malignant LNs. Their criterion of SWV >1.9 m/s had 95.0% sensitivity and 81.8% specificity. According to a recent meta-analysis of nine ARFI imaging studies that included 1084 LNs, the pooled sensitivity and specificity values for detecting malignancies were 87% (95% CI: 83%–91%) and 88% (95% CI: 82%–92%), respectively.[19]

Our study has few limitations. The sample size was small, and only enlarged LNs were included. Strain elastography using free hand compression is dependent on the compression technique, and excessive compression can alter tissue stiffness. A single expert radiologist performed all the elastograms, and no interobserver variability was studied. However, studies have reported fair to almost perfect interobserver agreement in strain elastography.[6]

Head-and-neck cancers account for nearly one-third of the cancer burden in India, and it is a well-known fact that status of cervical LN is the single most important prognostic factor in squamous cell carcinoma of the head and neck.[32] To the best of our knowledge, this is the first study from India to document the diagnostic performance of elastography in evaluation of cervical lymphadenopathy, and it has shown encouraging results.

Conclusion

Elastography has high diagnostic accuracy in differentiating benign and malignant cervical LNs and can be an effective noninvasive adjunctive tool in the evaluation of cervical lymphadenopathy. It is potentially useful in selecting the LN with high probability of malignancy, on which FNAC/biopsy can be performed, thereby reducing sampling errors. ARFI imaging can be a useful technique for differentiating benign from malignant cervical LNs.

Is CT Cisternography in CSF Rhinorrhea Really Antiquated? Clinical Review of 14 Cases with Pictorial Depiction

Prerna Garg*, R Rajakumar, Ashritha Bandla and Devanand

*PSG Institute of Medical Sciences & Research, Coimbatore, India .

Received May 25, 2020; Revised June 02, 2020; Accepted June 04, 2020

ABSTRACT

CSF rhinorrhea is a complex problem due to the intricacy of anatomy of the cranio-facial region and precision required in diagnosis and management. Detection of accurate site of leak is of paramount importance in this era of minimally invasive procedures. CT Cisternography provides us with both the site of leak and visualization of defect. CT Cisternography of late has lost its appeal with advent of Magnetic Resonance Cisternography, which is usually performed in combination with High Resolution Contrast Tomography (HRCT). In our series we pictorially depict various findings of CSF leak on CT Cisternography particularly emphasizing on its role in current scenario.

Keywords: Cerebrospinal fluid (CSF), Computed Tomography (CT), Computed Tomography Cisternography (CT C), High resolution Contrast Tomography (HRCT), Magnetic Resonance Cisterongraphy (MR C)

INTRODUCTION

CSF (Cerebrospinal Fluid) rhinorrhea was first reported as a physiological phenomenon by Galen in 18th century [1]. However, it was in mid-19th century that the complications of CSF leak like meningitis and abscess formation were identified, thus emphasizing the need for intervention [2-4].

An osseous and dural defect in the region of skull base resulting in communication between subarachnoid space and extracranial space usually the paranasal sinuses results in CSF rhinorrhea. CSF rhinorrhea is complex problem due to intricacy of regional anatomy and precision required in diagnosis and management. With advent of minimally invasive surgical technique exact localization is of paramount importance. Imaging modalities for detection of CSF rhinorrhea have evolved over time and include radionuclide study, CT Cisternography (CT C), completely noninvasive Magnetic resonance Cisternography (MR C), Contrast enhanced MR Cisternography and varying combination of these.

CT Cisternography is an imaging modality that involves injection of iodinated contrast into the spinal subarachnoid space and then imaging the cranial subarachnoid space using HRCT. It demonstrates the bony defect and also shows the leak. Of late it has fallen in disrepute due to the advent of MRI cisternography which is noninvasive and comprises of thin section heavily T2W contiguous images. As MRI is inadequate to demonstrate bony defect, it is usually combined with HRCT PNS to detect the bony defect.

We shall herein present a series of 14 cases of CSF Rhinorrhea in whom CT Cisternogram was performed, emphasizing on the current role of CT Cisternogram, along with review of clinical and imaging findings.

MATERIALS & METHODS

We retrospectively searched for cases of CSF rhinorrhea evaluated with CT Cisternography done over the past three years from September 2013 to September 2016 in the Hospital Information System-Picture Archiving and Communication System (HIS-PACS) system of our hospital. After excluding those with inadequate clinical and surgical records we found about 14 patients.

All the patients were evaluated by the otolaryngologist and neurologists of our hospital, the CSF leak was confirmed by clinical and biochemical investigations of nasal discharge.

Imaging was performed during clinically active CSF leak, as reported by the patient. In all cases, high-resolution CT and contrast-enhanced CT Cisternography were performed on the same day.

CT scan was carried out on 128 slice Somatom definition edge, Siemens Health care, Erlangen., Germany. All the patients initially underwent non-contrast high-resolution CT of paranasal sinuses from the level of hard palate superiorly including the frontal sinuses in cranio-caudal direction using slice thickness of 1 mm. Sub-millimetric reconstructions (0.5 mm) in bone and soft tissue kernels were performed.

Prior to starting the procedures pledgets one in each nostril were introduced. After lumbar puncture, 8-10 mL of an iodinated nonionic low-osmolar contrast agent (iopropamide/iohexol, 300 mg/ml iodine) was instilled into thecal sac. The patients were then placed in knee elbow position with dependent flexed head to provoke CSF leak andcontrast enhanced CT scan was performed with collimation similar to non-contrast CT.

The images were evaluated by two radiologists (7- and 15-years' experience) and discrepancies if any were settled by consensus.

On plain study note was made of site of visible defects, fractures in case of trauma, presence of pneumoencephalous and sinus opacification /extracranial fluid in communication with CSF.

On contrast study an increase in 50% of HU value of the paranasal sinus fluid /extra cranial fluid as compared to non-contrast study [2], a column of contrast extending from subarachnoid space to the extra cranial space (paranasal sinus) or opacification of the nasal pledget was considered positive for leak. Pooling of contrast material at a fracture site with deformity of a local sulcus as described by Fagerlund and Liliequist [5] was considered positive. Additonally, pneumoencephlous in communication with para nasal sinus air was also considered positive for CSF leak.

The demographic data, clinical presentation, treatment details of surgical or conservative treatment were evaluated and tabulated.

RESULTS

We retrospectively evaluated 14 patients who underwent CT Cisternography from the year 2013 to 2016. The medical records, surgical details, investigations and CT Cisternography images were evaluated. Of the 14 patients 9 were females mean age was 45.5 with age ranging from 29 years to 56 years. The procedure was tolerated well in most patients with minor headache controlled by NSAIDS and head rising in most, while the headache was severe in one patient warranting admission for 2 days post procedure. The demographic distribution, imaging and surgical details are as depicted in **Tables 1 and 2**.

All patients presented with typical history of persistent clear nasal discharge, which could not be sniffed back, and which increased on forward bending. The duration of symptoms ranged from 1 day to one and a half year. 2 of 14 patients one with spontaneous leak and the other with post traumatic leak had signs and symptoms suggestive of meningitis. The cause was non traumatic in 11 of 14 patients, while in others the cause was trauma accidental (n=3) or iatrogenic (n=1). Over all the cribriform plate and sphenoid sinuses were equally involved (n=5).

Of the patients with non-traumatic leak, thecribriform plate (n=5/11) was most commonly involved, the next common site was sphenoid sinus (n=4/10). Left cribriform plate was more frequently involved than left (n=3/5). In all patients with leak fromcribriformplate the defect was clearly appreciated and a continuous column of contrast extending from the subarachnoid space to the extra cranial space (intofrontoethmoidal recess) was noted with opacification of nasal swab **(Figure 1)**. One patient had two sites of leak from both the Fovea Ethmoidalis and Cribriform plate **(Figure 2)**, while in the other two no leak or defect could be appreciated. Of the four cases of sphenoid defect, one patient had defect in the inferolateral wall also known as Sternsberg Canal **(Figure 3)** and other three in the posterior wall **(Figure 4)**. These leaks were seen as continuous extension of contrast from subarachnoid space to the sinus **(Figures 2 and 3)**. In one patient significant spontaneous penumoencephalus prevented opacification of subarachnoid space. The defect was easily identified on HRCT with subarachnoid air seen communicating with para nasal sinus air **(Figure 5)**. All the patients with cribriform leak or absence of obvious leak on CT Cisternogram were treated conservatively and it subsided spontaneously, while those involving sphenoid sinuses were treated surgically **(Table 1)**.

The post trauma group of the 3 patients comprised of one iatrogenic leak and two post traumatic leaks. One patient presented immediately post trauma and CT Cisterogram was done within a week of trauma. This patient had fracture of anterior and middle cranial fossa and pneumoencephaolus with extra dural extravasation of contrast reaching upto the fracture with deformity of an adjacent sulcus **(Figure 6)**. This patient was treated with fracture fixation and duroplasty. The other patient has past history of road accident and nasal bleed. He presented with one-and-a-half-year history of CSF rhinorrhea. CT Cisternogram showed multiple defects in frontal sinus and roof of sphenoid and ethmoid sinus. Leak was however seen from the roof of ethmoid and sphenoid sinus as increase in density of sinus fluid by

more than 50% **(Figure 7)**. Frontal sinus encephalocele was also noted in this patient **(Figure 7)**. This leak was also surgically treated. We had one patient of iatrogenic cause of CSF rhinorrhea post microsurgery for trigeminal neuralgia. In this patient there was a right occipito-mastoid defect seen with extravasation of contrast into the defect and mastoid aircells, further extension into the middle ear and subsequently into the Eustachian tube and right nasopharynx were seen **(Figure 8)**. In this patient another defect was appreciated in the right lateral wall of sphenoid sinus with adjacent sinus opacification **(Figure 8)**.

DISCUSSION

CSF Rhinorrhea was classified by Oyammainto two groups traumatic (including iatrogenic) and non-traumatic [6]. He further subdivided the latter into nontraumatic with normal pressure and nontraumatic with CSF hypertension. The high-pressure leaks were those in whom the leak was secondary to congenital defects, infections or tumors resulting in raised intracranial tension [6,7]. While the other category that is low pressure leak is now identified as spontaneous leak and is thought to be a manifestation of benign intracranial hypertension considering its association with empty sella [7].

In literature few authors report traumatic CSF leak to be most common [8,9]. However, in our study we found the non-traumatic category to be common, which is consistent with research findings [10,11]. However, this could be because of the fact that plain HRCT is usually done for patients with significant head injury usually

Extensive spontaneous pneumocephalus (short arrow) with fluid level in left sphenoid sinus (long arrow) with 6mm defect in the posterior wall of the sphenoid sinus above the clivus (curved arrow) with air pocket in the prepontine subarachnoid space communicating with the sphenoid sinus (elbow arrow) .No demonstrable flow of contrast from spinal to the brain subarachnoid space.

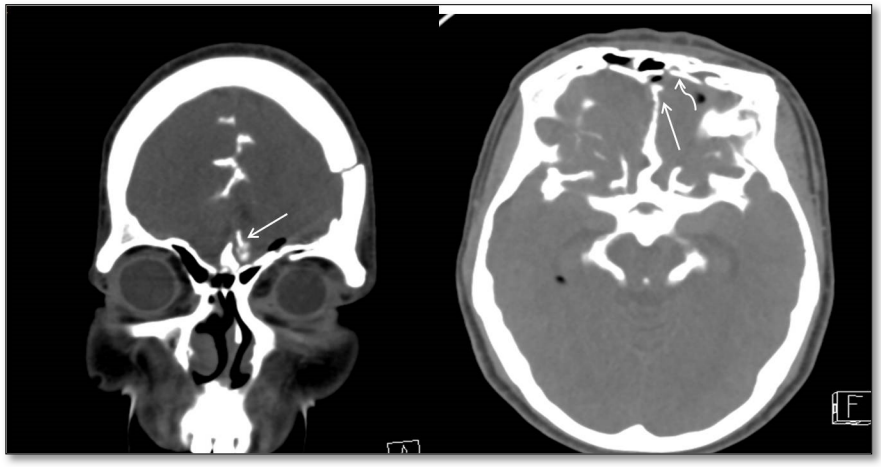

Figure 6. Contrast seen extending upto the fractures (curved arrow) in the inner table of left frontal sinus (straight arrow), distorted sulcus (straight arrow) with small pneumocephalus (curved arrow).

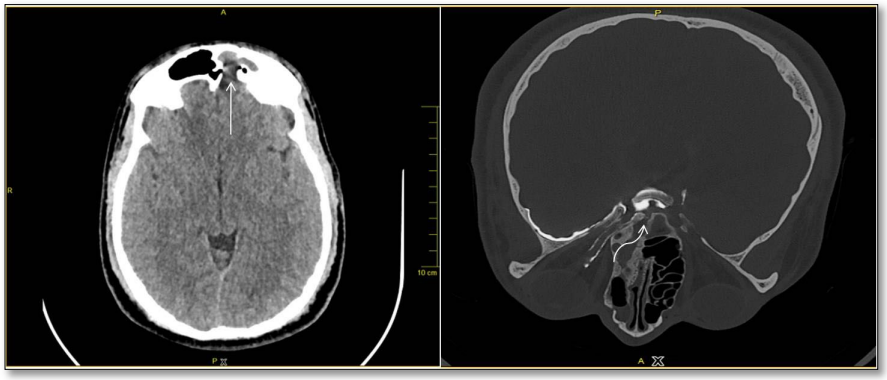

Figure 7. Defect in the inner table of left frontal sinus with herniation of brain tissue (straight arrow) but cisternogram showing CSF leak in the defect in the roof of the left sphenoid sinus and left posterior ethmoid sinus (curved arrow).

Figure 8. Post-surgery Right occipito-mastoid defect (long arrow), opacification of mastoid air cells and Eustachain tube (short arrow,defect in right lateral wall of sphenoid (curved arrow).

immediately after trauma, it usually suffices to detail the site of fractures in such cases and CT Cisternography is not feasible in acute settings.

The commonest site of leak was cribriform plate followed by sphenoid bone which was similar to other findings [8]. This is probably due to the fact that cribriform plate is thinnest and weakest portion of anterior cranial fossa [8,12]. All patients had typical findings of persistent nasal discharge which could not be sniffed back and increased on forward bending. Only two patients presented with meningitis, while hypotensive headache was present in all. Meningitis in the two cases was probably the reason of CSF rhinorrhea. Raised intracranial tension due to meningitis

was probably the cause for CSF leak in these patients rather than meningitis being a complication CSF leak.

Patients with CSF rhinorrhea pose a diagnostic challenge for both the otolaryngologists and radiologists. In this era of minimally invasive procedures where small skull base defects are routinely repaired using nasal endoscopes having limited field of view for, accurate localization of the leak is mandatory [3,8]. Also, symptoms in many patients with CSF leak resolve spontaneously or with conservative management [8]. Hence, we see that decision regarding management depends on the location and etiology. Plethora of imaging modalities have been described and discarded in an attempt to find the gold standard. The studies that are available for evaluation of CSF rhinorrhea are radionuclide study, HRCT alone, HRCT with CT cisternography, MRI cisternography with HRCT PNS and recently described CEMR cisternography. Of these the radionuclide study owing to its extremely low specificity is considered obsolete and is reserved only in cases where the diagnosis itself is in question [2,13]. There are few studies which say that HRCT alone suffices [14], but more than one site of leak and more than one defect are not rare. CT Cisternography has overtime undergone a drastic revolution due to the thin slice capabilities of current scanners and use of water-soluble contrast. It combines best of both worlds, that is it provides excellent localization of osseous defect and also shows the actual extra-cranial pooling of contrast. Of late it has lost its appeal with advent of MRI as it is slightly invasive in terms of requirement of lumbar puncture, patient discomfort in the form of post procedural headache, theoretical possibility of opening up of the defects, introducing infection, lumbar CSF leak and its low sensitivity in detecting the site in inactive leaks [3,15-17]. At present the most recommended modality is MRI Cisternography, HRCT PNS or combination of both which are non-invasive and quick [3,17]. In most of our patients we were able to isolate the site of leak with only mild patient discomfort. Post procedure complication rate was low and only one patient developed significant headache requiring admission.

We found that in patients who presented with recent trauma had multiple fractures on HRCT and pneumocephalus, which could interfere with visualization of leak on MRI. While with Cisternography though we could not see leakage into sinus of leak we could infer the possible site of leak using the distorted sulcal sign. Similarly, in a post-traumatic leak presenting late we found that the site of leak was different from the site of obvious defect or site of sinus opacification. In our only case of iatrogenic CSF leak post otomastoidectomy we additionally found a small defect in lateral wall of sphenoid sinus with adjacent sphenoid sinus opacification. However, on cisternography we found the leak to be into the mastoid air cells and subsequently into the naspharynx via Eustachian tube.

In non-traumatic category we found congenital defects in few patients. Sternberg's *Canal* which represents persistent lateral cranio-pharyngeal canal connecting intracranial space and sphenoid sinus due to congenital fusion defect between basi-sphenoid and greater wing of sphenoid was seen in one patient [18]. Additionally, defects in posterior wall were seen in three patients which requires surgical intervention as the sizes of defect were significant. In one patient placement of patient in knee elbow position probably induced spontaneous pneumocephalous, which prevented opacification of intracranial subarachnoid space. However, we could infer the site of leak as the subarachnoid air was seen in communication with sinus air through defect in posterior wall of sphenoid sinus. Other patients in non-traumatic group had leak from cribriform plate (seen as a column of contrast extending from subarachnoid space to extracranial space) and were treated conservatively. Multiple sites of leak from cribriform plate and fovea ethmoidalis were noted in one patient. In two patients no defects or leak could be appreciated probably due to inactivity of the leak during procedure.

Thus, in patients in both traumatic and non-traumatic categories wherein multiple defects, multiple sites of leak are anticipated CT Cisternogram provides concrete evidence regarding site of leak.

The major limitation of our study was lack of MRI for all patients due to which comparative analysis was not possible. Most of the post trauma patients rarely undergo CT Cisterography in acute settings and hence were not included in the study.

CONCLUSION

In conclusion, despite many limitations of CT Cisternography, it still holds importance as a problem-solving tool for detection of exact site of leak in patients where multiple sites of leak or multiple defects are suspected. Additionally, we have demonstrated spectrum of possible imaging findings of CSF leak on CT Cisternography.

Qualitative and Quantitative Assessment of Enhancement and Washout Characteristics of HCC and non HCC Hypervascular Liver Tumours

PRERNA GARG[1], SALIL PANDEY[2], MUTHUSUBRAMANIAN[3], CINDREL[4], B DEVANAND[5], V MAHESHWARAN[6], R RAJAKUMAR[7]

Introduction: The image based diagnosis of Hepatocellular Carcinoma (HCC) relies on assessment of arterial enhancement and venous or delayed phase washout. This assessment is based on visual analysis; however, studies quantifying such enhancement and washout are lacking.

Aim: To qualitative assessment of the imaging characteristics of HCC and non HCC hypervascular liver tumours followed by quantitative assessment of the enhancement and washout kinetics, and also to derive objective values that may help in differentiating HCC from non HCC on Computed Tomography (CT).

Materials and Methods: The present study was carried out in PSG hospitals, Coimbatore, Tamil Nadu, India. Retrospective analysis of hypervascular liver lesions was performed over a study period of four years (January 2012 to February 2016). These lesions were divided into two groups namely; HCC and non HCC. All non HCCs were pathologically proven, while HCC cases included those diagnosed on histopathology or typical imaging findings based on American Association for the Study of Liver Diseases (AASLD) (2010) and Liver Imaging Reporting and Data Systems (LIRADS) (2014) diagnostic criteria along with an elevated Alpha Fetoprotein (AFP) of more than 400 IU/mL.

A qualitative analysis of the enhancement and washout patterns was done followed by quantitative analysis using Regions of Interest (ROI) measurement of attenuation in Hounsfield units (HU). The quantitative parameters assessed were; Mean Attenuation (MA) of lesions in different phases, Attenuation Gain Percentage (AGP) on arterial phase, Arterial Phase Attenuation Change (AAC), Attenuation Loss Percentage in venous and delayed phases (ALP-V, ALP-D), Percentage Attenuation Ratio in venous and delayed phases (PAR-V, PAR-D) and Relative Washout Ratios from arterial to venous/delayed (RWR A-V, RWR A-D) and from venous to delayed phases (RWR V-D). Sensitivity and specificity were calculated for qualitative washout.

For quantitative variables comparative analysis between HCCs and non HCCs was done using Student's t-test. ANOVA was used to compare different categories. ROC curves were drawn for values that were significantly different to establish a cutoff value.

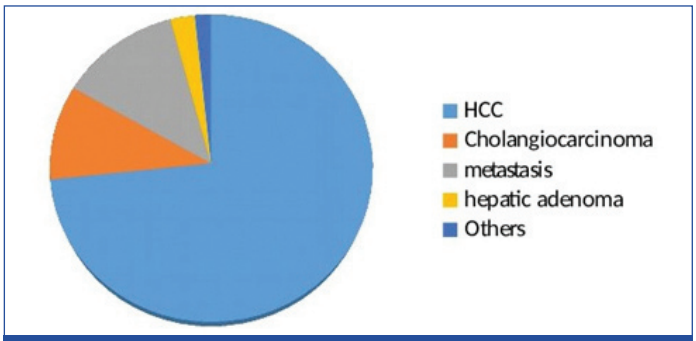
Results: A total of 120 lesions were evaluated consisting of HCCs (n=88) and non HCCs (n=32). Qualitatively majority (81) of HCCs demonstrated arterial enhancement and washout with eight cases of these demonstrating subtle washout requiring settlement by consensus. Washout were absent in seven cases. True mimics of HCC on qualitative analysis were hepatic adenomas, few cases of metastasis and hepatoblastoma were also there. The overall sensitivity of the washout appearance for predicting HCC was 92% while specificity was 78%. On quantitative analysis a PAR-V≥106 has sensitivity of 70% and specificity of 75%, RWR-V-D≥41.79 has sensitivity of 75% and specificity of 70% for HCC detection. Additionally significant difference was seen between RWR V-D of HCC when compared to cholangiocarcinomas (p-value 0.035) and metastasis (p-value 0.026) and also between PAR-V of HCC and metastasis (p-value 0.033).

Conclusion: The qualitative analysis combined with quantitative assessment of washout using percentage attenuation ratio in venous phase and relative washout ratio from venous to delayed phase offers good sensitivity and specificity in image based diagnosis of HCC.

Keywords: Hepatocellular carcinoma, Percentage attenuation ratio, Relative washout ratio

INTRODUCTION

The diagnosis of HCC on imaging relies on subjective assessment of arterial enhancement and venous or delayed phase washout. The arterial phase enhancement is attributed to an increase in intralesional flow with relative reduction in portal flow which occurs as the lesion progresses from dysplastic nodule to HCC [1,2]. Venous or delayed phase washout is decrease in attenuation of the lesion relative to background liver. Factors attributed to washout include early drainage of contrast material as compared to parenchyma and retention of contrast by surrounding fibrotic parenchyma [1-3]. There is ample literature on arterial enhancing mimics of HCC [1,3-7]. Arterial enhancing metastases, cholangiocarcinomas are known, similarly washout, a hallmark of HCC has been described in other tumours [5-7]. According to some studies Intrahepatic Mass-forming Cholangiocarcinoma (IMCC) showing arterial enhancement, was the most common lesion misinterpreted as HCC in preliver transplant imaging work up in recipients [5,9]. In cirrhotic livers lesions like regenerative nodules, dysplastic nodules, arterioportal or venous shunts and confluent fibrosis may also mimic this appearance [2,5-9]. Owing to typical enhancement characteristics of HCC, radiological imaging plays a crucial role in diagnosis and this combined with certain clinical and biochemical characteristics have been adopted as practice guideline for diagnosing HCC over the world. Differentiating HCC from other hypervascular tumours is important since HCC has therapeutic implications and prognostic factors which are very different from other lesions [2,8,10].



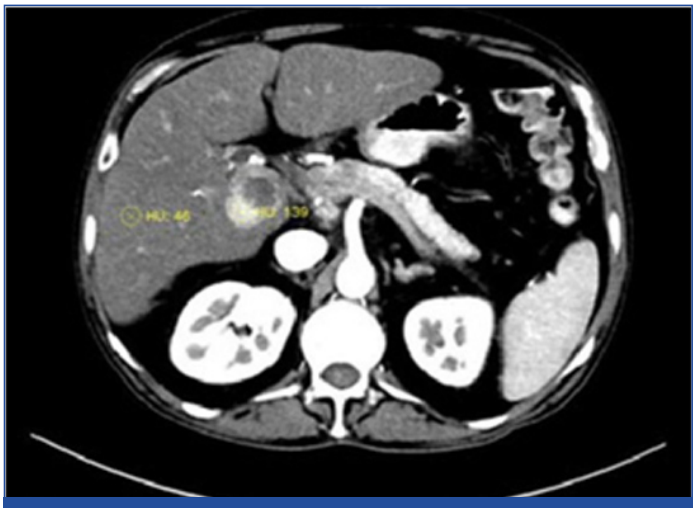
The assessment for hypervascularity of tumours and washout or persistent enhancement relies heavily on radiologist's subjective visual assessment. Only few studies have attempted to quantitate these variables and define the washout phenomenon [2,10]. In one

study, parameters such as relative contrast washout ratio between the arterial phase and delayed phase and attenuation ratio of the lesion to the background liver were studied and the attenuation ratio of the lesion to the background liver in the delayed phase was found to have excellent sensitivity and specificity for HCC detection and good correlation with subjective assessment [2]. In yet another study, an attenuation difference of greater than 10 HU between the arterial and delayed phase yielded optimal sensitivity and specificity for detecting HCC [10]. Certain studies have also quantitatively assessed the washout pattern on Magnetic Resonance Imaging (MRI), with a study evaluating the signal to noise ratio and liver to lesion contrast [11]. Overall the available literature is limited in this aspect with variable results. In present study, we analysed a large retrospective cohort of hypervascular liver tumours which were consecutively diagnosed over a period of four years in our hospital. We performed a qualitative assessment of the imaging characteristics of HCC and non HCC hypervascular liver tumours followed by quantitative assessment of the enhancement, washout kinetics and derived objective values that help in differentiating HCC from non HCC on CT. To the best of our knowledge this is the first such Indian cohort of hypervascular liver tumours being subjected to such qualitative and quantitative assessment.

MATERIALS AND METHODS

Institutional Ethics Committee approval was obtained and requirement for informed consent was waived after considering the retrospective nature of study. An extensive search of our Hospital Information System/Picture Archiving And Communication System (HIS/PACS-Vepro Medical Systems) for liver lesions on CT using keywords Hepatic, liver lesion, hepatic lesion, space occupying lesion, mass, HCC, Hepatocellular carcinoma and each of the individual common malignant and benign liver lesions revealed a total of 389 patients from January 2012 to February 2016 (four years duration). All Multidetector Computed Tomography (MDCT) examinations were performed on 64 slice MDCT (Somatom 64, Seimens healthcare) or 128 slice (Somatom Definition edge, Siemens healthcare) helical scanners. All studies were carried out in craniocaudal direction with patient supine with average 120 KV and 250-450 mA, values varying depending on patients build. Unenhanced images were obtained followed by administration of IV contrast (Iopromide 350-370 mg/mL), power injector was used for injection of contrast at a rate of 4 mL/sec. Automated bolus tracking was used. Images were obtained in arterial, venous and delayed phases, typically at 18-28 seconds, 55-65 seconds and 300 seconds after initiation of contrast administration.

Hypervascular tumours on arterial phase were studied; thus, all hypo or avascular lesions were excluded. Hypodense lesions with thin peripheral enhancement, the pattern which is most common in metastatic lesions, were also excluded. The other exclusion criteria were: i) HCCs without histopathology and not meeting the criteria mentioned below in confirmation of tumor subtype, ii) Diffusely infiltrative HCCs as enhancement pattern and washout characteristics are difficult to assess in them, iii) HCCs with changes related to treatments like thermal ablation or transarterial chemoembolisation, iv) Non HCCs without definitive histological diagnosis, v) Very small tumours less than one cm in size as placing ROI for measurements is difficult in them, vi) Benign lesions like hemangiomas, abscess and cysts were also excluded as they show fairly typical enhancement patterns and in most no histopathological confirmation is done. Histopathological confirmation was available for all non HCCs and HCC (35 cases). 53 HCCs, all in at risk population having underlying cirrhosis were diagnosed based on AASLD guidelines (2010) and LI-RADS (version 2014). First AASLD criteria was applied (a lesion of more than 2 cm showing arterial phase hyperenhancement and subsequent washout, in presence of cirrhosis and elevated AFP levels, we used AFP cutoff of >400 IU/mL to enhance specificity), tumours meeting these criteria are virtually diagnostic of HCC [13]. All of these 53 cases were LI-RADS 5 category (indicating 100% certainty of HCC), with 34 cases being LR-5, 17 cases LR-5V with macrovascular invasion and two cases being LR-5us (being 1-2 cm in size and being visible as discrete nodules on ultrasound) [14]. Two HCCs were histological variants, one a fibrolamellar HCC and another cholangiocellular variant. After application of exclusion and inclusion criteria we arrived at a study population of 120 patients (86 males and 34 females) mean age 58.5 years, range (3-78 years). There were 88 (73%) HCCs, 12 (10%) mass forming cholangiocarcinomas, 15 (12.5%) metastasis, 3 (2%) adenomas, 1 (0.08%) hepatoblastoma and 1 (0.08%) angiosarcoma [Table/Fig-1]. For purpose of comparability the tumours were divided in two broad groups of HCC and non HCC.



[Table/Fig-1]: Distribution of tumours.

A subjective or qualitative assessment was performed by two radiologists; having nine and five years of experience in abdominal imaging. After confirming the hypervascular nature of the tumour on the arterial phase assessment of subjective washout was done and presence or absence of washout on venous or delayed phases was noted. Presence of any delayed hyperenhancing central stroma was also noted. The examining radiologists were blinded to the results of histopathology and final diagnosis. Discrepancies if any were settled by consensus.

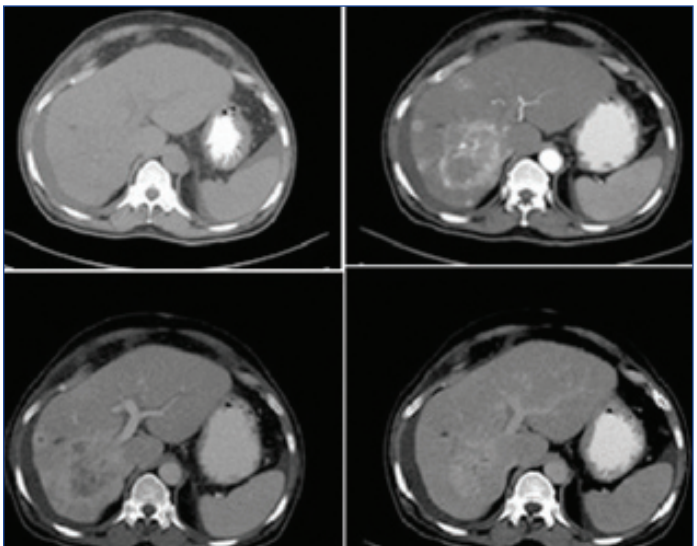
The quantitative analysis was done by one radiologist. The attenuation were measured in HU by drawing circular or oval ROI over the lesion. The ROIs were drawn to include maximally enhancing areas on arterial phase and ranged from 10 to 20 mm with similar ROI drawn on corresponding venous and delayed phase images. The necrotic areas of the tumour, major intratumoral feeding vessels or intratumoral arterioportal shunts were excluded [Table/Fig-2]. In case of large tumours with variable areas of enhancement, multiple ROIs were drawn in the enhancing regions of the tumour and averaged. Two ROIs were also obtained in the adjacent normal background liver in all the phases, taking care to avoid blood vessels. In case of multiple lesions, largest lesion was selected.

The following quantitative indices were calculated 1) Mean attenuation(MA) of lesions in different phases 2) Attenuation gain

[Table/Fig-2]: Hepatocellular carcinoma in caudate lobe with an eccentric necrotic component, ROI placement was done in the enhancing tumour component .

percentage on arterial phase (AGP): SOL a-BL a / BL a x100), Arterial phase attenuation change (AAC): SOL a –BL a (these indices assess the arterial enhancement of the lesions). 3) Attenuation loss percentage in venous and delayed phases (ALP-V, ALP-D): BL v/d-SOL v/d/ BL v/d x100; Percentage attenuation ratio in venous and delayed phases (PAR-V, PAR-D): 100x BL v/d/SOL v/d; Relative wash out ratio (RWR A-V, RWR A-D) from arterial to venous and delayed phases: 100x (SOL a-SOL v/d)/SOL a and from venous to delayed phases(RWR V-D): 100 x (SOLv-SOL d)/ SOL v.(these variables define the washout characteristics). (SOL a and BL a were attenuation of space occupying lesion and background liver attenuation on arterial phase respectively, SOL v/d and BL v/d were lesion and background liver attenuation on venous and delayed phases).

STATISTICAL ANALYSIS



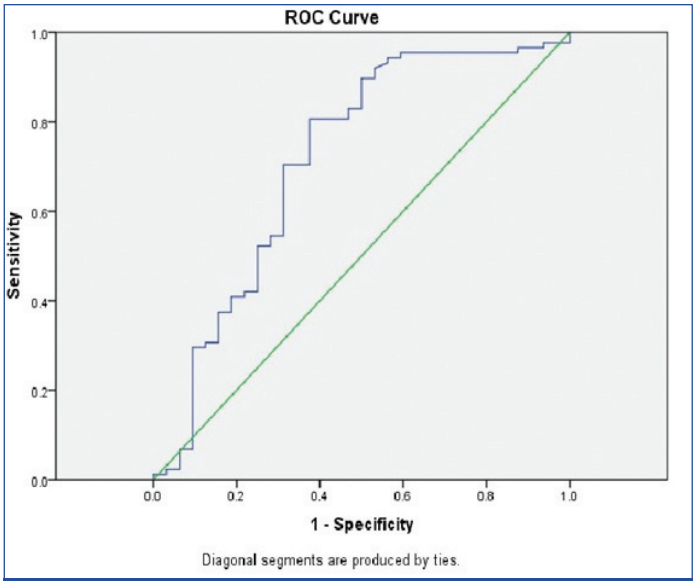
Statistical analysis was performed using IBM SPSS Statistics for Windows, version 20.0 (IBM Corp., Armonk, N.Y., USA). Sensitivity and specificity for washout appearance were calculated. For quantitative variables comparative analysis between HCCs and non HCCs was done using Student's t-test. ANOVA analysis was used for comparison between HCC and individual categories in Non HCC (cholangiocarcinomas, metastasis and others). ROC curves were drawn for values that were significantly different to establish a cutoff value.

RESULTS

The demographic and qualitative characteristics of the HCC and non HCC are as in [Table/Fig-3]. On qualitative analysis all HCCs showed homogenous or patchy enhancement on arterial phase. There was excellent interobserver agreement between the two radiologists for hypervascularity (Kappa value of 0.91) and presence of washout (Kappa value of 0.86) and discrepancies if any, were settled by consensus. Washout was noted on venous phase in 62/88 (69.3%) patients while on delayed phase additional 19 patients showed washout (81/88,92%). Overall 92% HCCs demonstrated washout in either venous or delayed phase. There was lack of subjective washout as perceived by both radiologists in 7/88 (8%) tumours [Table/Fig-4]. Of these however, two tumours did demonstrate a difference in quantitative washout if absolute values of HU obtained from ROI between the lesion and background liver were considered (though the difference was less than 10 HU). In addition in 8 (9%) tumours the washout was perceived as subtle and required either extensive window setting adjustments (in five cases) or settlement by consensus (three cases). The confounding factors encountered affecting visual assessment were presence of 1) steatosis in the background liver with lesion appearing hyperdense relative to the surrounding fatty liver in two cases, 2) presence of enhancing peripheral pseudocapusle in five cases and a delayed enhancing central fibrous stroma (noted in one case of fibrolamellar HCC). The metastases were the commonest non HCC lesion. Most of the hypervascular metastases were from adenocarcinomas with known or unknown primary sites. A qualitative washout appearance similar to HCC was noted in three cases (20%). Amongst the carcinoid metastasis or neuroendocrine tumours in present study sparing one which washed out the other two were hyper or isodense to parenchyma. Both cases of sarcoma metastasis (n=2) had peripheral enhancement, while washout was seen in one, the other was seen filling in from periphery to the centre. Thus, most of metastatic lesions showed no washout in the venous or delayed phase except one case of transitional cell carcinoma, one of neuroendocrine tumour and one sarcoma. Most of the adenocarcinoma metastases were isodense to parenchyma on delayed phase. The metastasis from gastrointestinal stromal tumour had peripheral fill in pattern.

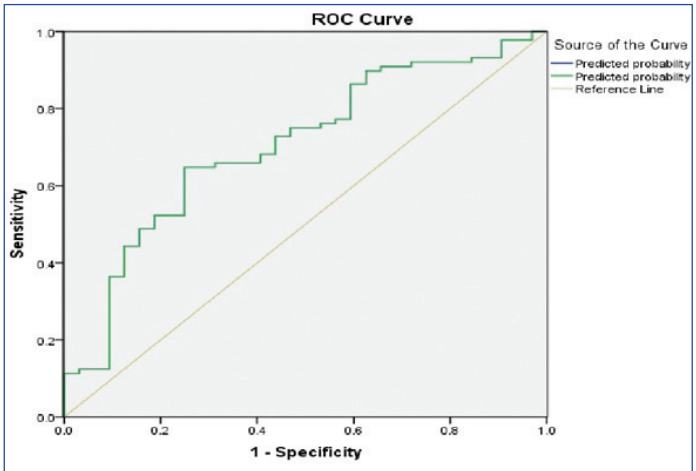
	HCC	Non HCC	p-value
Females	21	13	0.107
Mean age (years)	63.8	54.03	0.000
Size <3 cm	18 (20.45%)	3 (9.37%)	0.1868
Mean size (cm)	6.55±4.17	7.00±3.7	0.5916
Washout present (%)	81 (92%)	7 (21.8%)	0.001

[Table/Fig-3]: Demographic and qualitative parameters of HCC and Non HCC. The difference is significant at p<0.05
HCC*- Hepatocellular carcinoma



[Table/Fig-4]: Histopathologically proven hepatocelluar carcinoma, multinodular in alcohol related cirrhosis, showing progressive enhancement pattern with lack of subjective or quantitative washout.

Amongst cholangiocarcinomas, none demonstrated washout on delayed phase, all the lesions appeared isodense, hyperdense or showed central enhancing stroma in the delayed phase. The true HCC mimics on qualitative analysis were the three cases of hepatic adenomas and one case of hepatoblastoma which had an enhancement and washout appearance similar to HCC. The only case of angiosarcoma showed hyperdense appearance on delayed phase. Thus, hepatic adenomas, few hypervascular non adenocarcinoma metastasis and hepatoblastoma showed washout appearance in venous or delayed phase; thus, mimicking HCC. The overall sensitivity of the qualitative washout appearance for predicting HCC was 92% while specificity was 78%.



The difference between the mean attenuation of the HCCs and non HCCs was significant in noncontrast (p-value 0.01), arterial (p-value 0.002) and delayed phases (p-value 0.013), while the difference was not significant in the venous phase (p-value 0.614). The quantitative indices are as listed in [Table/Fig-5]. There was no significant difference between the two groups in attenuation change in arterial phase (AAC), while AGP was significant (p-value 0.018). Of the washout parameters, in venous phase significant difference (p-value 0.002) was found in PAR-V in venous phases with no significant difference seen between the two groups in PAR-D. The washout parameters assessed were relative washout from arterial to venous or delayed phase (RWR A-V, A-D) and from venous to delayed phase (RWR-V-D). The relative washout from arterial to venous or delayed phases was (RWR A-V,A-D) was found to be significant (p-value 0.022, 0.004). Washout from venous to delayed phase (RWR-V-D) was also significant between the two groups (p-value 0.000). ALP-V that is attenuation loss percentage in venous phase was also significant (p-value 0.001). However, area under curve was significant for RWR V-D and PAR-V only (r-value >0.7) and analysis of ROC curves for PAR-V and RWR-V-D revealed good sensitivity and specificity for detection of HCC [Table/Fig-6,7].

	HCC (Mean)	Non HCC (Mean)	p-value
MA-NCCT	66.31	52.71	0.01
MA-Arterial	105.96	89.8	0.002
MA-Venous	89.34	91.73	0.614
MA-Delayed	51.75	63.09	0.013
AAC	13.5	2.46	0.070
AGP	27.9	7.17	0.018
PAR-V	116.29	101.89	0.002
PAR-D	117.33	116.09	0.810
RWR A-V	9.3	-6.6	0.022
RWR A-D	45.05	25.6	0.004
RWR V-D	43.27	31.38	<0.001
ALP-V	10.83	-1.16	0.001
ALP-D	12.01	9.73	0.487

[Table/Fig-5]: Details of quantitative variables assessed.
MA-NCCT*-Mean Attenuation Non Contrast CT
AAC*- Arterial phase attenuation change, AGP*- Attenuation gain percentage, PAR-V*- Percentage attenuation ratio-venous phase, PAR-D*- Percentage attenuation ratio-delayed phase, RWR A-V*- Relative washout ratios arterial-ratio, RWR A-D*- Relative washout ratios arterial-delayed, RWR V-D*- Relative washout ratios venous-phase, PLP-V*- Attenuation loss percentage-venous phase, ALP-D*- Attenuation loss percentage-delayed phase

[Table/Fig-6]: Receiver operating curve (ROC) for RWR-V-D, area under curve >0.7

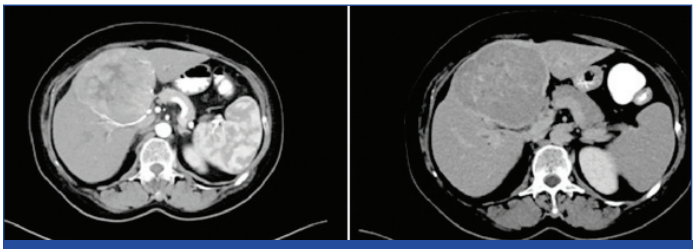
[Table/Fig-7]: Receiver operating curve (ROC) for PAR-V, area under curve >0.7

On individual comparison of HCC with metastasis, cholangiocarcinoma and others category, significant difference was seen between RWR V-D of HCC (mean 43.27) when compared to cholangiocarcinomas (mean 31.2, p value 0.035) and metastasis (mean 33.63, p value 0.026).

DISCUSSION

Studies show that combination of arterial hypervascularity and washout appearance of HCC on MDCT offers a specificity approaching 100% for HCC >20 mm in at risk populations. According to the AASLD guidelines (2010) a lesion of more than 10 mm showing arterial phase hyperenhancement and subsequent washout, in presence of cirrhosis can be considered as HCC and treated as such. Similar guidelines have been proposed by European Association for the Study of the Liver (EASL) in 2012 [13-15]. More recently LIRADS (2014) has been developed for categorising liver lesions in at risk population; this classification aims to facilitate clear communication between different personnel involved in care of these patients. The lesions falling in LR-5 category are nearly certain to be HCCs and consists of hypervascular lesions of more than 2 cm with one or more combinations of washout, capsule, threshold growth. In addition macrovascular mainly portal vein invasion constitutes LR-5V category [14].

A comprehensive quantitative analysis may help in providing further parameters that assists differentiation between HCC and non HCC. A quantitative assessment may also reduce interobserver variability and lay foundation for development of diagnostic algorithms and computed aided detection parameters. To the best of our knowledge, this is also the first study of this kind in India with no previous Indian cohort of hypervascular liver tumours having being subjected to this kind of qualitative and quantitative assessment.



HCCs showed uniform or nonuniform enhancement with most showing washout appearance. The overall sensitivity of the qualitative washout appearance for predicting HCC was 92% while specificity was 78%. The venous phase washout was seen in 69.3% patients while in delayed phase this number increased to 92%. About 8% of HCC did not washout at all while another 9% had a subtle washout. Latter could be resolved subjectively itself and washout even though subtle could be resolved qualitatively with a consensus agreement of two experienced radiologists. Thus, a qualitative washout assessment in a tertiary level setup with high volumes and experienced radiological staff does hold an excellent sensitivity and a reasonable specificity for HCC detection. The specificity may approach 100% if additionally presence of imaging features of cirrhosis is taken into account since none of the non HCCs had underlying cirrhosis. The overall sensitivity of the qualitative washout appearance for predicting HCC was 92% while specificity was 78%.

On quantitative evaluation there was significant difference in the attenuation between the two groups on noncontrast, arterial and delayed phases. Of the arterial parameters the AAC was found to be significantly different between the HCCs and non HCCs. However, when comparing the HCCs with individual subgroups of non HCCs the significance could not be elicited. The AGP was found to be significantly different between the two groups however, it merely represents arterial hypervascularity and doesn't quantitate washout. The PAR as suggested by Liu Y et al., is a measurement of washout appearance of HCC, measured as a ratio of liver and lesion attenuation [2]. The values for PAR in venous phase showed significant difference between the HCC and non HCC while in delayed phase the difference was not statistically significant. The mean PAR-V of HCC was higher than Non HCC. The absence of difference of PAR in delayed phase is probably because there were lesions like adenoma and certain metastases that washed out significantly more than HCC from venous to delayed phase as compared to HCC resulting in almost similar values of PAR-D. A cutoff of PAR-V of 106 provided 70% sensitivity in diagnosing HCC. Relative Washout Ratio (RWR) from arterial to delayed and venous phase was significantly different between the two groups but seems irrelevant as many of the values were negative, since maximum enhancement was obtained in venous phase in many tumours. Considering the fact that attenuation of the lesion was maximum in

venous phase, the calculated RWR from venous to delayed phase (RWR-V-D) showed that the HCC washout significantly more than non HCC and this temporal parameter of washout from venous to delayed phase seems more relevant than ascertaining washout from arterial to venous or arterial to delayed phase. As discussed earlier the washout phenomena is an appearance based on a lot of factors and RWR from venous to delayed phase seems to be one of the parameters that may differentiate the HCC and non HCC negating the effect of liver parenchymal attenuation. It is likely that gradient of loss of attenuation of lesion from venous to delayed phase is much more significant. The mean values of RWR-V-D of HCC (43.27) and non HCC (31.38) were significantly different and a cutoff of 41.79 offered a sensitivity of 75%.

When comparing individual groups there was a significant difference between the mean RWR-V-D values of HCC (mean 43.27) versus hypervascular IMCC (mean 31.2) and metastasis (mean 33.63). Loyer EM et al., compared the kinetics of HCC versus IMCC and found that HCC loose enhancement from venous to delayed phase while IMCC gain enhancement from the corresponding phases, however they included all cases of cholangiocarcinomas and not just the hypervascular variants [16]. Liu Y et al., used PAR ratio as a simple tool to measure the washout appearance [2]. In present study it is apparent that there are some arterial phase enhancing mimics showing the washout appearance complicating the oversimplified guidelines. We also had a much larger study population. In present study PAR-V was significant offering good sensitivity and specificity. This is in contradistinction to the study by Liu Y et al., which found PAR-D to be significant [2]. RWR-V-D was also significantly different between two groups and this gradient may actually help in cases that are not so straight forward.

In present study we found some true HCC mimics; however, which have similar qualitative appearance and quantitative indices like HCC, something which has not been highlighted in the other studies. These mimics were hepatocellular adenomas, hepatoblastoma and certain hypervascular metastasis [Table/Fig-8]. Hypervascular liver metastases from neuroendocrine tumours mimicking hepatocellular carcinoma in enhancement and washout pattern has been described in literature [16,17]. These mimics should be considered as differentials for HCC arising in noncirrhotic liver. The value of quantitative indices also appears to be doubtful for these mimics and appeared to be similar in both subgroups. Although, proving this statistically was difficult in present study due to the small sample size of the mimics. Thus, while a qualitative assessment combined with some useful quantitative parameters, can provide a noninvasive image based diagnosis in majority of cases in the settings of cirrhosis, the same may not hold true for HCC in noncirrhotic livers. A thorough clinicoradiological assessment can however, point to correct diagnosis with hepatocellular adenoma having distinct age group and predispositions, hepatoblastoma usually arising in pediatric age groups and metastatic lesions usually being accompanied by their primary known tumours, though biopsy may be needed for confirmation. Nevertheless a thorough qualitative assessment combined with assessment of certain useful quantitative indices mentioned above, can permit confident noninvasive image based diagnosis for a majority of HCCs in most radiological setup.

[Table/Fig-8]: Neuroendocrine tumour metastatic to liver, showing arterial phase enhancement and delayed phase washout, a pattern indistinguishable from HCC.

LIMITATION

There were some limitations of present study, firstly the lack of histopathology for all HCCs and the use of AASLD guidelines and LIRADS classification with AFP levels for identifying the same (partly because obtaining a biopsy is now almost unethical in patients with cirrhosis meeting the classic imaging diagnostic criteria), but we were stringent in including patients with image based diagnosis, only cirrhotic patients with AFP of more than 400 IU/mL with washout were included. The incidence of cholangiocarcinomas which is known to be the most common mimic would be very low in this group and is unlikely to alter the results. The other limitations included, HCCs less than 1 cm which were not included in our data set. Thus, their behavior was not assessed, heterogeneity within the non HCC group and the sample size of the non HCC group was small compared to HCC. Retrospective nature of analysis also limits the evaluation.

CONCLUSION

While there are number of guidelines which include the more popular likes of AASLD and LI-RADS for diagnosis of HCCs and categorising liver lesions; yet, most of these continue to be subjective in nature with lack of quantification of hypervascularity or washout. A quantitative analysis defining the washout is useful additional determinant adding objectivity to image based diagnosis. Quantitative variables like PAR-V (threshold value 106), RWR-V-D (threshold of 41.79) complement the qualitative analysis, for diagnosis of HCC and have future implications like incorporation into guidelines and development of diagnostic algorithms for computed aided detection software packages.

Congenital Biotinidase Deficiency-Clinching the Diagnosis with Classic Imaging Features

Dr.Maheswaran Viyannan, Dr.SuganyaPalanisamy,
Dr.DevanandBalalakshmoji,
Dept of Radiology and Imaging, PSG Institute of Medical Sciences and Research, Coimbatore.

Abstract: *Congenital biotinidase deficiency (CBD) is a rare inborn error of metabolism, resulting in biotin deficiency. The recognition of clinical, laboratory and magnetic resonance imaging findings can help us to arrive at a correct diagnosis at the earliest which can enable institution of appropriate early treatment and prevention of late complications. We present the typical MRI findings in a 3 ½ month old baby who presented with multiple episodes of seizures which finally turned out to be profound biotinidase deficiency.*

Key Words*: Congenital biotinidase deficiency, recurrent seizures, skin manifestations, bilateral symmetrical diffusion restriction, cerebral atrophy.*

Date of Submission:24-10-2019 Date of Acceptance:09-11-2019

I. Introduction

Congenital biotinidase deficiency (CBD) is a rare autosomal recessive congenital neuro- metabolic disorder,[1] which leads to profound deficiency of biotin which is an essential cofactor for many enzymes[2] Biotin deficiency can lead to neurological, cutaneous and visual problems.-4 Making a diagnosis based on clinical manifestations alone is difficult. Brain imaging especially Magnetic Resonance Imaging (MRI) with advanced MR techniques like diffusion weighted imaging and MR spectroscopy (MRS) has typical features which can clinch the diagnosis. As MRI plays a key role in making the diagnosis at an early stage of the disease it should be considered in all patients who present with clinical features suggestive of metabolic disorders.

II. Case Report

A 3 ½ months old baby girl presented with complaints of recent onset of multiple episodes of seizures, lethargy, hypotonia, skin peeling and alopecia. The antenatal and birth history were unremarkable. The baby was born of a non-consanguineous marriage. Baby was immunized up to the age. The baby was developmentally normaltill 3 months of age and attained social smile at 2 months. Head control has not yet been attained. The baby started to develop recurrent episodes of seizure for 15 days and regression of previously attained social smile. At presentation the child weighted 5.1kg. Head circumference measured about 40cm.In view of multiple episodes of seizures and lethargy, baby was admitted in neonatal intensive care ward and started on empirical antibiotic therapy. Routine blood investigations revealed markedly elevated lactate (11.6mmol/L), reduced bicarbonate (2.7mmol/L) and pH of 6.9. Further blood investigations showed elevated ammonia (200microgram/dl.) and urine ketones(3+). Blood culture and cerebrospinal fluid (CSF) culture were negative. In view of multiple episodes of seizures, skin manifestations, alopecia, severe metabolic acidosis and hyperammonemia, the diagnostic possibility of inborn errors of metabolism was suspected and referred to department of radiology for further evaluation with MRI of the brain.

Figure 1: Clinical photograph of the child showing severe alopecia and skin peeling.

MRI of the brainrevealed prominent cortical sulci and fissures, mildly dilated ventricles– suggesting loss of brain volume. In addition there wereconfluent areas of T2/ fluid attenuated inversion recovery (FLAIR) sequence hyperintensities with T1 hypointensities involving bilateral fronto-parietal white matter, bilateral cerebellar white matter, and cerebellar vermis. There were also bilateral symmetrical areas of diffusion restriction seen in corona radiata, posterior limb of internal capsule, cerebellar white matter, cerebellar vermis, midbrain and left medial temporal gyri. In addition to the above findings, subdural hygroma noted along bilateral frontal convexities (more on the left side). No evidence of mass lesion / hemorrhage seen within brain parenchyma. MRS showed elevated lactate and glycine. Based on the above MRI findings, the diagnostic possibility of inborn errors of metabolism such as CBD, Maple syrup urine disease (MSD)andLeigh's syndrome (LS)were suggested.

With the combination of clinical and radiological findings, biotinidase deficiency was considered as most probablediagnosisand baby was started on oral biotin.Subsequently the diagnosis was confirmed with tandem mass spectroscopy which revealed profound biotinidase deficiency. The baby responded well to oral biotin with reduction of lactate and ammonia and rise in bicarbonate and pH levels.

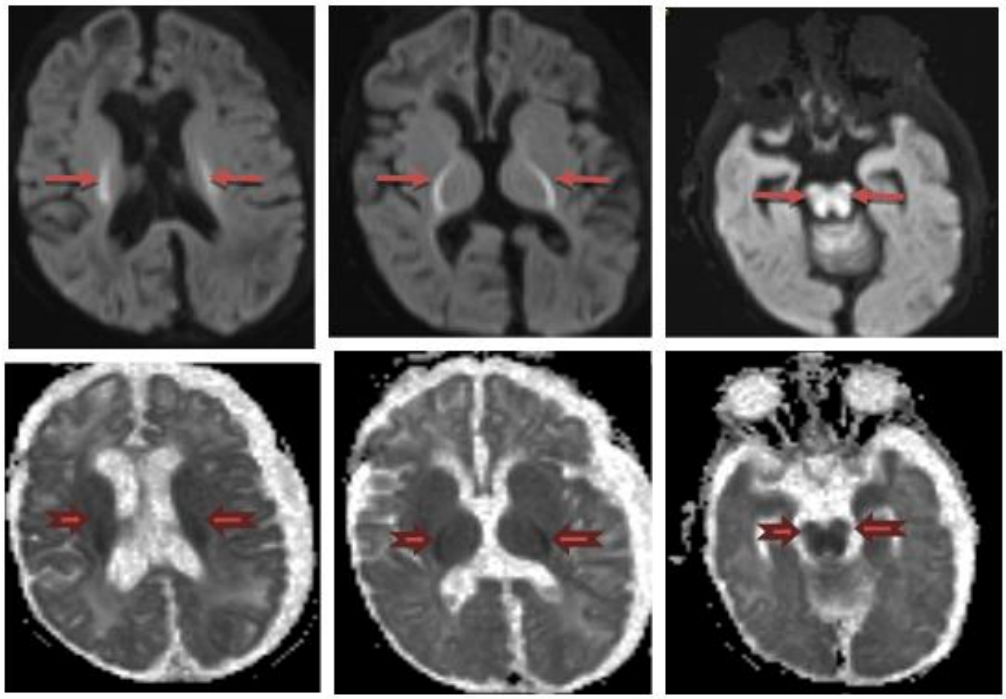

Figure 2: Diffusion weighted images (top row) and Apparent Diffusion Co-efficient (ADC) maps (bottom row) showing bilaterally symmetrical areas of diffusion restriction in the corona radiata, posterior limbs of internal capsule and midbrain which appear hyperintense in DWI (horizontal regular arrows in top row) and hypointense (horizontal notched arrows in bottom row) in ADC.

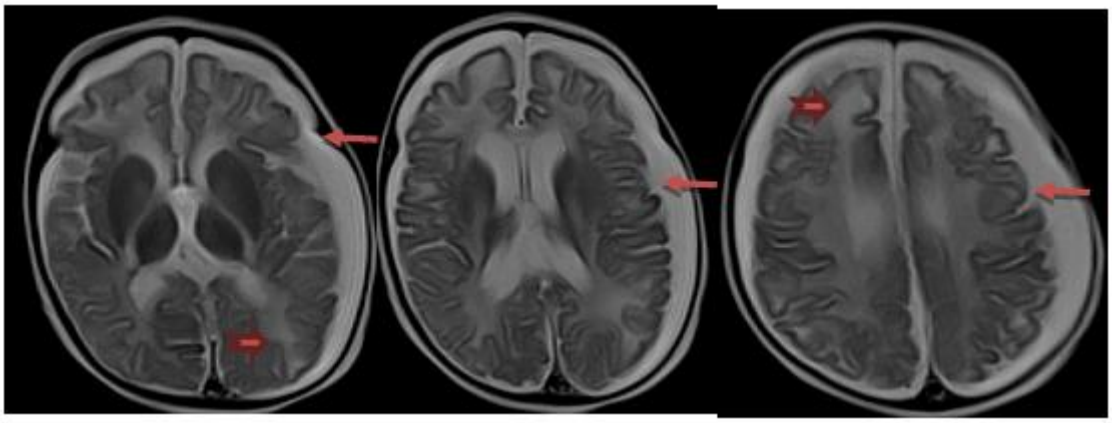

Figure 3: T2Weighted images showing bilateral prominent subdural hygroma (horizontal regular arrows) and abnormal hyperintense areas in the frontal and parieto-occipital white matter (Notched arrow)

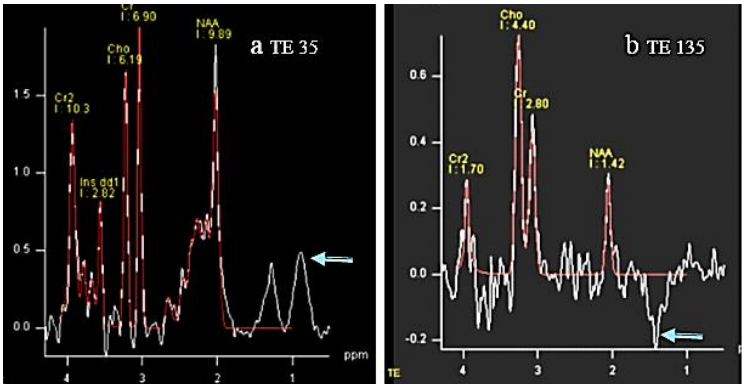

Figure 4: Magnetic resonance imaging H1 spectroscopy images (a, b) acquired with short time to echo (TE 35ms) and intermediate time to echo (TE 135ms). With short TE there is doublet peak at 1.3ppm (Horizontal arrow in a) and reversal of doublet in intermediate TE (horizontal arrow in b), consistent with lactate peak.

III. Discussion

CBD a neurocutaneous disorder,is a rare inborn error of metabolism with autosomal recessiveinheritancein which the body is unable to breakdown the conjugated form of biotin (vitaminB7)and clinical biotin deficiency[4]. This condition manifests due to mutation in biotinidase(BTD) gene at chromosome 3q25. The estimated prevalence of profound biotinidase deficiency (<10% of normal level) is approximately 1: 137000 newborns. The partial biotinidasedeficiency(<30%of normal) is estimated at 1:60,000 newborns[1]. The symptoms manifest in early to mid-infancy (mean age of onset – 3.5 months) [5].

Biotinidase deficiency causes biotin deficiency through multiple mechanisms such as, prevention of release of biotin bound to protein in food particles thus preventing absorption of biotin from intestine, impaired recycle of biotin from carboxylases and histones. The biotin serves as a co-factor for many enzymes such as pyruvate carboxylase, acetyl co-A carboxylase, propionyl Co-A carboxylase, beta methylcrotonyl-coA carboxylase and hence the enzyme biotinidase plays a role in fatty acid synthesis, amino acid catabolism and gluconeogenesis. The substrates accumulated in case of biotinidase deficiency are 3-hydroxy isovaleric acid, 3-methyl crotonylglycine, methylcitrate and 3-hydroxy propionate[6].When biotin is deficient,the activity of pyruvatecarboxylase in CNS falls, leading to localized lactic acidosis. The alopecia and dermatitis in these patients are possibly due to depletion of fatty acids as a result of deficient acetyl –CoA carboxylase.

Clinically, the babies present with multiple episodes of seizures, lethargy, hypotonia, ataxia, developmental delays, coma, alopecia, skin rash (mucocutaneous candidiasis) [2]. Hearing loss and decreased visual acuity are the late complications and are seen less frequently. Biochemically, there will be severe metabolic acidosis, ketosis, hyperammonemia, lactic acidosis and abnormal organic acids in urine. Ketosis and skin manifestations are the atypical features.

Radiologically, MRI will reveal, features of delayed myelination likeabnormalT2/FLAIR hyperintensities with T1 hypointensities in bilateral fronto-parietal white matter, bilateral cerebellar white matter, and cerebellar vermis. There can be bilateral symmetrical areas of diffusion restriction involving corona radiata, posterior limb of internal capsule, cerebellar white matter, cerebellar vermis, anterior midbrain, medial

temporal gyri, hippocampi and parahippocampal gyrus[1].The changes of restricted diffusion will be seen more in the myelinated white matter fibers. MR spectroscopy will show elevated lactateandglycine and decreased N-Acetylaspartate and choline. Some studies have shown involvement of the corpus callosum as well, which was not seen in our study[4].

There are few other conditions in which the MRI findings can closely mimic CBD, which should be considered in the differential diagnoses. They are 1.Maple syrup urine disease[7] (MSUD)–here the onset of clinical signs and symptoms is relatively early, during first week of life with poor feeding, vomiting, dystonia and seizures. Skin manifestations will be absent. Biochemically – ketoacidosis and characteristic maple syrup odor in urine. In MRI, diffusion restriction is seen in deep cerebellar white matter, dorsal brain stem, cerebralpeduncles, and posterior limb of internal capsule, basal ganglia and thalami. Basal ganglia and thalami are typically spared in CBD. 2.Leigh'ssyndrome (LS) – mitochondrial disorder which presents later, towards the end of first year with hypotonia, psychomotor deterioration, ataxia, ptosis and swallowing difficulties without any skin manifestations[8]. In MRI grey matter is more frequently involved, diffusion restriction can be less pronounced and seen only in acute phase in corpus striatum, sub thalamic nucleus, deep cerebellar nuclei, pons, medulla and periaqueductal grey matter. In MRS there will be large lactate peakand small NAA peak.

IV. Conclusion

When a baby presents in early infancy with multiple episodes of seizures, skin manifestations, elevated lactate, metabolic acidosis, ketosis and hyperammonemia with typical MRI findings of bilateral symmetrical areas of diffusion restriction and brain atrophy, the likely diagnosis ofCBD has to be considered which will help to institute proper and timely treatment and thereby avoiding complications and long term sequeale of permanent neuronal damage. Since the structural changes are reversible, it is of paramount importance to make correct and prompt diagnosis of CBD.

Abstract:

Background: Variceal bleed the major cause of mortality in cirrhosis. Upper gastrointestinal (GI) endoscopy remains the main stay of diagnosis and treatment in variceal bleed. Splenic elastography using Acoustic Radiation Force Impulse (ARFI) technique can be used to non-invasively predict presence and severity of esophageal varices.

Material and methods: It is a hospital based prospective case control study, done in 100 patients with chronic liver parenchymal disease, who had undergone upper GI endoscopy. Fifty consecutive patients with esophageal varies and 50 consecutive patients without esophageal varices were included in the study and subjected to splenic ARFI. Data was analyzed with SPSS version 20.0 software using chi-square test or Fischer exact test, independent sample-t test. The receiver operating characteristics (ROC) curve was plotted and the area under the curve was used to determine the cut off points for statistically significant variables.

Results: Spleen ARFI showed significant correlation between cirrhotics with esophageal varices and without varices groups. The cut off of ≥ 3.16 m/s (AUROC: 0.906) precisely detects varices with sensitivity of 94% and specificity of 92%. Spleen ARFI also correlates with severity of varices. Cut off of ≥ 3.29 m/s (AUROC: 0.874) can confidentially differentiate low grade from high grade varices in cirrhotics with sensitivity of 85% and specificity of 100%.

Conclusions: Amongst the noninvasive parameters analyzed in this study, spleenic ARFI exclusively showed highest sensitivity and specificity in the detection of varices and differentiation of high grade varices from low grade varices.

Key words: Splenic ARFI, cirrhosis, Endoscopy, Esophageal varices.

Introduction:

Diverse insults on the liver lead to a common endpoint as cirrhosis. Cirrhosis is pathologically characterized by extensive fibrosis, regenerative nodules and distortion of hepatic parenchymal architecture [1]. Alcoholism and viral hepatitis have been the most common etiologies leading to cirrhosis, however nonalcoholic fatty liver disease is emerging as an important underlying pathology.

Complications of cirrhosis can be categorized as portal hypertension related and portal hypertension unrelated complications. Most common portal hypertension related complications is development of esophageal varices and variceal bleeding [2]. Till date, invasive upper gastrointestinal endoscopy (UGI scopy) remains the mainstay

www.ijbamr.com P ISSN: 2250-284X , E ISSN : 2250-2858

for the detection and grading of esophageal varices [3]. In addition to diagnostic advantage, UGI scopy plays a major role in treatment such as band ligation and sclerotherapy. Despite its diagnostic and therapeutic utility, UGI scopy is an invasive procedure, has its inherent complications such as bleeding, perforation, infection and cardio-respiratory complications related to sedation [4].

With current advances in the field of Ultrasonography, estimation of elasticity of the tissue has been made possible with Elastography. It is analogous to manual palpation and in fact offers better information, based on the principle that pathology changes the stiffness of the tissue. Shear Wave Elastography (SWE) is a technique of elastography that uses "shear wave" generated within tissue secondary to the acoustic push, the so called Acoustic Radiation Force Impulse (ARFI). In this technique as no external compression is required and a push impulse can be directed anywhere, it is possible to attain a fine elastogram of entire organ. Additionally, quantification of elasticity of particular region of interest based on shear wave velocity (SWV) is possible [5].

Elasticity of the spleen will be decreased in cirrhosis due to portal venous congestion and hyperplasia of splenic tissue; hence the splenic stiffness will be increased. Portal venous congestion results in esophageal varices. Screening UGI scopy is recommended in all cirrhotic patients in accordance with recent guidelines as primary prophylaxis against variceal hemorrhage[6]. Implementing these guidelines is confronted with cost, complications and invasiveness of UGI scopy. Hence, it necessitates accurate and noninvasive methods for detecting and grading the severity of esophageal varices.

Aim:

To evaluate splenic ARFI as a noninvasive tool for detection of esophageal varices and grading of varices as to high and low grades in chronic liver parenchymal disease.

Materials and methods:

It is a prospective case control study done on 100 patients over a period of 14 months, who were referred to the department of radiology with a diagnosis of chronic liver parenchymal disease. Subsequently all these patients underwent UGI scopy and were divided into two groups. Consecutive 50 patients without esophageal varices comprised the first group and 50 patients with esophageal varices comprised second group. Study was undertaken after obtaining necessary clearance from the institutional human ethics committee. Patients who are of less than 18 years of age and who did not undergo UGI scopy were excluded from the study. All the patients were subjected to splenic ARFI and UGI scopy.

Splenic ARFI protocol:

Splenic ARFI was performed with Siemens Acuson S2000^{TM} / Siemens Acuson S3000 ^{TM} ultrasound systems with ARFI enabled 6C1 / 4C1 curvilinear transducers. Patient was made to lie in right lateral decubitus position and assessment was done by intercostal approach. In order to cover uniformly the spleen, we adopted the stratified random sampling method used in the previous studies [7] (Figure 1). Spleen will be subdivided into cranial external(1), cranial central(2), cranial internal(1), intermediate external(1), intermediate central(1), intermediate internal(1), caudal external(1), caudal central(1) and caudal internal(1) segments. Numbers in the parenthesis represents the number of ARFI values obtained in each segment. In breath hold position, region of interest measuring 10mm in depth and 5mm in width was placed in parenchyma devoid of visible blood vessels and >1 cm below the level of spleen capsule and ARFI evaluation was done (Figure 2). Total of 10 successful measurements were obtained for each patient. Mean ARFI values were automatically calculated and expressed

www.ijbamr.com P ISSN: 2250-284X , E ISSN : 2250-2858

in meters per second (m/s).

The data obtained was coded and entered in Microsoft Excel Spreadsheet. Data was analyzed using SPSS version 20.0 statistical software. Categorical variables were expressed as percentages and the comparative analysis was done using chisquare test or Fischer exact test. Continuous variables were expressed as mean ±standard deviation (SD) and the comparative analysis was done by independentsample 't' test. The receiver operating characteristics (ROC) curve was plotted and the area under the curve was determined to the cut off points for statistically significant variables. A probability value (p value) of less than or equal to 0.05 at 95% confidence interval was considered as statistically significant.

Various radilogical parameters like liver size, portal vein diamater, portal vein flow velocity, spleen size, liver ARFI and splenic ARFI were analysed for their value as predictors of presence or absence of esophageal varices, if present, to differentiate high grade varices from low grade varices using various statistical methods as mentioned above.

Discussion:

Recent guidelines endorse that endoscopic screening should be done for all cirrhotic patients at the time of diagnosis to recognize those at high risk of bleeding and possibly to benefit from primary prophylaxis [6]. Implementation of these guidelines imposes huge burden on UGI scopy units and frequent testing over time can decrease the compliance of patient. By noninvasive prediction of the presence of EVs, one can recommend the appropriate category of patients to undergo invasive UGI scopy, thereby reducing unnecessary endoscopic examinations and burden on endoscopy units.

Previous studies have correlated various radiological and laboratory parameters either alone or in combination with the presence or absence of EVs in cirrhotics. Although, the efficiency of parameters or combination of parameters reported in each study differ amongst them, due to the heterogeneous nature of the studies. Good predictive value of several non-endoscopic variables for the presence or absence of EVs have been documented

www.ijbamr.com P ISSN: 2250-284X , E ISSN : 2250-2858

by many previous studies, but the data is limited from our part of the country. This study was performed to assess the effectiveness of various clinical, laboratory and radiological parameters, in reliably detecting the existence of EVs and high grade EVs in cirrhotic patients.

In the present study, there is no significant association of demographic parameters between the two study groups. Previous studies by Zaman et al [8] and Cherian et al [9], showed that Child Pugh class B or C cirrhotic patients, as compared to class A cirrhotics, have high propensity towards the detection of EVs on UGI scopy. In contrary, our study inferred no significant association between Child Pugh class and the presence of EVs (p = 0.799). In addition, we assessed MELD scores and found significant affiliation with presence of EVs, in congruence to the results of previous studies by De Mattos et al [10] , Tafarel et al [11] and Chandail VS et al [12].

Our study showed no significant variation in either portal vein diameter or portal vein flow velocity between cirrhotic patients with EVs and without EVs. Our study in contradiction to previous studies inferred that there is no significant difference in liver stiffness measured by elastography between cirrhotics with EVs and cirrhotics without EVs (p= 0.458).

In agreement with previous studies, our study also showed significant difference in the values of spleen stiffness measured by ARFI between cirrhotics with EVs and without EVs (p= 0.000). We acquired the optimal cutoff of ≥ 3.16m/s (AUROC: 0.906) with sensitivity of 94% and specificity of 92%, thereby validating spleen ARFI as a non-invasive radiological marker for the presence of EVs in cirrhotics.

In the present study, we furthermore evaluated the utility of the above discussed noninvasive clinical, laboratory and radiological parameters in the detection of high grade EVs in cirrhotics. Of all the noninvasive parameters analyzed, spleen ARFI exclusively showed significant difference between the two subgroups (p= 0.001). We derived the optimal cutoff of ≥ 3.29m/s (AUROC: 0.874) with sensitivity of 85% and specificity of 100%, which is in very close approximation with spleen ARFI cutoff of ≥ 3.30m/s obtained by Takuma et al[13]. Thereby substantiating spleen ARFI as a non-invasive radiological marker for the presence of high grade EVs in cirrhotics. In other words, the presence of high grade EVs can be reliably ruled out with the spleen ARFI cutoff of < 3.29m/s in patients with chronic liver parenchymal disease. Our study was limited by only few patients with grade IV EVs being included in this study. It is due to the lower prevalence of grade IV EVs, as in part by the practice of generous prophylactic and therapeutic measures which delays or eliminates progression of low grade EVs to high grade EVs. Inter observer variability is not assessed in this study. Future studies on this context should focus on multicenter design with evaluation of equipment of various manufacturers and assessment of inter observer variability.

Conclusions:

Amongst the noninvasive parameters analyzed in this study, spleenic ARFI exclusively showed highest sensitivity and specificity in the detection of varices and differentiation of high grade varices from low grade varices.

ABSTRACT:

Background: Cervical spondylosis is a common degenerative disease of spine generally seen in old age, frequently causing compression of spinal cord and /or nerve roots by protruding disc or osteophytes. Magnetic Resonance Imaging (MRI) is the modality of choice for evaluation of patients with features of cervical spondylotic myelopathy. In addition to routine MRI sequences, advanced MR techniques like diffusion tensor imaging (DTI) can be used to obtain specific information about the spinal cord.

Materials and methods: It is a prospective observational study conducted in 30 patients who presented with clinical and neurological features of cervical spondylotic myelopathy, who had undergone MRI.

Result: All the patients had undergone routine MRI along with diffusion tensor imaging. The Apparent Diffusion Coefficient (ADC) and Fractional Anisotropy (FA) values of the spinal cord were measured at the level of normal spinal canal dimension and at the level where there is narrowing of the spinal canal. The ADC values were found to be high and the FA values were low at the level of the spinal canal stenosis in comparison with values measured at the level of normal spinal canal dimension, which were statistically significant.

Conclusion: DTI parameters showed significant correlation with the clinical parameters, suggesting that DTI can be used to detect microscopic changes related to compressive myelopathy, before changes are apparent in the routine MR sequences. This can enable us to intervene early to avoid irreversible damage to the spinal cord.

Key words: Cervical spondylotic myelopathy, Diffusion tensor imaging, Fractional anisotropy.

Introduction

Cervical spondylosis is a common degenerative disease of spine generally seen in old age, frequently causing compression of spinal cord and /or nerve roots by various pathological entities like protruding disc, osteophytes and thickening of ligamentous structures around the spinal cord.[1] Spondylotic myelopathy refers to compression of the spinal cord by the above mentioned structures leading to impairment of spinal cord function.[2] Cervical spondylotic myelopathy (CSM) is usually seen after the 5th decade. Patients with CSM usually present with symptoms of numbness and weakness in limbs, pain over shoulder and neck, incoordination. Magnetic Resonance Imaging (MRI) of cervical spine is non-invasive and accurate imaging tool in assessing the structural changes of spinal cord due to its high contrast and soft tissue resolution[3]. It helps to ascertain the site and the

severity of degenerative compressive myelopathy. It is also useful to exclude any other pathology, like neoplasm which can cause compressive myelopathy and mimic degenerative disc disease.

Classical MRI finding seen in compressive myelopathy is focal T2 hyperintensity in spinal cord at the level of a compressive lesion. This signal change is suggestive of either spinal cord oedema in acute cases, or gliosis and myelomalacia in chronic cases[4,5]. Oedema is associated with swelling of the spinal cord and chronic changes on the other hand show thinning of the spinal cord. Other imaging modalities like Computed Tomography (CT) and radiography play a complementary role in the evaluation of CSM. Due to its inherent high spatial resolution CT is better than MRI in the assessment of cortical bone, osteophytes and other calcified ligamentous structures. These structures can also cause spinal canal compromise. Plain radiography is still being used as an initial tool for evaluating degenerative disc changes[6]. The ultimate aim of doing imaging studies is to identify the spinal cord abnormalities early and take remedial measures to prevent further damage[7].

Aims:

1. To compare Fractional Anisotropy (FA) and Apparent Diffusion Coefficient (ADC) values of the spinal cord obtained at the level with above and below the level of spinal canal stenosis.
2. To compare the Diffusion Tensor Imaging (DTI) parameters with Nurick score and neurological examination findings.
3. To detect the early microscopic level structural abnormalities of spinal cord using DTI before overt, irreversible changes manifest in routine MR sequences.

Materials and methods:

It is a prospective observational study performed in 30 patients who were referred by the department of neurology. These patients presented with clinical symptoms and neurological findings suggestive of cervical myelopathy. The study period was from January 2018 to March 2019 at the department of Radiology and imaging sciences PSG Institute of Medical Sciences & Research. Prior to commencement of the study, clearance has been obtained from Institutional Human Ethical Committee and informed written consent has been taken from the participants. Patients with clinical and neurological features of CSM were included in the study. Patients with following abnormalities were excluded from the study: 1.focal or diffuse signal abnormality in the spinal cord. 2. History of cervical spine injury / surgery. 3. Focal lesions in the brain which may be the underlying pathology causing the neurological abnormality.

Prior to undergoing MRI all these patients were assessed symptom wise for the severity of CSM using Nurick score and neurological examination was performed to assess the power of lower and upper limbs. In Nurick score patients were categorized from grade 0 to 3, based on clinical history alone, where grade 0 represented mild form of disease with only symptoms suggestive of nerve root involvement (radiculopathy), grade 3 represents more severe neurological deficit where the patients are wheel chair bound with no independent mobility (myelopathy). On clinical examination muscle power of the limbs was assessed using standard grade 1 to grade 5.

All the patients underwent MRI in Siemens 1.5 Tesla 16 channel machine.

MRI protocol:

1. Routine non contrast T1 and T2 weighted images to look for overt signal changes in T2 Weighted Images.
2. DTI acquisition using EPI yielding the following set of images:

www.ijbamr.com P ISSN: 2250-284X , E ISSN : 2250-2858

1. Diffusion weighted imaging, 2.Trace weighted, 3.FA and ADC mapping 4.Tensor imaging.

DTI parameters:

Diffusion directions measured – 20.

The b factors – 0, 100 and 1000

TR/ TE - 3600 /94ms

Field of view - 230mm

Slice thickness - 5mm.

Images were analysed using Siemens Syngo via work station. Initially presence of any focal or diffuse spinal cord lesions was excluded. After that dimension of the spinal canal was measured at all the vertebral level. Subsequently DTI analysis was performed by drawing region of interest at the level of maximum spinal canal stenosis, one vertebral level above the spinal canal stenosis and one level below (Figure 1a). DTI Parameters assessed were FA and ADC, the values of which were displayed as a table in the system (Figure 1b) along with images of visual maps of ADC (Figure 2a) and FA (Figure 2b).

Statistical analysis:

The data has been analysed using SPSS 23.0 version. To describe the data descriptive statistics frequency analysis, percentage analysis were used for categorical variables and the mean & standard deviation (SD) were used for continuous variables. To find the significant difference in the multivariate analysis for repeated measures the repeated measures of ANOVA was used with Bonferroni correction to control the type I error on multiple comparison. To assess the relationship between the variables Pearson's Correlation was used. In all the above statistical tools the probability value .05 is considered as statistically significant.

Results:

A total of 30 patients were enrolled in our study of which 20 were men and 10 were women (Figure 3). Nurick Score distribution is given in the table 1.

All the patients had muscle power grade between III and V. (Figure 4). No patient in our study had muscle power less than 3.

Diffusion tensor parameters (ADC and FA) were measured at 3 levels of the spinal cord (Figure 1a). One measurement at the level of the spinal canal stenosis and 2 measurements (above and below the level of stenosis) at the level of normal canal dimension. The values of ADC and FA measured at different levels of the spinal cord are given in table 2.

Pairwise comparison of ADC and FA was performed and results are given in table 3 and table 4. Patients were found to have high ADC and low FA values at the level of stenosis when compared with ADC and FA values at the level of no stenosis. The differences were found to be statistically highly significant with a p value of 0.0005 (ANOVA test was used). There was negative correlation between the mean FA and ADC at the level of stenosis with r value of -0.424 and p value of 0.019. There was negative correlation between the mean FA and ADC at the level of no stenosis with r value of -0.0545 and p value of 0.002. There is negative correlation between Nurick score (clinical grading) and muscle power (neurological examination) r value of -0.07 and P value of 0.001.

www.ijbamr.com P ISSN: 2250-284X , E ISSN : 2250-2858

Correlation of FA and ADC with muscle power:

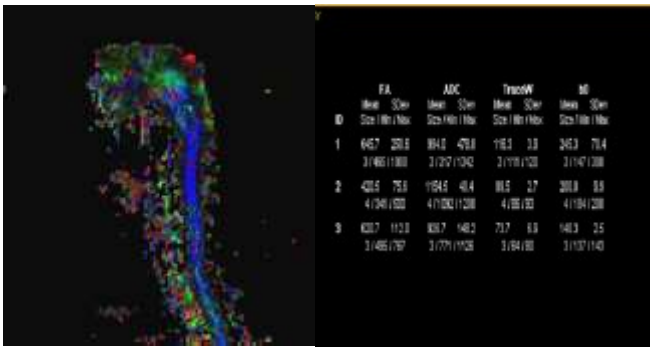
At the level of stenosis:

There was a positive correlation between muscle power and mean FA value with r value of 0.2 and p value 0.1. There is a negative correlation between muscle power and mean ADC value at the level of stenosis with r value of -0.1 and p value 0.1 and p value of 0.3.

At the level of no stenosis:

There is a positive correlation between muscle power grade and mean FA value at the non- stenosis level with r value of 0.18 and p value 0.32 and p value of 0.4. There is a negative correlation between muscle power grade and mean ADC value at the non-stenosis level upper with r value of -0.25 and p value 0.17.

Correlation of FA and ADC with Nurick score:



At the level of stenosis:

FA and Nurick score has negative correlation with r value of -0.4 and p value of .0005. ADC and Nurick score has a positive correlation with r value of -0.1 and p value of – 0.2

At the level of no stenosis:

FA and Nurick score had positive correlation with r value of 0.1 and p value of –0.4. ADC and Nurick score had negative correlation r value of -0.05 and p value of– 0.7

ROC analysis of FA in predicting microscopic level structural cord abnormality in the spinal cord at the level of the spinal canal stenosis. (Figure 5) was done. Subsequently test result variables (table 5) and sensitivity and specificity (table 6) were calculated. Likewise ROC analysis of ADC in predicting microscopic level structural cord abnormality was done (Figure 6). Test result variables (table 7) and sensitivity and specificity (table 8) were also calculated for ADC. Both FA and ADC showed good sensitivity and specificity in predicting the early microscopic level changes in the spinal cord caused by degenerative disease, ADC was slightly more specific than FA.

Discussion:

MRI has revolutionized the evaluation of pathology related to spinal cord. Exceptionally high contrast resolution and soft tissue resolution place MRI way above other imaging modalities in the evaluation of spinal cord.[2] Recent advances in respect to high field strength and fast and robust sequences have greatly contributed to the superior performance of MRI[8]. Very small yet important structures like the nerve roots and the thin ligaments need to be assessed in almost all patients which can harbour the pathology. However significant degree of anatomical and structures abnormalities need to be present before they are visible in routine MRI sequences, primarily in the spinal cord[6]. Hence the need for imaging technique which is similar to a biomarker to pick up early microscopic level changes in the neural structures, specially the spinal cord. Role of DTI in the evaluation of the brain pathologies has been proved and it is being used routinely, however its usage in the evaluation of spinal cord is still evolving.

The application of DTI in the evaluation of spinal cord is hindered by various factors. Spinal cord is a very narrow structure with a high elasticity and situated in anatomically complex location, which are the factors

www.ijbamr.com P ISSN: 2250-284X , E ISSN : 2250-2858

making evaluation difficult. Other factors like CSF pulsation, motion artefacts and breathing related artefacts make usage of DTI difficult as a routine sequence. Newer techniques like reduced field of view with oblique spin echo and OVS (outer volume suppression) have been used to overcome the limitations and better images can be obtained. All these improved techniques provide high resolution images not only in the cervical cord but also the entire spinal cord.

Budzik et al[9] studied the feasibility of DTI and fiber tracking in CSM. FA values showed correlation with the patients' clinical scores. High signal intensity of the spinal cord on T2WI did not correlated either with the DTI parameters or with the clinical symptoms, suggesting that FA is better in depicting the early structural abnormality of the spinal cord when compared with T2W imaging[10, 11]. But they did not study the relationship of DTI scalars with cervical canal width. In our study all the patients had spinal canal stenosis, in that about 73% of the patients had relative narrowing and 27% has absolute narrowing.

In our study degenerative changes like disc bulge, protrusion, osteophytes and ligament thickening led to spinal canal narrowing. These pathological changes caused disruption of the white matter tracts and other secondary changes in cervical cord. Secondary changes like cord edema and macrophage proliferation lead to increased diffusivity of water molecules with in the spinal cord parenchyma, especially in the white matter which can alter the FA and ADC values[12]. These changes were apparent much before macroscopic changes appear in routine T1 and T2W images.**UzeyirAhmadli et al**[13] investigated the utility of DTI sequence in patients with CSM symptoms for early detection of microscopic changes in the spinal cord at the level of narrowed spinal canal without any T2 signal alterations. FA values with in the cord were reduced and ADC increased at site of canal stenosis when compared with non-stenotic segments above the level of canal stenosis. However no significant difference was noted in FA and ADC values between stenotic segment and non-stenotic segment distal to the level of stenosis.

In our study there was statistically significant reduction in the FA values and increase in the ADC values at the site of stenosis when compared to the non-stenotic levels (upper and lower). There was no statistically significant reduction in FA value noted at the non-stenotic levels (upper and lower). The reduction in FA value at the stenotic level is presumably due to reduced neuronal fibers with increase in the extracellular space or due to extracellular edema which can result in increased diffusivity of water molecules and consequently facilitated diffusion.

Jones et al[14] reported a significant correlation between FA and modified Japanese orthopedic association score and Nurick score, and reported that patients who had a higher FA at the compressed level of spinal cord tended to have a better recovery of functionality after surgery when compared to patients undergoing surgery who had a lower FA value pre operatively. In our study there was significant correlation between the patient’s symptoms and the DTI parameters. We graded clinical symptoms using only Nurick score, modified Japanese orthopedic association score was not used.

FA and Nurick score had a negative correlation with r value of -0.4 and p value –0.0005, which implies that the FA values tend to be less when the Nurick score is on the higher side. ADC and Nurick score had a positive correlation with r value of-0.1 and p value of – 0.2, which is equal to higher ADC means higher Nurick score.There was also a significant correlation between the DTI parameters and muscle power. There was positive correlation between muscle power and mean FA value at the level of stenosis with r value of 0.2 and p

www.ijbamr.com P ISSN: 2250-284X , E ISSN : 2250-2858

value of 0.1. There is a negative correlation between muscle power and mean ADC value at the level of stenosis with r value of -0.1 and p value of 0.3. ROC was calculated between the stenotic and non stenotic level. The mean was calculated between the upper and lower non-stenotic level and it was compared with the stenotic level. FA showed a sensitivity of 86.7% and specificity was 86.7% when the cut was kept at 0.57 (Table 6). ADC showed a sensitivity of 86.7% and specificity was 90.0%, when the cut off is kept at 1.1. (Table 8).

Conclusion:

- Our study showed significant correlation between the patients' clinical symptoms and DTI parameters.
- DTI has the potential to detect microscopic structural changes in the spinal cord, before the T2 signal changes appear on conventional MRI.
- DTI can be used as a tool for detecting early changes in cervical spondylotic myelopathy, which would prognosticate the clinical and surgical outcome[14, 15].
- DTI technique should be routinely used on patients with clinical symptoms of cervical spondylotic myelopathy.

Limitations:

- The sample size of the study population was relatively small
- The long-term follow-up of the patients were not done
- It was impossible to determine the percentage of patients with early cervical spondylotic myelopathy who would have advanced to T2 hyperintensity changes in spinal cord, when left untreated.
- Cost and the availability of MRI.

Further studies have to be done on large group with long term follow up of those patients to determine the potential utility of quantitative diffusion tensor imaging.

Conflicts of interest:

There are no conflicts of interest to declare.

Analysis of different pathologies presenting as acute abdomen and performance of MDCT in making the diagnosis with clinical, intra-operative and histopathology correlation

Maheswaran Viyannan, Sucharitha Periyasamy and Balalakshmoji Devanand

DOI: http://dx.doi.org/10.33545/26644436.2020.v3.i1a.56

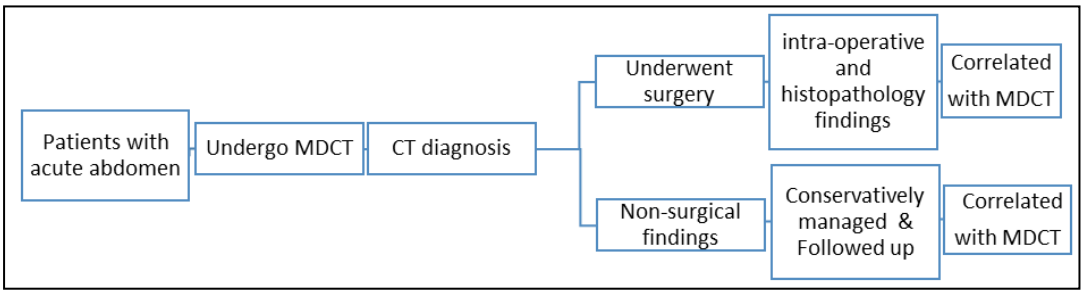
Abstract
Background: Acute abdomen is one of the most common emergencies presenting in the emergency room which requires immediate attention. Making an accurate diagnosis is of paramount importance in managing these patients, since most of these patients frequently require a surgical intervention. The divergence of patient population and the underlying pathology in acute abdomen calls for high quality imaging studies to make quick and precise diagnosis. Multi-detector computed tomography is an ideal tool in this regard.
Materials and Methods: It is a prospective study conducted on 73 patients who presented with acute abdomen and subsequently underwent multi-detector computed tomography to ascertain the underlying pathology. The radiological findings in computed tomography were correlated with clinical, intra-operative and histopathological findings whenever available.
Results: In our study the performance of multi-detector computed tomography, when compared with diagnosis made based on intra-operative findings, post-operative histopathology and clinical findings showed sensitivity of 97% and specificity of 75%. Overall Positive Predictive value of 98.5% and negative predictive value of 60% and accuracy of 96%.
Conclusion: Since most of the patients presenting with acute abdomen have non-specific and overlapping clinical findings, making an accurate clinical diagnosis is challenging. In this scenario MDCT comes as a handy tool with high accuracy and good sensitivity and specificity. The results obtained in our study are comparable with other studies conducted worldwide.

Keywords: Acute abdomen, MDCT performance, acute abdominal pain

Introduction
Acute abdomen is a clinical entity in which patients present with sudden onset of intense abdominal pain necessitating emergency medical/surgical management [1]. Majority of these patients present to the emergency department. The underlying pathology in acute abdomen could be anything ranging from acute inflammatory conditions involving the appendix, gallbladder, pancreas to non-specific pain usually associated with mesenteric adenitis, especially in children. In a given patient there are numerous differential diagnoses and making a single specific diagnosis is seldom seen and it is very difficult, given the overlap of presenting symptoms and clinical examination findings in various pathologies. Further evaluation with laboratory blood tests and radiological investigations is part of management of these patients.

Patients presenting with acute abdomen are in severe pain and very sick. Hence it is essential to make a prompt and accurate diagnosis in these patients [2]. Most of these patients are initially evaluated with abdominal radiograph and ultrasound. The role of these basic radiological investigations is limited by various factors. Major limiting factors are two dimensional nature of radiographs. In ultrasound limiting factors are inability of the patient to cooperate for the study due to severe pain, thick body habitus of the patient, excessive bowel gas and lack of adequately filled urinary bladder. However radiograph has fairly good specificity in diagnosing pneumoperitoneum. It gives useful information in only in less than 50% of patients [2].

Ultrasound has its own advantages. It is cheap, easily available, no need to administer contrast and it is free of ionizing radiation, hence better suited for children and pregnant women. Ultrasound is a valuable tool in the assessment of pathology related to gallbladder and acute ureteric colic, especially when the obstruction is at the vesico-ureteric junction, which is by far the most common site.



Though these basic radiological investigations do indeed provide valuable information, in a good number of patients computed tomography (CT) examination is essential. Multi-Detector CT (MDCT) is a widely accepted primary investigation of choice in these patients [3, 4, 5]. The scanning is fast, (acquisition time of 2-3 minutes), and yields specific diagnosis. In MDCT, multiple images can be acquired in a single tube rotation. The whole abdomen and pelvis can be scanned within a single breath hold at a slice thickness of less than a millimeter (0.3-1mm). These sub millimeter sections can be used to obtain good quality reconstructed images like multi-planar reconstructions (MPR) maximum intensity projection (MIP) and 3dimentional (3D) reconstruction**.** MDCT is a great tool for comprehensive evaluation of entire abdomen. There is excellent visualization of the solid organs, hallow viscera, vasculature, peritoneum and retroperitoneal structures along with lung bases.

Our study aims at analyzing the incidence and frequency of various pathologies presenting as acute abdomen in a tertiary care hospital and the accuracy of 128 slice MDCT in making a correct diagnosis by correlating the CT diagnosis with intra-operative and post-operative histopathology diagnosis, whenever available and clinical diagnosis if the patient does not undergo surgery. Intra-operative and post-operative histopathology are considered as gold standard.

Materials and Methods

It is a prospective study performed on 73 subjects who presented with acute pain abdomen, who were referred to radiology department for MDCT abdomen. The duration of this study was from May 2015 to June 2016. Prior to the commencement of the study, necessary clearance was obtained from the institutional ethics committee and written informed consent was taken from the participating patients. Inclusion criteria: Patients who are presenting with clinical symptoms of acute abdomen and undergoing MDCT. Exclusion criteria: Patients who have contraindication to iodinated contrast media either due to contrast allergy or due to impaired renal function. Patients lost to follow up.

CT protocol: MDCT was performed with Siemens SOMATOM definition edge 128 slice scanner. Oral iodinated contrast was not given in patients who are kept nil by mouth in view of immediate surgical exploration, who cannot tolerate oral liquids (pancreatitis), suspected high degree of bowel obstruction, and suspected vascular pathology where the study is done in abdominal angiogram protocol (oral contrast interferes with vascular reconstructions). All the other patients were administered oral and rectal contrast as per routine protocol. All patients underwent a non-contrast study followed by contrast study. Approximately 80-90ml (1-2ml/kg body weight) iodinated non-ionic contrast was given intravenously using a pressure injector at 4ml/sec rate. Images were obtained at arterial (20-25sec), venous (50-60seconds) and delayed phases (>120 sec) using bolus tracking and automatic triggering of acquisition. Raw data was acquired with slice thickness of 0.625mm with a pitch of 0.8-1.5. The images were reconstructed in 5mm thickness for viewing purpose and in 1mm thickness for doing various reconstructions [6].

Study design

Results

In this study 73 patients with acute abdomen underwent MDCT. The findings of MDCT were correlated with the intraoperative findings and histopathological findings in patients who had undergone surgery. In conservatively managed patients the MDCT findings were correlated with clinical course. Table 1 shows the age distribution in the study population.

Table 1: Age group wise distribution of acute abdomen in the study population

Age (years)	Frequency	Percentage
0 to 10	4	5
11 to 20	6	8
21 to 30	8	11
31 to 40	16	22
41 to 50	12	16
51 to 60	9	12
61 to 70	11	15
71 to 80	6	8
91 to 100	1	1
Total	73	100

The sex distribution of the study population is shown in figure 1.

Specificity	75.00%
Positive Predictive Value	98.53%
Negative Predictive Value	60.00%

Discussion

The current generation of the MDCT scanners with cutting edge technology have become the main stay of evaluation of patients with acute abdomen. The technology enables acquisition of isotropic images with exquisite spatial resolution and significantly reduced radiation exposure. The multi-row multi-detector spiral scanning technology has reduced scanning time significantly, leading to improved output and reduced movement related artefacts. The large volumetric data obtained in the axial plane allows reformations into any required plane with same resolution [7]. The advances in reformation techniques have made the process automatic which saves time. Further increase in the computing speed has facilitated faster radiological interpretation in critically ill patients. The shear speed and accuracy of CT in acute abdomen has made the role of plain radiography nearly obsolete.

In our study group of 73 patients 53 were males and 20 were females, ranging from 5 to 93 years. We analyzed various pathologies presenting as acute abdomen. Most common pathology found in our study was acute appendicitis, seen in 22% followed by bowel obstruction in 18%, acute pancreatitis 15% and bowel perforation 14%. Among which appendicitis is the most common cause and is consistent with most of the studies carried out internationally [8].

However we did not encounter any definitive gynecologic pathology, which may be due to the fact that patients with gynecological pathology were primarily evaluated by ultrasound which itself can yield a specific diagnosis.

In our study 16 patients had CT findings suggestive of acute appendicitis and related conditions (Figure 7). CT diagnosis in one out of these16 cases was non-concordant with intraoperative surgical findings. Intra-operatively it was found to be ileo-cecal tuberculosis which was confirmed by histopathological examination. The actual CT findings in this case were masked by clumping of bowel loops in the right iliac fossa, which made visualization of appendix difficult. This was erroneously diagnosed as inflammatory appendicular mass.

The sensitivity and Positive Predictable Value in acute appendicitis were 100% and 93.75% respectively. Intra operative findings very well correlated with CT findings except for one case. This is consistent with study conducted by Rao PM *et al.* [9] which shows 91% to 100% sensitivity for CT in the diagnosis of appendicitis. In another study done by Mawiah H. Alshebromi *et al.* [10] CT showed high sensitivity of 100% and poor specificity of mere 16%.

Fig 7: Axial and coronal MPR images showing a typical case of appendicitis with thickened and enhancing appendix (arrow in a). Coronal MPR (arrow in b) in same patient

In our study 13 out of 73 cases were diagnosed to have bowel obstruction. The various etiologies of bowel obstruction are stricture, adhesion, hernia and mesenteric band [11]. The sensitivity and positive predictable value were 100%. Our results are comparable with Mallo *et al.* [12] in which sensitivity of MDCT in diagnosis of bowel obstruction was 81% to 100% and specificity 68% to 100%. A study conducted by Suri S *et al.* [13] shows that CT is highly sensitive in determining level and cause of obstruction. This is made possible by the exquisite coronal and sagittal reformatted MPR images [14] which are very useful in identifying the transitional zone (Figure 8a). MPR images in any oblique or orthogonal plane are good in identifying intussusception and the underlying pathology as well (Figure 8b)

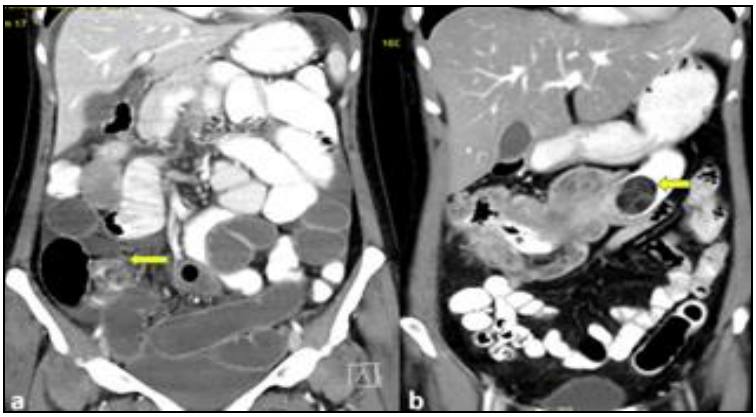

Fig 8: Case of acute bowel obstruction. Coronal MPR shows the transitional zone, in this case it was adhesion causing obstruction (a); Colo-colic intussusception and the underlying pathology, lipoma are shown well in coronal MPR (b).

We encountered 11 cases of pancreatitis out of 73 cases. In all the cases MDCT correctly identified the pathology. In all of the cases diagnosis was confirmed by abnormal levels of elevated pancreatic enzymes. The sensitivity of MDCT in acute pancreatitis was 100%. Comparable results were shown by B. Gianni *et al.* [15]. This is a disease entity where CT clearly scores over ultrasound, because visualization of pancreas itself, in most of the cases of pancreatitis is interfered by bowel gas. Estimation of pancreatic necrosis is impossible with ultrasound, which is the key factor in management and prognostication. CT also is better in identifying and quantifying the peripancreatic collections, pseudo cysts and identifying air in emphysematous pancreatitis (Figure 9).

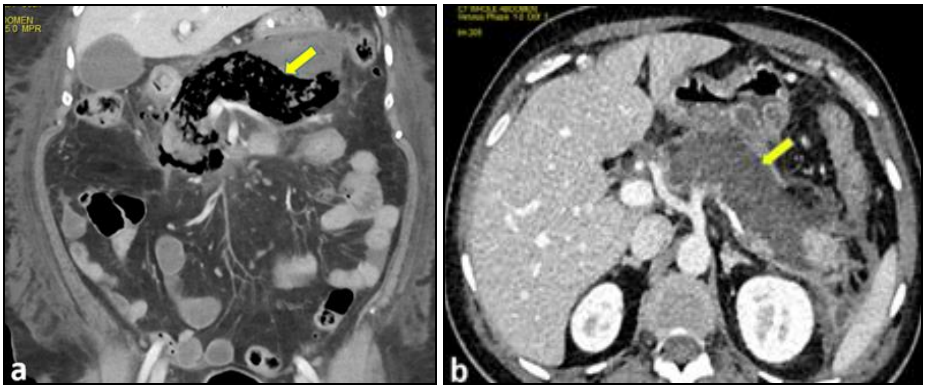

Fig 9: Coronal MPR showing extensive air replacing the entire pancreas, suggestive of emphysematous pancreatitis (arrow in a). Axial post contrast image shows extensive necrosis of the pancreatic parenchyma (arrow in b)

In our study 8 out of 10 cases of confirmed perforation were correctly diagnosed by MDCT. Two missed cases presented very late in the course of the disease, nearly after a week. Because of this delay in presentation these cases lacked the typical imaging features. Hence the perforation had already been sealed off and the pneumoperitoneum had been absorbed, the diagnosis was missed. In hallow viscus perforation the site of perforation can be exactly identified with MDCT. The early and occult perforations and sealed off perforations can be made out with MDCT, due to its ability to detect even smallest amount of free air. The sensitivity and accuracy for bowel perforation in our study was 80%, which was comparable to the study done by Sung Hwan Kim *et al.* and other investigators [16, 17, 18] who gave an accuracy of 82% to 90% for predicting site of perforation by CT.

In our study 5 out of 73 cases had urolithiasis, all the 5 cases were correctly identified by MDCT with sensitivity of 100%. The above findings are comparable with study performed by Isabelle Boulay *et al.* and others [19, 20, 21]. Leschka Sebastian *et al.* [5] state that thin slices and good multi-planar reconstructions helps in identifying even sub-millimeter calculi (Figure 10). This is complemented by the fact that nearly 100% of the renal calculi are radio-opaque.

Fig 10: Coronal MPR image showing the dilated calyces, and ureter in its entirety with an obstructing calculus in the mid ureter (arrow).

In our study 4 out of 73 cases had CT findings suggestive of cholecystitis with sensitivity of 100% which is comparable to other international studies. However the limitation of CT in gall bladder pathology is its failure to detect radio-lucent calculi, which could be the underlying predisposing factor for cholecystitis. Ultrasound and Magnetic Resonance Imaging (MRI) have better sensitivity in identifying Cholelithiasis. MDCT clearly performs better than ultrasound in detecting the complications like emphysematous cholecystitis and gangrenous cholecystitis. MDCT is the most sensitive modality in identifying complications related to cholecystitis as stated by L. Turturici *et al.* [22]

In 3 out of the 73 patients no significant abnormalities were detected by MDCT. And this was the case even in diagnostic laparoscopy. These patients were considered to have non-specific abdominal pain. The pathology in these patients presumed to be due to transient pain caused by intestinal colic or pain caused by a passing ureteric calculus, which would have completely passed out from the urinary bladder also, hence not seen in CT.

In our study the overall accuracy, sensitivity, specificity and positive and negative predictable values of MDCT were 96%, 97%, 75% and 98% and 60% respectively which were comparable to the study results of Monica Mangini *et al.* [23]

Conclusion

Acute abdomen is a commonly encountered, usually a surgical emergency. In our study the most commonly encountered pathologies were appendicitis, bowel

obstruction, bowel perforation and acute pancreatitis. It is essential to make a speedy and accurate diagnosis in these patients to decide on the management as to subject them to surgery or treat conservatively. For this purpose we need to employ a robust diagnostic tool. The clinical examination and laboratory parameters have very poor sensitivity and specificity, hence cannot be dependent upon. Very good sensitivity and specificity of MDCT makes it an ideal tool in the evaluation of acute abdomen. Recent advances in hardware, software and computation speed have made MDCT a powerful diagnostic tool in acute abdomen. MDCT scores over all other imaging modalities because of its speed and versatility.

Limitations of the study: Our study employed relatively small sample size, mainly because many patients were taken up for surgery based on ultrasound/radiography findings alone without CT. Though ultrasound may not give a specific diagnosis, these patients were taken up for surgery without CT, in the background of a given clinical scenario, like presence of guarding and rigidity in a suspected case of hallow viscus perforation where ultrasound showed free fluid and radiograph showed pneumoperitoneum which necessitated immediate laparotomy. Baring few specific conditions like gallbladder pathology and gynecological pathology MDCT is the primary modality of choice for evaluating acute abdomen.

Evaluation of acoustic radiation force impulse (ARFI) elastography as a tool for non invasive detection and grading of liver fibrosis with histopathology correlation

Viyannan Maheswaran, Vinu Adithi Vaishnavi and Balalakshmoji Devanand

DOI: http://dx.doi.org/10.33545/26644436.2020.v3.i1a.53

Abstract
Background: Chronic insult caused by viral infection, autoimmune disease, alcohol and other toxins can damage the liver parenchyma and ultimately lead to liver fibrosis and cirrhosis. Acoustic Radiation Force Impulse (ARFI) elastography is emerging as a valuable tool in the detection and grading of fibrosis in liver.
Materials and Methods: It is a prospective comparative study performed in 36 patients between December 2016 and March 2018 who presented with deranged liver function test and referred for ultrasonography, ARFI elastography of liver followed by liver biopsy. The findings of Elastography were correlated with histopathology.
Results: When compared with histopathology ARFI had a sensitivity of 82%, specificity of 85%, positive predictive value of 90% and negative predictive value of 75% in detecting liver fibrosis when we used optimum cut values of ARFI.
Conclusion: ARFI elastography is a valuable tool in non-invasively detecting liver fibrosis and can be included as part of routine ultrasonic examination protocol of liver. ARFI technology allows the quantification of liver fibrosis and can be effectively used to stage fibrosis. Hence ARFI can be used as an alternative to liver biopsy and it might substitute liver biopsy in future.

Keywords: Elastography, ARFI, liver fibrosis grading

Introduction
The incidence of chronic liver parenchymal disease is constantly on the raise. The major underlying causes are alcoholism and viral hepatitis [1]. In response to continuous inflammation and injury there is fibrosis [2, 3, 4] and regeneration which result in liver cirrhosis and the attendant complications like portal hypertension, variceal bleed, ascites, liver failure, hepatic encephalopathy and even development of hepatocellular carcinoma[1]. Generally cirrhosis is considered to be irreversible, however accumulating evidence suggests that it could be reversible to some extent, especially when targeted therapy is given [1, 3, 5]. Hence, early detection and grading the severity of liver fibrosis is of utmost importance for treatment. The degree of hepatic fibrosis is an important factor which influences the treatment and determines the prognosis of the underlying liver disease [1]. Therefore, there is tremendous need for quantitative assessment and grading of hepatic fibrosis. The method used traditionally for assessing the degree of liver fibrosis is liver biopsy. Which is considered as gold standard method for determining the extent of liver fibrosis. However it is an invasive procedure which is associated with patient discomfort and occasionally severe complications like bleeding, infection and rarely death [1]. Histopathological examination (HPE) of liver fibrosis is greatly dependent on the size of the sample and segment from which the sample is obtained. Generally a biopsy specimen of size 1.5-2cm is required by the pathologist for accurate evaluation. The distribution of fibrosis within the liver is very non-uniform and sampling errors are bound to happen. [4, 6, 7]These disadvantages associated with liver biopsy have been the thrust behind pursuing alternate methods to assess liver fibrosis. ARFI Elastography is a recently introduced technology to evaluate tissue stiffness non-invasively.

The technology of ARFI Elastography involves the mechanical excitation of tissue using short-duration acoustic pulses (push pulses) in a region of interest, producing shear waves that spread away from the region of interest, perpendicular to the acoustic push pulse, generating localized, micron-scale displacement of the tissue [8, 9]. Simultaneously, detection waves of lower intensity than that of the push pulse (1:100) are generated. By recording the shear wave front at several locations and correlating these measurements with the elapsed time, the shear wave velocity (SWV) can be quantified in meter per second unit. Generally, the stiffer a region in the tissue, the greater the SWV as it travels through this region. This technique can be used in various organs and it is well suited for liver in view of the size and relative superficial location of the organ. The advantage of this technology is that it is incorporated in an ultrasound machine and the operator can use the ultrasound to measure the stiffness of the tissue of interest in real time.

Materials and Methods

It is a prospective study performed from December 2016 to March 2018. Before starting the study necessary clearance was obtained from the institutional ethics committee and informed written consent was obtained from the patients. The study population includes 36 patients with clinical and laboratory features of altered liver function who were referred to radiology department for further evaluation with ultrasound. All the patients underwent liver sonography, ARFI Elastography and subsequently, with in a period of two weeks, liver biopsy. The findings of Elastography were correlated with HPE. Inclusion criteria: patients under evaluation for altered liver function parameters, nonalcoholic-steatohepatitis, chronic viral infections, patients undergoing liver biopsy for assessment of fibrosis. Exclusion criteria: Patients with bleeding disorders, altered coagulation parameters, patients unable to hold their breath and uncooperative. Ultrasound protocol: Examination was performed in SEIMENS S2000 machine in supine position. B mode Ultrasound: to assess the size, echogenicity and echo-texture of liver. ARFI Elastography: Total of 8 measurements of shear wave velocity were taken, at least 2 from each segment of right lobe. Measurement was calculated by placing a 0.5 x 1cm box at least 1.5 to 2cm deep to the liver capsule (Fig. 1) and away from major vessels. The velocity was calculated in meter per second and the mean and median velocity of all 8 measurements were used to grade the stiffness of the liver.

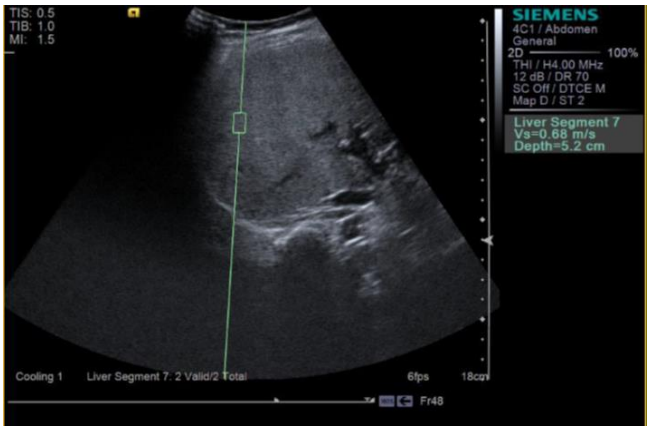

Fig 1: Measurement of ARFI by placing an ROI in each segment of the right lobe of liver.

Biopsy: Biopsy of the liver was obtained using 18G fully automatic gun (Bard MaxCore) with 22mm long cutting needle harvesting a 20mm long core. The specimen was fixed in formalin and sent for HPE. Fibrosis was scored in histopathology using the METAVIR scoring system. The cut of value [10] of shear wave velocities corresponding to METVIR grades is shown in Table 1:

Table 1: METAVIR Score and corresponding mean SWI in ARFI

Metavir Score	Histopathology	Mean Shear Wave Velocity
F0	No fibrosis	1.09+/- 0.42m/s
F1	Portal fibrosis without septa	1.22+/- 0.41m/s
F2	Portal fibrosis with few septa	1.37+/- 0.48m/s
F3	Numerous septa without cirrhosis	1.70+/- 0.59m/s
F4	Cirrhosis	2.23+/- 0.71m/s

Results

In this study 36 patients were evaluated with Ultrasonography and Elastography, the findings were compared with the HPE findings. In our study out of 36 patients 10 (28%) patients were female and 26 (72%) were male who presented with liver disease and altered liver function tests with different underlying pathologies like Nonalcoholic steatohepatitis (NASH), chronic viral hepatitis, storage disease and Cryptogenic cirrhosis. Our study had patients ageing from 11 years to 60 years with an average of 30 years. We had 14 (39%) patients below the age of 30 and 22(61%) patients more than 30 years of age. The distribution of various grades of fibrosis in the study population is shown in figure 2. The number of patients in the study population with various grades of fibrosis in ARFI and HPE is shows in table 2.

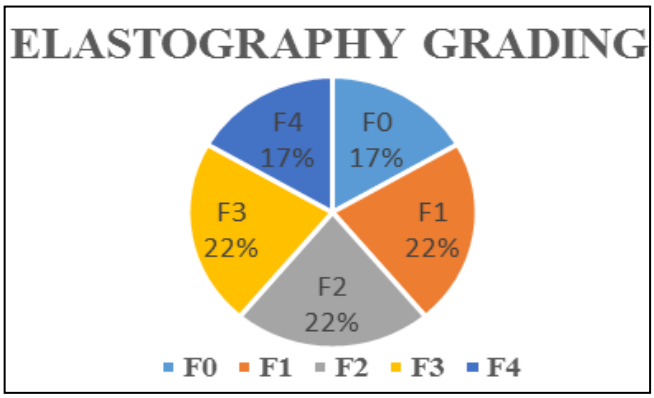

Fig 2: Distribution of various degrees of fibrosis in the study population in ARFI.

Table 2: Grading of fibrosis

	ARFI		HPE	
	Frequency	Percent	Frequency	Percent
F0	6	17	10	28
F1	8	22	4	11
F2	8	22	8	22
F3	8	22	4	11
F4	6	17	10	28
Total	36	100	36	100

B mode ultrasound findings of liver are shown in Table 3. Out of the 36 patients 4 had normal appearing liver, majority showed diffuse fat infiltration in the liver and 8 patients had altered echo-texture of liver parenchyma.

Table 3: Ultrasound findings in study population

Frequency		Percent
Normal	4	11
Steatosis	24	67
Altered echo texture	8	22
Total	36	100

In our study of 36 patients, ARFI showed clinically insignificant fibrosis in 16 patients with a METAVIR score of F0, F1 which was commonly seen with patients of acute hepatitis and nonalcoholic steatohepatitis. Clinically significant fibrosis (F2, F3, and F4) was seen in 20 patients with a majority of them affected by chronic viral hepatitis. (Tables 4).

Biopsy showed clinically insignificant fibrosis (F0, F1) in 14patients (39%) and clinically significant fibrosis (F2, F3, F4) in 22 patients (61%). Of the 14 patients who had insignificant fibrosis, different underlying etiologies such as NASH, storage diseases and autoimmune hepatitis were found, patients with significant fibrosis had viral hepatitis. (Tables 4).

Table 4: Significance of fibrosis in ARFI and HPE

	ARFI		HPE	
	Frequency	Percent	Frequency	Percent
Significant fibrosis	20	56	22	61
Insignificant fibrosis	16	44	14	39
Total	36	100	36	100

The cross tabulation comparing various grades of fibrosis in ARFI and HPE are shown in table 5.

Table 5: Elastography Grade Vs Histopathology Grade Cross Tabulation

			HPE Grade					Total
			F0	F1	F2	F3	F4	
ARFI Elastography Grade	F0	Count	2	0	2	0	2	6
		% with ARFI grade	33.3	0	33.3	0	33.3	100%

Discussion

Generally fibrosis is thought to be an irreversible process till the discovery of hepatic stellate cells (HSC) in the 1980s. HSCs play an important role in fibrosis. Following chronic liver injury HSC under inflammatory milieu proliferate and activate to produce pro inflammatory and fibrogenic factors. Activated HSC produce large amounts of extracellular matrix (ECM). The extracellular matrix accumulates and distorts the liver architecture and forms a fibrous scar along with regeneration of hepatic tissue which subsequently lead to formation of the nodules. Studies carried out in the 1990s demonstrated that hepatic fibrosis was a reversible process if the cause was to be treated [2, 3, 4]. Since then researchers have taken keen interest in developing therapies for reversing/slowing down progression and severity of liver fibrosis. Thus, assessing the stage and severity of fibrosis precisely has taken the center stage in the management of chronic liver disease. In fibrosis and cirrhosis the pathological changes in tissue lead to alteration of mechanical properties like stiffness which can be measures noninvasively. The gold standard for assessing liver fibrosis

is biopsy and HPE. Liver biopsy, though safe, is an invasive procedure with a small risk of complications like severe hemorrhage. The risk of significant bleed is more when there is alteration of the coagulation parameters or in the presence of significant ascites. Both these risk factors are seen more frequently in patients with liver parenchymal disease, which in the first place is the indication for doing a biopsy. Percutaneous liver biopsy yields only a tiny fragment of the liver (1 in 50000 of the total volume of the liver) [11] which may lead to errors in staging of fibrosis, since there can be non-uniform distribution of fibrosis with in the liver. Bedossa *et al* [12] proved that the chance of under diagnosis of the stage of fibrosis, when the length of biopsy core is less than 2.5 cm can reach up to 25%. They have also proved that in almost half of the cases where liver fragments obtained from both the lobes of liver in the same session showed different stages of fibrosis. Hence in many ways liver biopsy is a flawed gold standard. For the past 10-15 years, enormous efforts have been made by several groups for establishing a reliable and reproducible noninvasive marker for liver fibrosis as a substitute to the invasive liver biopsy technique. In our study of 36 patients we have attempted to study the efficacy of ARFI compared to histopathology. The accuracy of ARFI elastography for assessing the severity of liver fibrosis and grading was evaluated. Calculating the sensitivity, specificity, positive predictive value and negative predictive value of the noninvasive test ARFI demonstrated a good sensitivity and specificity. Accurately grading and quantifying the severity of hepatic fibrosis secondary to an underlying disease is of great importance for planning appropriate treatment strategies. Studies comparing the non-invasive methods for evaluating the severity of fibrosis in chronic liver disease to liver biopsy are being performed to assess if these techniques would replace the invasive test. Virtual touch tissue imaging application enables ARFI technology to evaluate the deep tissues. SWI in meter per second can be quantified in a region of interest with ARFI technology in a precise anatomical location, which represents the elasticity property of the tissue. In our study we encountered 4 false negative patients. One of them was hepatitis B patient and another one patient with Hepatitis C. In these cases we presume values taken in the areas of necrosis may have contributed to low values. Another 2 patients were cases of alcoholic hepatitis, in whom the steatosis may have contributed to the falsely low values. We also had 2 false positive patients encountered in our study. One of them had hepatitis B acute stage and another one patient had hepatitis A. Hepatitis is known to have both inflammation and fibrosis, one of which may predominate depending upon the stage of disease [13, 14]. In acute stage because of inflammation, we can get erroneous high values [15, 16]. There are no possible means to differentiate the high values due to inflammation from that due to fibrosis. This may explain the false positivity in the hepatitis patients.

A study by Takahashi *et al*. [17] of 80 patients with mixed etiologies using ARFI (Siemens Healthcare), had a sensitivity and specificity of 91% and 80% respectively for F>2 stage of fibrosis. This is in concordance with the results in our study. In a similar study by Sporea at al. [18] using 114 patients with mixed etiologies, also had a sensitivity and specificity of 89% and 68% respectively. We attempted to study whether ARFI was sensitive in patients with NASH, who form the majority of the mixed etiology liver disease without viral hepatitis group. 10%-15% of NASH patients show a progression in the severity of fibrosis and architectural remodeling, and liver cirrhosis is seen in 15%-25% of cases. Three to 5% of people with fatty liver may develop cirrhosis. Cirrhosis due to NASH and cryptogenic cirrhosis have risk of developing HCC. HCC may rarely occur in a non-cirrhotic NASH patient. Hence lies the importance of detecting early fibrosis in patients with NASH [18, 19]. In a study conducted by Fraqueli *et al* [20] using 200 patients with mixed etiology liver diseases other than viral hepatitis, the sensitivity and specificity of ARFI was 72% and 84% respectively. In a study of 106 patients with HBV and HCV conducted by Friedrich-Rust *et al* [21] the sensitivity and specificity was 69% and 92% respectively. In our analysis of 28 HBV and HCV patients, we had a sensitivity of 90% and specificity of 75%. The liver stiffness assessment is challenging in patients with viral hepatitis because of the nature of underlying disease. There may be increased necro-inflammatory changes in the acute phase of the disease which undergoes fibrosis later on. The necrotic areas will give lower stiffness values compared to the other areas of inflammation thus may decrease overall sensitivity. The higher sensitivity in our study may be because these patients were assessed in the advanced stage of the disease. Review of previous publications and our own study has shown that US elastography definitely has a role in the staging of fibrosis where it has the potential of replacing liver biopsy. Another upcoming and exciting non-invasive modality to evaluate liver fibrosis is MR Elastography which has the advantage of avoiding sampling errors and operator variability. New MR imaging contrast agents that target specifically the collagen and other extracellular matrix macromolecules may be developed in the near future. A collagen-specific MR imaging contrast agent and also contrast agents that selectively target hepatic stellate cells and other cells involved in the pathogenesis of liver fibrosis may permit imaging of fibrogenesis or fibrolysis. All such data may provide valuable information for guiding antifibrotic therapy development and monitoring patients in clinical trials. Thus these noninvasive methods may help in the assessing the severity of fibrosis.

Conclusion

Acoustic Radiation Force Impulse (ARFI) elastography is a promising noninvasive tool to quantify liver fibrosis. It also has the advantage of routine ultrasound assessment of the liver during the same session of elastography study. ARFI measurements are done in real time under vision. As many number of measurements as the operator wishes can be obtained in a single study. The assessment can be repeated frequently as and when required. The technique has good sensitivity and specificity and less operator dependent when compared with other ultrasound techniques as the calculation is done automatically by the system and there are tools which are useful to obtain a good quality study. The technique has good sensitivity and specificity which has the potential to replace invasive biopsy. Limitations: Our study is limited by the relatively small sample size. The small sample size is primarily due to limitation in the number of patients undergoing biopsy. ARFI elastography is a relatively new technology that has not been extensively investigated, hence large prospective studies are needed to ascertain its efficacy and to form strict cut off values for the shear wave velocity. Different technologies and

measurement calculations are adopted by different ultrasound venders. Because of this standard values are not available for comparison across different ultrasound systems [22], which needs to be addressed by various ultrasound manufacturing vendors and an amicable consensus to be arrived at.

Abstract

Hereditary hemorrhagic telangiectasia (HHT) or Osler–Weber–Rendu syndrome is a rare condition which can result in significant *systemic and hepatobiliary* abnormalities. Liver involvement in HHT consists primarily of the consequence of various intrahepatic shunts. Even though these vascular shunts are present in the majority of patients with HHT, symptoms occur only in *minority* with clear predilection to *female gender*. The symptoms and imaging findings of liver vascular malformations can be easily overlooked or misdiagnosed which can result in delay in treatment or potentially harmful vascular interventions. In this case report, we discuss the pathophysiology of HHT in liver involvement, role of imaging in diagnosis, and the possible role of interventional radiologist in the treatment.

Key words: Embolization for shunt reduction; hereditary hemorrhagic telangiectasia; intrahepatic shunts; liver vascular malformation

Introduction

Hereditary hemorrhagic telangiectasia (HHT) is an autosomal dominant disorder seen approximately in one in 5000–8000 individuals.[1] It presents with vascular malformations (VM) in the nose, skin, liver, gastrointestinal tract, brain, and lung. Telangiectasia is the VM seen in HHT where there is direct communication between the arterioles and venules without the intervening capillaries. This abnormal communication can result in shunts between various vascular beds in the solid organs and hallow viscera. Definitive clinical diagnosis of HHT can be made based on the presence of at least three of four Curacao criteria,[2] published in 2000. They are 1. Epistaxis, 2. Cutaneous or mucosal VM, 3. Presence of visceral telangiectasia, and 4. Positive family history. Liver involvement is seen in approximately 75% of people with HHT.[2] Although only a small 8%–10% of these patients develops symptomatic liver pathology, the rest remains asymptomatic.

Case Report

We are presenting a patient who presented with upper gastrointestinal (GI) bleed and epistaxis with anemia. On further evaluation, she was found to have telangiectasia in the nose and multiple angioectasias in the stomach and in the duodenum in upper GI endoscopy. This

triad of findings, 1. Spontaneous recurrent epistaxis, 2. Telangiectasia of nose, and 3. Visceral telangiectasia, fulfill 3 Curacao criteria to qualify for definitive diagnosis of HHT. Further evaluation with contrast-enhanced computed tomography (CECT) was done to rule out chronic liver parenchymal disease. The CECT revealed heterogenous enhancement of the periphery of the liver in the arterial phase [Figure 1A] which becomes homogenous in the venous phase [Figure 1B]. In addition, there was moderately enlarged proper hepatic artery measuring 10 mm in diameter (normal <7 mm) and abnormally dilated intrahepatic branches of the hepatic artery and early filling of the portal venous branches [Figures 2A, B and 3]. There were abnormal tortuous vascular channels along the ligamentum teres with early filling of the branches of portal vein [Figures 3 and 4]. There were faintly enhancing tortuous vascular channels along the intrahepatic branches of the hepatic artery. There was slight reduction in the volume of the left lobe of liver. The surface of the liver was smooth. All these imaging features were suggestive of intrahepatic arterio-portal shunts with possible secondary chronic liver parenchyma disease. She was treated symptomatically with cauterization of the nasal telangiectasia, nasal packing, and blood transfusion for anemia. Few small telangiectasia lesions in the stomach showed active bleed during endoscopy and these lesions were treated with argon plasma coagulation.

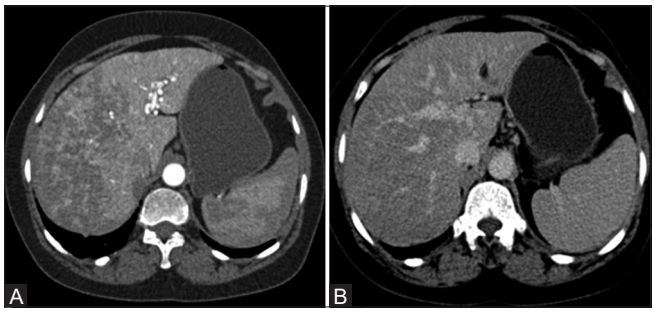

Figure 1 (A and B): Contrast-enhanced CT axial section shows heterogenous enhancement of the liver parenchyma in the arterial phase (A) which becomes homogenous in the venous phase (B)

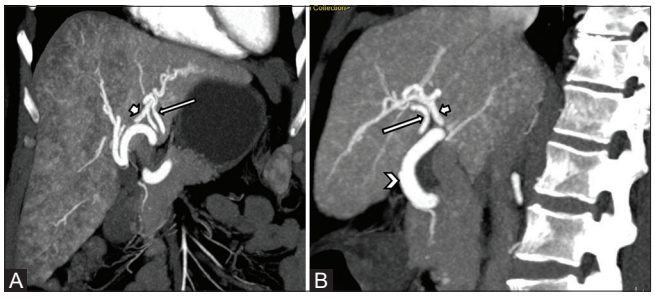

Figure 3 (A and B): Coronal (A) and sagittal (B) maximum intensity projection (MIP) images showing enlarged hepatic artery branches—long thin arrows (in A and B)—and early filling of the portal venous branches—short thick arrow (in a and B). The enlarged main hepatic artery is marked with arrow head in B

Discussion

In HHT, clinical symptoms occur in approximately 8% of the people.[3] There is a distinct female preponderance in symptomatic patients, with majority of the patients presenting in their fourth decade.[3] Presenting features are secondary to high-output cardiac failure (most common),[3] portal hypertension, GI bleed either from varices due to portal hypertension or angioectasia of the mucosa of the GI tract, and biliary disease. Other less common forms of clinical presentation in the liver and GIT are portosystemic encephalopathy and abdominal angina. The basic pathophysiology in liver involvement is development of intrahepatic VMs. Liver vascularity is unique by the way of presence of dual arterial supply and presence of dormant, potential portosystemic shunts, like paraumbilical vein, which can open up in any form of disturbance in the equilibrium of liver circulation.

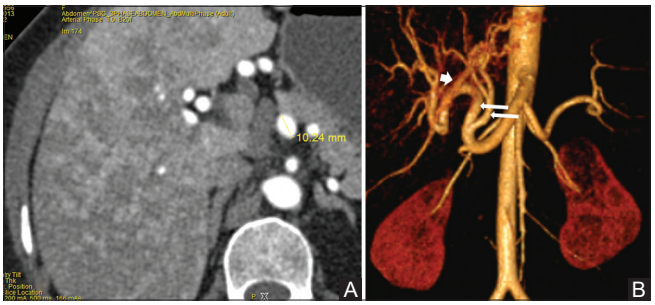

Figure 2 (A and B): Axial CT image in the arterial phase acquisition (A) and 3D volume rendered image (B) showing enlarged hepatic artery proper, measuring more than 10 mm. There is enlarged proper hepatic artery and its branches (long thin arrows in B) and early filling of the portal venous branch (short thick arrow in B) seen with fuzzy margins

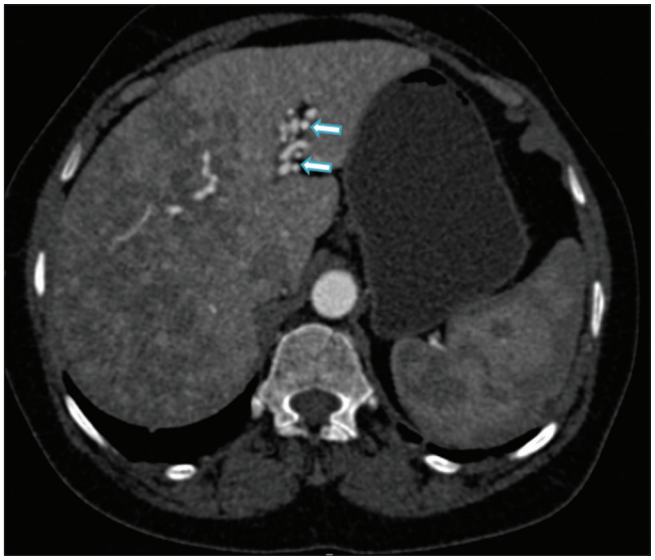

Figure 4: Axial CT image showing multiple tortuous early filling portal venous branches along the ligamentum teres (arrows) seen along with the left hepatic artery branches

The VMs in the liver can lead to three different types of vascular shunts.[3,4] These are 1. Arterio-venous (AV) shunt (between the hepatic artery and hepatic vein), 2. Arterio-portal (AP) shunt (between the hepatic artery and portal vein), and 3. Portal venous (PV) shunt (between portal vein and hepatic vein).[1] Shunts are usually extensive. The shunts can be visualized by imaging studies if they are macroscopic. Frequently they can be microscopic and not seen in imaging. Each predominant type of shunt gives rise to distinct clinical manifestation.

AV shunt

This is the most common symptomatic VM. It usually affects women. The presenting clinical feature is related to high-output cardiac failure.[1] AP shunt can also involve liver leading to biliary ischemia and ischemic necrosis of the bile duct[5] due to steal phenomenon. The loss of integrity of the bile duct due to ischemia can lead to biliomas and intrahepatic biliary cysts mimicking Caroli's disease. In chronic cases, *secondary sclerosing cholangitis* develops with stricture and abnormal dilatation of intrahepatic bile ducts. Biliary ischemia-related complications are seen *exclusively* in women.[3]

AP shunt

This is the second most common shunt after AV shunting. Shunting of blood from the hepatic artery to the portal vein causes *portal hypertension*. Secondary to portal hypertension, there can be ascites, varices formation, and GI bleed. In addition, there can be formation of focal nodular hyperplasia and *nodular regenerative hyperplasia in the liver*. It equally affects men and women. The diagnosis is made based on hepatic venous pressure gradient which should be more than or equal to 10 mmHg.

PV shunt

This is the least common type of shunt and usually causes high-output cardiac failure. Rarely, this can cause focal nodular hyperplasia and nodular regenerative hyperplasia in the liver which can lead to portal hypertension and cirrhosis.

Diagnosis of HHT is made based on the Curacao criteria.[2] Imaging is indicated to confirm the diagnosis if three of the four clinical criteria are not met. In addition, imaging has to be done to look for associated complications like liver cirrhosis. In a known case of HTT, the presence of ascites, GI bleed, and abdominal pain should raise the suspicion of liver involvement and imaging should be performed. Doppler study can show abnormal tortuous vessels in the liver. CECT and MRI can reveal multiple liver VMs. There can be enlarged hepatic artery, normal ≤7 mm,[1] heterogenous enhancement of the liver in the arterial phase of contrast study which becomes homogenous in the venous phase.

CT is the recommended *imaging modality* of choice. In CECT, the type of shunt can be determined in two-third of patients. The majority of patients with liver disease will show AV shunt. Biliary disease is generally seen in the late phase of the disease. The gold standard to establish the type of shunt is angiography.[3] Angiography can clearly demonstrate the early, subtle VMs and mesenteric steal syndrome. However, in the majority of the patients, the diagnosis can be established with less invasive imaging methods like CECT.

Treatment

No treatment needed in asymptomatic patients with liver involvement. Primarily, the management is medical with treatment of anemia and correcting coagulation abnormalities.[6] High-output cardiac failure and complications of portal hypertension are treated in the standard way like treating cardiac failure and portal hypertension due to other etiologies. It should be noted that trans-jugular intrahepatic porta systemic shunt (TIPS) creation may not be effective in the treatment of GI bleed secondary to telangiectasia of the GI tract. Shunt reduction procedures like embolization may be considered in patients with cardiac failure and mesenteric ischemia.[7] However, these procedures are associated with high morbidity and mortality and have only transient therapeutic effect. In carefully selected patients, few sessions of endovascular embolization may be effective in reducing portosystemic shunt and alleviating mesenteric ischemia. Ultimately patients might require liver transplantation, which can be curative.

Conclusion

HHT is a rare cause of vascular dysplasia involving many organs and systems. Although the majority of the patients remain asymptomatic, high index of suspicion should be kept not to miss liver involvement by the disease. Radiologists should be aware of the imaging findings and possible treatment options like shunt reduction embolization offered by us. Life-threatening complications like high-output cardiac failure not responding to maximum medical therapy and severe biliary ischemia should be recognized and these patients should be referred for an early liver transplant.

Abstract

Background Acute ureteric colic is one of the most commonly encountered acute abdominal conditions. Diagnosis of obstruction caused by ureteric calculus occasionally becomes challenging if there is inadequate dilation of the urinary tract proximal to obstruction. In such a situation, intra-renal artery Doppler parameters can be used as a diagnostic tool. Our study compared intra-renal arterial Doppler in patients with obstructed and non-obstructed kidneys presenting within 24 h of onset of symptoms of unilateral acute renal colic.

Results The resistivity index (RI) in the segmental arteries of all 54 patients with obstructed kidneys was significantly higher than in those with non-obstructed kidney: 0.75 vs. 0.56, with a p value less than 0.001, a sensitivity of 85% and a specificity of 93%.

Conclusion Doppler ultrasound is a useful diagnostic tool in the evaluation of acute renal obstruction, thus enabling practitioners to avoid ordering unnecessary CT and exposing patients to ionizing radiation. An RI value > 0.7 has good sensitivity and specificity in our study. The results obtained in the study were comparable to those of pioneer studies conducted worldwide.

Background

Acute renal colic (ARC) is one of the common causes of patients presenting to the emergency room (ER). It accounts for 30–35% of urologic emergencies [1, 2]. The recurrence rate over a period of 5 years is 30–40% [2]. Ultrasonography (US) remains the most commonly used modality in the initial evaluation of patients presenting with acute abdomen, especially in children [3], and the utility of ultrasound in the diagnosis of ARC cannot be overstated in cases where ARC is one of the most common pathologies presenting as acute abdomen. Absence of significant dilatation of the pelvicalyceal system, in spite of severe obstruction being present, is a well-recognized finding in some patients. In some

Published online: 18 November 2020

Author's personal copy

studies, the absence of significant dilation in ARC has been reported in up to 30% [4] of patients. The dilated collecting system seen in US need not always be due to obstruction in the downstream urinary tract. These conditions include a baggy extra-renal type of pelvis, a compound upper pole calyx, due to over-distended urinary bladder, vesico-ureteric reflux, congenital type of mega calyces, infection and residual dilatation due to previous obstruction. Very rarely, pseudo-aneurysms of intra renal arteries can mimic renal pelvi-ectasis. This kind of vascular pathology can also be easily diagnosed with CDUS [5]. Acute complete ureteric obstruction is associated with changes in renal blood flow, as well as with an increase in renal pelvic pressure. In the first few hours, renal blood flow increases, and after 3 to 5 h, renal blood flow decreases, probably because of efferent arteriolar vasoconstriction produced by prostaglandins and other vasoactive substances [6, 7]. These changes can be effectively demonstrated by the RI of intra-renal arteries, as measured by Doppler ultrasound.

Methods

A prospective study was done on 54 patients who were referred to the department of radiology with clinical features of ARC for further evaluation with ultrasound or non-contrast CT. The study period is from January 2015 to December 2017. Prior to the commencement of the study, necessary clearance was obtained from the institutional ethics committee, and informed written consent was obtained from all the participating patients.

Inclusion criteria

All patients with symptoms of acute ureteric obstruction presenting to the emergency department within 24 h of onset of unilateral ARC were included.

Exclusion criteria

(a) Patients with history of renal parenchymal disease, chronic renal obstruction, renal trauma, or bilateral renal obstruction; (b) patients with a single kidney; and (c) patients in whom ureteric obstruction could not be confirmed either with USG or with CT were excluded.

All patients underwent gray-scale ultrasonography (US) and Doppler evaluation of intra-renal arteries. Computed tomography (CT) was done for those patients in whom US could not confirm the cause of obstruction.

Evaluation by ultrasound and Doppler study

The kidney on the side of obstruction was treated as the case kidney, and the contralateral normal (non-obstructed) kidney served as control. All patients underwent B-mode US and color doppler ultrasound (CDUS) with Philips iU22 using a C 1–5 transducer and Siemens Acuson S3000 using a 6C1 HD transducer. The presence or absence of pelvicalyceal system dilatation in each kidney was assessed using the gray-scale images. At least three Doppler spectra were obtained from inter-lobar arteries along the border of the medullary pyramids, and their mean was taken (Fig. 1).

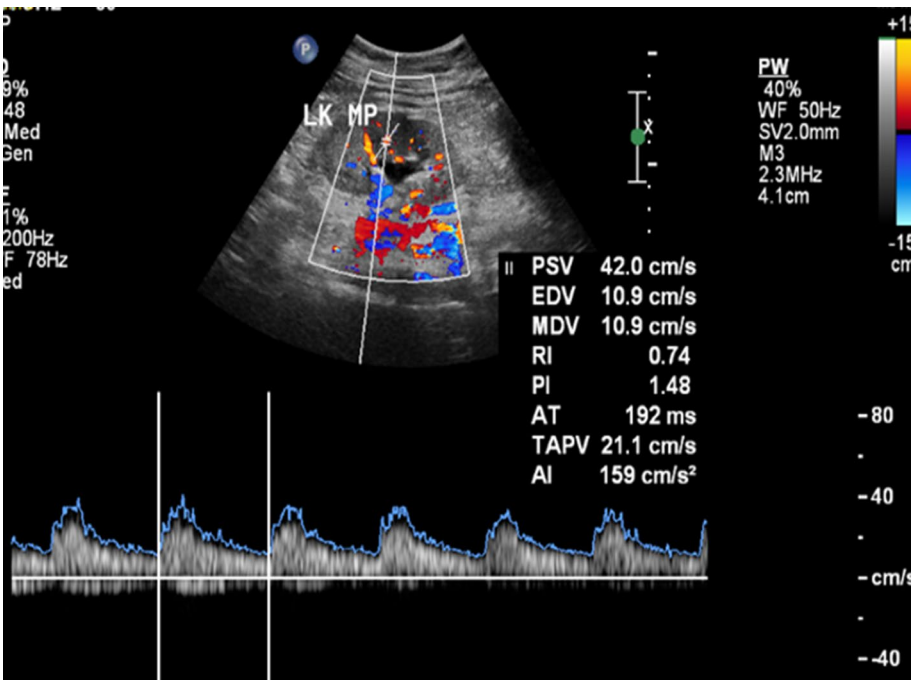

Fig. 1 Doppler US demonstrating an RI value of 0.74 in the mid pole of left kidney (obstructed kidney)

Author's personal copy

The Doppler waveforms were made using the lowest pulse repetition frequency possible without aliasing. This maximized the size of the Doppler spectrum and decreased the percentage error in the measurements. In addition, the lowest possible wall filter for each ultrasound scanner was used. The Doppler sample width was set at 2–3 mm. The renal RI was calculated using the standard formula. The mean RI value was calculated for each kidney.

Evaluation by computed tomography

Siemens SOMATOM Definition Edge 128 slice Computerized Tomography (CT) equipment was used for the study. Non-enhanced CT of the abdomen, extending from the dome of the diaphragm to the pubic symphysis, was performed in all patients in whom the site and cause of obstruction could not be confirmed with US. Raw data was acquired with 0.6 mm thickness and pitch of 0.8. Reconstruction from the raw data was done in 5 mm thickness for viewing purposes and in 1 mm thickness for coronal and sagittal multi-planar reconstruction (MPR) (Fig. 2). The sites of ureteric obstructions were identified. Those patients not confirmed to have obstructions by CT were excluded from the study.

Statistical methods

All data were systematically collected, tabulated and analyzed using Microsoft Excel and Strata 6 for Windows. The Student *t* test was used in univariate analysis for the continuous variables, and Chi square test was used for analysis of noncontiguous variables. A *p* value of less than 0.05 was considered to be statistically significant.

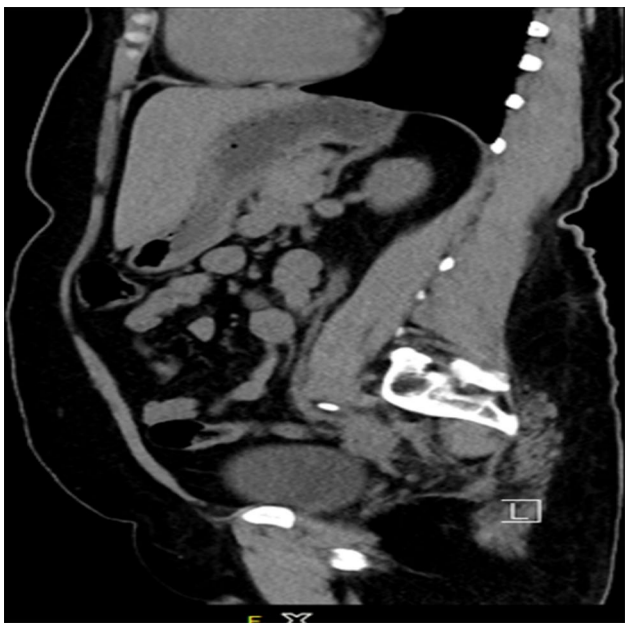

Fig. 2 Sagittal reconstruction of non-enhanced CT showing a calculus in the left distal ureter who presented with acute left renal colic

Results

This study evaluated 54 patients who had presented to the EMD with unilateral ARC within 24 h of the onset of symptoms. All the patients underwent B-mode US, CDUS and CT if the obstruction could not be confirmed in US. The presence or absence of PCS dilatation in each kidney was assessed using the grey-scale images. In this study population, 34 patients were males and 20 were females, as shown (Fig. 3). The mean age of the male patients was 46.8 years and that of the female patients was 38.5 years. The age range of the male patients was 19–79 years, and that of the female ones was 18–61 years.

The modalities used in the diagnosis and the site of obstruction are shown in Tables 1, 2.

Out of 54 patients, 26 cases proximal obstructions, while 28 had distal obstructions. The mean RI of the obstructed kidneys was higher in cases of distal obstruction (0.79 ± 0.004) than in those of proximal obstruction (0.76 ± 0.006).

Of the 54 patients, 45 patients had mild hydronephrosis, FIVE patients had moderate hydronephrosis and four patients did not have any dilatation of the collecting system despite the presence of ureteric obstruction (Fig. 4).

Of the 54 patients who were included in this study, 27 patients had elevated renal parameters, but did not have history of chronic renal impairment (Table 3).

In our study, we found that the RI in obstructed kidneys was significantly higher than in unobstructed kidneys (0.75 vs. 0.56; $p < 0.001$). The RI was higher in obstructed kidneys in all cases. The difference in RI between the obstructed and unobstructed kidneys (delta RI) ranged from 0.09 to 0.38, with a mean delta RI of 0.24 (Table 4).

The RI values in obstructed kidneys ranged from 0.68 to 0.84 (Fig. 5). The mean RI value in obstructed kidneys was 0.75, compared to 0.56 in unobstructed kidneys.

The group statistics of RI are shown in Tables 5, 6. The receiver operating characteristic curve (ROC) curve depicting the sensitivity of RI in ureteric obstruction is shown in Fig. 6.

By using a cut off RI value of > 0.70 in acute unilateral renal obstruction, the sensitivity obtained in the study was 85% and the specificity was 93% (Table 7).

Discussion

Grayscale ultrasound is the investigation method of choice in the initial evaluation of ARC, as it is easily available, portable and involves no ionizing radiation [8, 9]. However,

urinary system dilatation seen on conventional gray-scale USG has been shown to be sensitive (90%), but not specific (65–84%), in the diagnosis of renal obstruction.

The most sensitive, gold standard test for diagnosing obstructive uropathy is renal scintigraphy. However the availability of scintigraphy and radiation associated with it continue to be problematic [10]. Traditionally, the evidence of renal obstruction provided by US has been indirect and dependent on the anatomical criterion of dilatation of the pelvicalyceal system and ureter proximal to the level of obstruction. However, US fails to reveal hydronephrosis in acute obstruction of the kidney in up to 35% of cases [11]. More direct functional evidence of obstruction usually requires scintigraphy, but recently Doppler US techniques have been used to obtain functional information in suspected renal obstruction [11]. US imaging may miss (false negative) the diagnosis of obstruction in a variety of situations. Mild dilatation may be overlooked or considered clinically insignificant. Some patients with obstructive renal failure may show no pelvicalyceal system (PCS) dilatation. The reasons for this are unclear; in some patients, it may be related to dehydration or due to decompression of the pelvicalyceal system by rupture of a calyceal fornix [12]. It is commonly explained by urologists to be caused by the use of non-steroidal anti-inflammatory drugs (NSAIDs), by dehydration or by the renin angiotensin effect [13]. If that is true, such impairment will be detected through measurement of glomerular filtration rate (GFR). Measurement of GFR is commonly done using Technetium c-99 m diethylene-triamine-penta-acetate (DTPA), and does not require blood or urine sampling [14]. There is a growing evidence that renal impairment in acute unilateral ureteric obstruction is due to absorption of obstructed urine, with its high amount of creatinine, back into systemic circulation. This is considered false renal impairment with normal GFR [15]. In a study, El-Shazly et al. [16] measured renal function through measurement of estimated GFR (eGFR) usingTc-99 m DTPA. The authors showed that differences between eGFR on admission and after passage of stone or relieve of obstruction were non-significant. Their results support the hypothesis of false impairment in this clinical scenario. This tends to change the practice, as there is no need to embark on urgent intervention to relieve the ureteric obstruction, and conservative medical management is justifiable.

Routine B-mode US can be falsely positive or negative in acute ureteric obstruction [10]. PCS dilatation may be missed if the system is filled with blood clots, calculus, tumors or pus, in which case the usual anechoic appearance

of the PCS is lost. Intermittent ureteric obstruction, particularly that caused by ureteric calculi, may also lead to a failure to visualize dilatation of collecting system with US. On the other hand, in an attempt not to miss the diagnosis of obstruction in patients with only mild PCS dilatation, the false positive rate was found to be as high as 26% Causes of a false positive diagnosis include: (i) dilatation of non-obstructed PCS, when there are anatomical variants such as extra-renal pelvis; (ii) over-distended urinary bladder, with or without diuresis; (iii) vesico-ureteric reflux (VUR), (iv) residual dilatation of PCS due to previous obstruction or infection; (v) advanced pregnancy; and (vi) central renal fluid collections other than in the PCS, including in normal vessels, renal artery aneurysms and para-pelvic cysts.

Acute unilateral ureteric obstruction results in a complex sequence of changes in renal blood flow and ureteric

Cut off RI	Sensitivity	Specificity
> 0.70	85%	93%

pressure [17]. In the first two hours, the renal blood flow increases, because of afferent arteriole vasodilatation and the ureteric pressure increases. From two to six hours after obstruction, the renal blood flow decreases, secondary to vasoconstriction of the efferent arterioles, and the ureteric pressure remains elevated. Subsequently, at 6 to 18 hours, the renal blood flow remains reduced because of vasoconstriction of the afferent arterioles, and the ureteric pressure decreases.

The role of renal CDUS in the evaluation of ARC has been vigorously debated. Rodgers et al. [18] found an elevated RI in acutely obstructed kidneys, especially when compared with the RI in normal contralateral kidneys and with a control group of healthy subjects. Similar results were obtained by Platt et al. [19] in a study of 23 patients with acute unilateral ureteric obstruction. However, others have reported that Doppler ultrasound is highly insensitive for detecting ARC. Tublin et al. [20] correlated the results of Doppler USG with those of urography in 32 patients presenting with symptoms of renal colic. The RI value of normal kidneys is usually less than 0.7 [21, 22]. When the published discriminatory thresholds for obstruction (mean RI ≥ 0.70 and ΔRI ≥ 0.10) were applied, the sensitivity and specificity of Doppler USG were only 44% and 82%, respectively.

In our study of 54 patients, we found that the RI in obstructed kidneys was significantly higher than in the unobstructed kidneys (0.75 vs. 0.56; $p < 0.001$). The RI was higher in obstructed kidneys in all cases. The difference between the obstructed and unobstructed kidneys (delta RI) ranged from 0.09 to 0.38, with a mean delta RI of 0.24.

Saboo et al. [6] stated in their study that delta RI ≥ 0.006 was highly sensitive and specific, and with a higher delta RI specificity remained the same whereas the sensitivity fell rapidly. Our results correlate well with those reported in earlier studies by Badr et al. [23] and Miletic et al. [24].

We also studied the effect of the level of obstruction on RI values. When we compared levels of ureteric obstruction (proximal vs distal), distal obstructions had a higher mean RI value (0.79) than proximal obstructions (0.76), and the values were not statistically significant. However, the study done by de Toledo *et al.* [25] showed that patients with proximal ureteric obstructions have RIs higher than those with distal obstructions.

We also analyzed the utility of CDUS in patients who did not show dilatation of the PCS on ultrasound. Patients who did not have PCS dilatation on US were later confirmed to have obstruction on CT. RI values were higher in all these patients (0.71), with a delta RI of 0.24. Discriminatory RI ≥ 0.70, which is higher than the delta RI found in the study done by Platt JF et al. [26], was found to be highly sensitive (85%) and specific (93%) in this study.

Conclusion

Using the discriminatory threshold RI of ≥ 0.70, the overall sensitivity of CDUS in diagnosing acute ureteric obstruction is 85% and the specificity is 93%. CDUS is a useful tool for demonstrating altered renal perfusion in acute ureteric obstructions before pelvicalyceal system dilatation occurs, thus increasing the sensitivity and specificity. Gray-scale US should therefore, be complemented by CDUS as an adjunctive test in patients presenting with acute renal colic, as it is a very simple, noninvasive and easy-to-calculate parameter. The utility of this tool cannot be overemphasized in special cases like pregnant women and children, in whom a dilated pelvicalyceal system without acute obstruction is encountered more frequently. It is mandatory to differentiate obstructive and non-obstructive causes with US alone in this subset of patients, as further evaluation with CT is not desirable due to the hazard of ionizing radiation. Given the high propensity of any group of patients with urinary tract calculi to undergo frequent imaging studies due to recurrent ureteric colic and the presence of significant residual hydronephrosis, we should strive hard to minimize radiation dosage by avoiding frequent CT studies. At the same time, maintaining acceptable diagnostic accuracy is of paramount importance.

Author's personal copy

Limitations of the study: US is an operator-dependent examination and the results are affected by patients' body habitus and availability of good window. An increase in the RI of intra-renal vessels is also found in case of vascular or parenchymal diseases (renal vein thrombosis, acute renal insufficiency, etc.). The CDUS changes can return to normal after 48 h [27], after which its utility is doubtful with reduced sensitivity and specificity.

Abstract:
Objectives:*To evaluate the role of fetal transcerebellar diameter (TCD) as an independent parameter in predicting the gestational age in the third trimester of pregnancy. To derive nomogram from sonographically measured foetal transcerebellar diameter for estimating the gestational age in Indian population.*
Materials and methods:*Hospital based prostective study.148 healthy pregnant patient in third trimester were included in the study who underwent obstetric sonography using GE Voluson P8 machine. In all the patients following parameters were obtained - BPD, HC, AC, FL, TCD, foetal heart rate, estimated foetal weight, AFI and placental position. Transverse cerebellar diameter is obtained in the axial plane in the cerebellar view. Gestational age for the measured TCD is obtained from the reference chart by Hill et.al.,TCD/AC ratio was calculated according to the following formula: TCD/AC ratio (%): TCD (mm)/AC (mm) x 100*
Conclusion:*TCD correlates with clinical gestational age as the first best parameter and also positively correlates with BPD, HC, AC and FL. So TCD can be reliably be used for gestational age assessment in third trimester. TCD/AC ratio remains fairly constant in third trimester with value of 14.59 +/- 2SD, So the ratio is independent of gestational age and can be used in assessing the fetal growth in pregnancies with unknown dating.*

Keywords: *Foetal growth, Gestational age,TCD/AC ratio, Third trimester, Transcerebellar diameter.*

Date of Submission: 11-08-2018 Date Of Acceptance: 25-08-2018

I. Introduction

Ultrasound assessment of gestational age is becoming increasingly important[1]. Obstetric surveillance and management of complicated pregnancy and decisions regarding the optimal timing of delivery remains paramount important. Estimation of gestational age using ultrasonographically derived fetal parameters is perhaps the cornerstone in obstetrics and is an important component in the management of pregnancies [2].

Many parameters are being used for establishing gestational age, for example biparietal diameter (BPD), head circumference (HC), abdominal circumference (AC) and femur length (FL) (1). Identification of aberrant growth as well as growth disturbance across the spectrum of GA in both healthy fetuses and those with genetic abnormalities will be helpful for optimal fetal surveillance [2]. Evaluation of the posterior fossa of the fetal cranium has been accepted as part of routine obstetric ultrasound examination. Parameters such as BPD, HC and AC compute the gestational age more correctly in the earlier gestation.

Fetal transcerebellar diameter can predict the gestational age reliably at any trimester since cerebellum is not liable to change in its form and also its size. The fetal cerebellum grows progressively along with gestational age[1]. The cerebellum and posterior fossa are aligned perpendicular to the plane of maximum extrinsic compression and withstand deformation by extrinsic pressure than the parietal bones [3]. So fetal transcerebellar diameter has remained consistently superior in predicting GA in second and third trimester, both singleton and twin gestations and in variation of fetal head shape such as dolicocephaly and brachycephaly and in normal fetus and in intrauterine growth restricted fetus (IUGR). Fetal transcerebellar diameter to abdominal circumference ratio is used to determine the correct gestational age and also to predict intrauterine growth restriction (IUGR) [1,2].

II. Objectives

(i) To evaluate the role of fetal transcerebellar diameter as an independent parameter in predicting the gestational age in the third trimester of pregnancy.
(ii) To derive nomogram from sonographically measured foetal transcerebellar diameter for estimating the gestational age in Indian population.

III. Inclusion and Exclusion Criteria

3.1 Inclusion criteria:

Healthy women with uncomplicated pregnancy between the 25^{th} week of gestation and term.

3.2 Exclusion criteria:

Unknown or inaccurate date of last menstrual period (LMP), irregular menstrual cycles, oligohydramnios.

Polyhydramnios, diabetic mother, pregnancy induced hypertension, pre eclampsia, dolichocephalic and brachycephalic skull, multiple gestation fetal chromosomal abnormalities, fetal anomalies intrauterine growth restriction and any other known maternal and foetal abnormality.

IV. Materials and Methods

4.1 Hardware

GE Voluson P8.

4.2 Methods

Hospital based prostective study. Ethical clearance was obtained from the institutional ethical review committee of Karpagam faculty of medical science research, Coimbatore. All the statutory requirements under PC-PNDT act were followed. All relevant clinical history was obtained and the correct LMP was confirmed.

148 healthy pregnant patient included in the study who underwent obstetric sonography in Department of Radiology, and Karpagam faculty of medical science research, Coimbatore. In all the patients following parameters were obtained - BPD, HC, AC, FL, TCD, foetal heart rate, estimated foetal weight, AFI and placental position.

Transverse cerebellar diameter is obtained in the axial plane in the cerebellar view i.e with a slight rotation of the transducer approximately 30^0 from the conventional thalamic plane where the biparietal diameter is measured using the cavum septi pellucidi, third ventricle and thalami as landmarks. In this plane posterior fossa with cerebellum is visualized. The cisterna magna is just posterior to the cerebellum. This plane provides the widest transcerebellar diameter.

Gestational age for the measured TCD is obtained from the reference chart "Predicted menstrual age for transverse cerebellar diameter of 14 mm to 56 mm"by Hill *et.al*., in his study "Transverse cerebellar diameter as a predictor of menstrual age" in 1990. TCD/AC ratio was calculated according to the following formula: TCD/AC ratio (%): TCD (mm)/AC (mm) x 100

Figure 1: The caliper on the edge of the cerebellar hemisphere demonstrates the method to obtain transcerebellar diameter.

4.3 Statistical analysis

The following methods of statistical analysis have been used in this study.

The results for each parameter (numbers and percentages) for discrete data and averaged (mean + standard deviation) for continuous data are presented in Table and Figure.

4.3.1 An evaluation was made of the linear relationship between two variables using Pearson's correlation. Pearson Correlation technique used to test the direction and strength of the relationship between gestational age obtained using transverse cerebellar diameter vs individual parameters such as biparietal diameter, head circumference, abdominal circumference and femoral length. It uses the statistic R which falls between -1 and +1. The + and – signs are used for positive linear correlations and negative linear correlations, respectively.A correlation greater than 0.8 is generally described as strong, whereas a correlation less than 0.5 are generally described as weak.

The coefficient of determination, r^2, is useful because it gives the proportion of the variance (fluctuation) of one variable that is predictable from the other variable. It is a measure that allows us to determine how certain one can be in making predictions from a certain model/graph.

4.3.2 The student't' test was used to determine whether there was a statistical difference between the parameters measured. Student's t test is as follows:

. $t=\dfrac{\bar{x}_1-\bar{x}_2}{s\sqrt{\dfrac{1}{n_1}+\dfrac{1}{n_2}}}$ ~~~ $t_{n1+n2-2}$ Where $s^2=\dfrac{(n_1-1){s_1}^2+(n_2-1){s_2}^2}{(n_1+n_2-2)}$

In the above test the "p" value of less than 0.05 was accepted as indicating statistical significance. Data analysis was carried out using Statistical Package for Social Science (SPSS, V 10.5)

V. Results

The age of 148 patient included in the study was in the range of 17 to 36 years with the mean age of 26.6 years.

5.1 Third trimester correlation

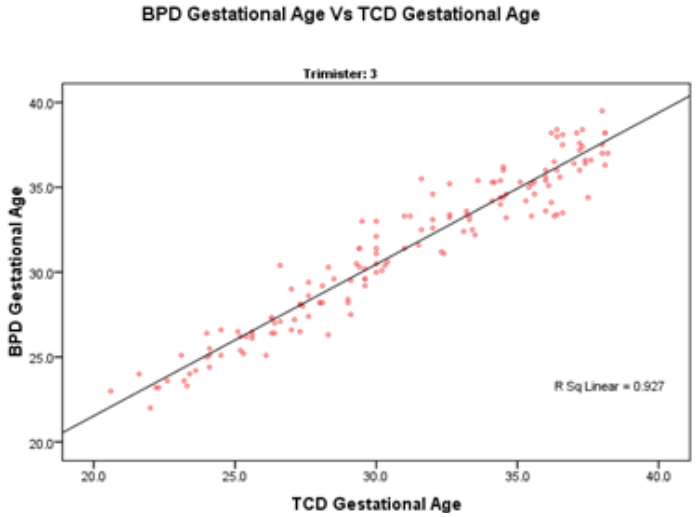

Figure 3. A scatter diagram showing the correlation and regression analysis of the TCD with BPD in third trimester. Here TCD is correlated with BPD by 92.7 %.

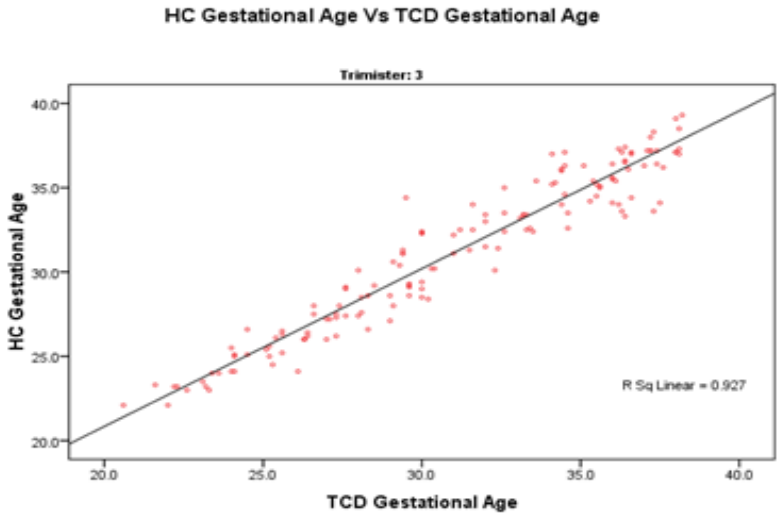

Figure 4. A scatter diagram showing the correlation and regression analysis of the TCD with HC in third trimester. Here TCD is correlated with HC by 92.7 %.

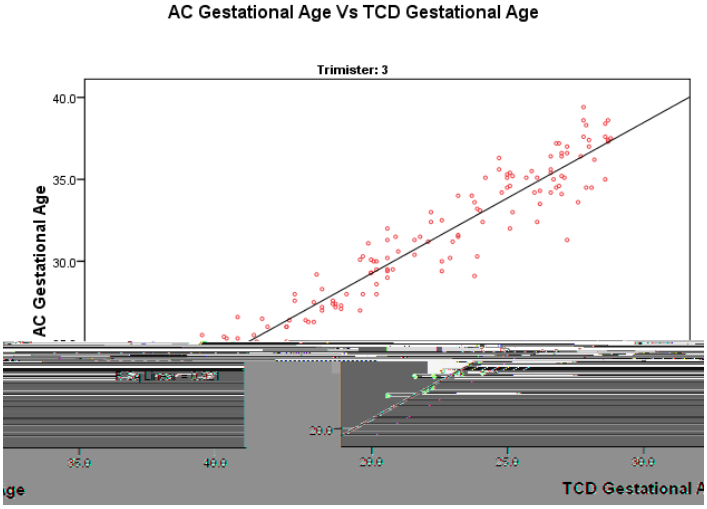

Figure 5. A scatter diagram showing the correlation and regression analysis of the TCD with AC in third trimester. Here TCD is correlated with AC by 92.1 %.

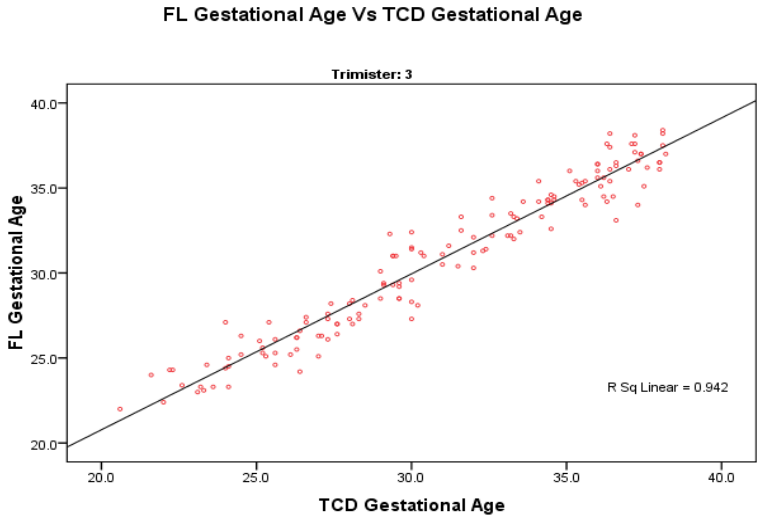

Figure 6. A scatter diagram showing the correlation and regression analysis of the TCD with FL in third trimester. Here TCD is correlated with FL by 94.2 %.

TCD is correlated with Clinical GA, BPD, HC, AC and FL in third trimester by 92.2%, 92.7%, 92.7%, 92.1% and 94.2% respectively.

TABLE 1. Correlation co-efficient of TCD with CGA, BPD, HC, AC and FL in third trimester

Combination Of Parameters	***Pearson's Correlation Co-Efficient (r)***	***Significance***
TCD VS CGA	0.960	P<0.001
TCD VS BPD	0.963	P<0.001
TCD VS HC	0.963	P<0.001
TCD VS AC	0.960	P<0.001
TCD VS FL	0.970	P<0.001

This table reveals the association between the foetal measurements and TCD. The correlation was best for TCD vs FL (r : 0.970). The correlation for TCD vs CGA, BPD, HC and AC was almost similar (r : 0.960, 0.963, 0.963 and 0.970 respectively). All the correlations were statistically significant.

TABLE 2. Correlation co-efficient of CGA with BPD, HC, AC, FL and TCD in third trimesters

Combination of Parameters	***Pearson's Correlation Co-Efficient (r)***	***Significance***
CGA VS BPD	0.937	P<0.001
CGA VS HC	0.947	P<0.001
CGA VS AC	0.952	P<0.001
CGA VS FL	0.960	P<0.001
CGA VS TCD	0.960	P<0.001

The above table shows the association between foetal measurements with CGA. The correlation was best for CGA vs FL and CGA vs TCD (r : 0.960). All the correlations were statistically significant.

5.2 TCD/AC Ratio:

TCD/AC remain fairly constant, between 25th week and term with values of TCD/AC ratio 14.59 +/- 2SD (SD: 1.14). There was a strong linear relationship between TCD and AC.

Table 3. Nomogram

TCD (mm)	***Gestational age***	***TCD (mm)***	***Gestational age***
29	25.3	43	33.4
30	25.7	44	34.1
31	26.5	45	34.4
32	27.2	46	34.7
33	27.8	47	34.9

34	28.6	48	35.7
35	29.2	49	36.1
36	29.7	50	36.4
37	30.3	51	36.8
38	31.0	52	37.2
39	31.4	53	37.4
40	31.9	54	37.8
41	32.5	55	38.0
42	33.2	56	38.1

VI. Discussion

In this study of 148 healthy women with uncomplicated pregnancy shows correlation between the gestational age and TCD. This has also been proven by various other studies. There is a linear relationship between the cerebellar growth and the gestational age in the third (24 wks to term) trimester. This relationship of foetal cerebellar growth and gestational age is statistically significant. In the present study the correlation of TCD with other foetal biometric parameters such as BPD, HC, AC and FL were statistically significant with the P value of 0.963, 0.963, 0.960 and 0.970 respectively. TCD correlate with the clinical gestational age with the statistically significant P value of 0.960. So in the present study TCD correlates well with gestational age with high correlation coefficient of 0.96 in the third trimester along with FL, as the first accurate parameters for assessing the gestational age.

The fetal cerebellum visualized as early as 10-20 postmenstrual weeks, grows in linear pattern in second trimester but its curve flattens in third trimester [1]. The normal foetal TCD increase with advancing gestational age and exhibit a more than two fold increase in size during the second half of pregnancy [4]. Normal sonographic anatomy of the developing cerebellum can be misinterpreted for pathological conditions [5,6]. So caution is warranted in making an early diagnosis of foetal cerebellar dysgenesis [5].

Sonographic transverse cerebellar diameter is not affected by the alteration in the shape of the foetal skull which affects the biparietal diameter and increase the variability [7-9]. TCD correlates well with gestational age and is more useful indicator of the accurate gestational age in case of dolichocephaly or brachycephaly and facilitate antenatal detection of congenital disorders [8]. Difference in actual gestational age and gestational age predicted by TCD is 0-4 days for 17-21 weeks, 0-2 days for 22-28 weeks, > 5 days for 29-36 weeks and 9 days for 37 weeks [10]. Foetal TCD correlates well with the clinical gestational age in third trimester also [1,10].

The foetal TCD / AC ratio is a gestational age independent method of assessing foetal growth [1,11-13]. In normal pregnant women the TCD / AC ratio was fairly constant with the mean of 13.68 +/- 0.96 irrespective of gestational age [1,12,13]. A value exceeding 2 SD of the mean was significantly associated with birth of a small for gestational age infants but not useful for identifying large for gestational age infant [12]. In the present study we found that TCD/AC ratio remains fairly constant in third trimester with value of 14.59 +/- 2SD (SD: 1.141). There was a strong linear relationship between TCD and AC. TCD/AC ratio was 13.6 +/- 0.95% in study done by Campbell *et. al.* in 1991 [13]. Meyer and his colleagues described that TCD/AC ratio is 13.69+/-0.94% in there study in 1993 [12]. According to studies by Malik *et. al*. in 2003 [14] and 2006 [1] TCD/AC ratios were 0.14064 +/-0.059 and 0.13 respectively.

The foetal TCD is not independent of the ethnic origin of the patient [15,16]. A study in 2001 on 153 normal pregnant women on Thai population concludes that growth rate of TCD was slightly less than that of a western study after 28 weeks of gestation [16]. In our study, all the patients were of Indian origin and the normogram for predicting gestational age from TCD was obtained. The values were compared with a study conducted by Hill *et. Al* [17]and it was observed that the values reported in our study are slightly smaller. This is probably due to the difference in the ethnic origin of patients.

The foetal TCD is useful for prediction of gestational age at the extremes of foetal growth [18-20]. There is relative preservation of normal cerebellar growth in growth restricted fetuses and a similar rate of growth in singleton and multifoetal gestation. In most of growth restricted fetuses, except for TCD all other biometric parameters will be < 10^{th} percentile [18]. The difference between actual and predicted gestational age based on TCD in IUGR foetus is within 3 days in 97.5% in the second trimester and 93.3% in the third trimester. In large for date foetus the difference between actual and predicted gestational age based on TCD is within 3 days was 100% in both second and third trimesters [19].

VII. Conclusion

TCD correlates gestational age as the first best parameter and also positively correlates with BPD, HC, AC and FL.So TCD can be reliably be used for gestational age assessment in third trim. TCD/AC ratio is independent of gestational age and can be used in assessing the fetal growth in pregnancies with unknown

dating. The results of present study show that transcerebellar diameter along with other parameters can improve the accuracy of antenatal sonography as well as sensitivity and specificity for fetal growth abnormalities.

Abstract

Background: With the advancement in radiological interventions and diagnostic imaging iodinated contrast has an important role to play. Research and advancement in contrast media safety makes this pharmaceutical agent safe to use in daily practice. Our study is done to assess the safety of present generation iodinated contrast media over the kidneys in patients with heterogenous clinical setting undergoing contrast enhanced CT with serum creatinine and e-GFR as a tool for renal function assessment. The study concludes low-osmolar non – ionic contrast is safe in general population; however, we would advise judicious use of intravenous low-osmolar non-ionic contrast in patients with associated comorbid conditions due to mild but insignificant rise in serum creatinine values. **Subjects and Methods:** ?. **Results:** ?. **Conclusion:** ?.

Keywords: Contrast induced nephropathy; low-osmolar contrast media.

Introduction

The role of iodinated contrast in medical diagnostic imaging and intervention procedures are inevitable. Their value has been long recognised as attested by their increased usage in various diagnostic and intervention procedures. Under normal circumstance nearly all the intravenous contrast media are eliminated through kidneys. The purpose of this study is to evaluate the renal safety of present-day contrast media in patients with heterogenous clinical settings using serum creatinine and e-GFR.

Subjects and Methods

This is a prospective study done with 158 patients at A.J. Institute of Medical sciences between 2011-2014 undergone computed tomography with Low-osmolar non-ionic iodinated contrast media (Iopromide) with iodine strength 350mg/ml and is given as per the standard regime i.e., 1 - 2 ml/ kg. Sr, creatinine is evaluated in the subjects blood sample collected 4-6hrs before and 48-72hrs after procedure. eGFR is calculated using Cockcroft-Gault formula1.

Collected data were also analysed for sensitivity, specificity, positive predictive value and chi-square test. P-value <0.05 are considered significant and P – value >0.05 are considered insignificant.

Results

Table 1: Influence of Age Over Creatinine Variation

Creatinine Variation	Age in Years							Total
	19 – 29	30 – 39	40 – 49	50 – 59	60 – 69	70 – 79	80 – 90	
0 – 5 %	2	3	9	6	5	2	0	27
6 – 10 %	1	3	5	13	9	5	0	36
11 – 15 %	4	5	7	14	11	4	1	46
16 – 20 %	6	2	12	2	7	3	1	33
21 – 25 %	2	3	4	1	5	1	0	16
Total	15	16	37	36	37	15	2	158

CHI – Square Test Value: 26.70 P-value : 0.31

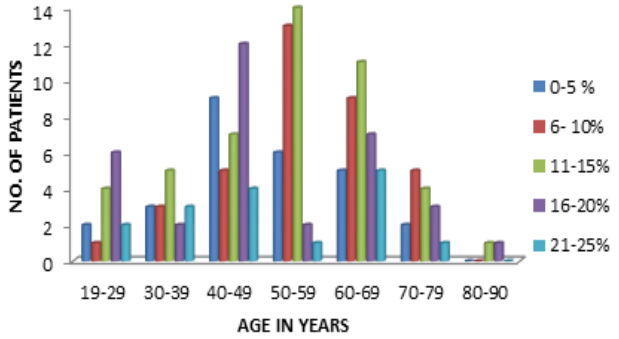

Figure 1: Influence of Age Over Creatinine Variation

The above table and column chart [Figure 1] represent the comparison of age with the creatinine variation to know the influence of age over the variation in creatinine value. The statistical analysis using Pearson Chi-Square test with value of 26.70 and P-value 0.31 confirms that age does not have direct influence on percentage of creatinine variation when using non-ionic contrast.

Table 2: Comorbid Conditions Over Creatinine Variation

Creatinine variation	Comorbid Conditions				Total
	Absent	DM	HTN	BOTH	
0 – 5 %	27	0	0	0	27
6 – 10 %	24	8	0	4	36
11 – 15 %	32	7	1	6	46
16 – 20 %	22	10	1	0	33
21 – 25 %	2	9	0	5	16
Total	107	34	2	15	158

CHI – Square Test Value: 44.70 P – VALUE: 0.0001

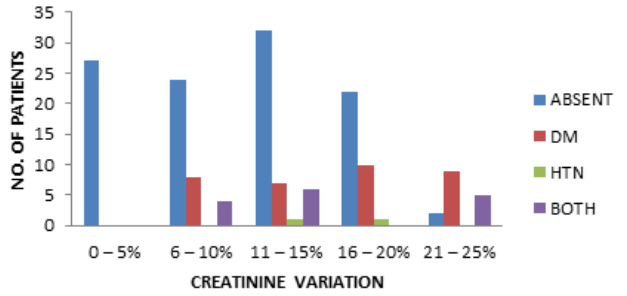

Figure 2: Creatinine Variation.

The above table and column chart [Figure 2] analysis the incidence of contrast induced nephropathy and percentage of creatinine variation among the study population with associated comorbid conditions. There is no incidence of contrast induced nephropathy among the study population with associated comorbid conditions. However, the statistical analysis with Pearson Chi-Square test value 44.70 and P-value 0.0001 confirms that subjects with comorbid conditions have direct influence on percentage variation on creatinine value. It is evident from the column chart that majority of population among the higher percentage (21 – 25%) creatinine variation group are with Diabetes or both Diabetes and Hypertension.

Discussion

Contrast-induced nephrotoxicity (CIN) is a sudden deterioration in renal function following the recent intravascular administration of iodinated contrast medium in the absence of another nephrotoxic event. Low and iso-osmolar contrast is relatively safe in comparison with high-osmolar contrast media.[2,3] Unfortunately, very few published studies adequately isolate patients undergoing contrast enhanced CT in whom iodinated contrast medium exposure is the only nephrotoxic event.[4-7] CIN appears within 48 hours after the administration of radiographic contrast media and is maintained for 2–5 days.[8] An overall incidence of CIN in the general population is reported to be 0 –2.3%.[9]

There are no standard criteria for the diagnosis of CIN; criteria used in the past have included percent change in the baseline serum creatinine (e.g., an increase of variously 25% to 50%) and absolute elevation from baseline serum creatinine (e.g., an increase of variously 0.5 to 2.0 mg/dL).[10,11] One of the most commonly used criteria has been an absolute increase of 0.5 mg/dL.

The risk of developing contrast-induced nephropathy is influenced by diabetes, hypertension, age and reduced eGFR.[12] The risk of CIN was found to be 0.6% in patients with eGFR greater than 40 mL/min/1.73m2 and 4.6% in patients with an eGFR of 30 to 40 mL/min/1.73m2.[13] The CIN rate was 7.8% with an eGFR > 30 mL/min/1.73m2.

We in our study have aimed at analysing changes in renal functions in patients with heterogenous clinical settings undergoing computed tomography with low-osmolar iodinated contrast media keeping serum creatinine and eGFR as baseline investigation.

The major preventive action against CIN is to ensure adequate hydration.[14] We during our study maintained adequate hydration with 0.9% normal saline infusion at 100 mL/hr, beginning 6 to 12 hours before and continuing 4 to 12 hours after intravascular iodinated contrast medium administration for the inpatient and oral hydration for outpatients with comorbidity such as diabetes and hypertension.[15]

Among the 158-study population 110(69.6%) were male patients and 48 (30.4%) were female patients with wide range of age distribution. Among the 158 patients 34 are diabetic, 2 are hypertensive, 15 had both diabetes and hypertension, rest of the 107 patients did not had any comorbidities. The percentage increase in serum creatinine did not had any direct relation to the age or sex. However, the statistical analysis [Table 2] with value 44.70 and P-value 0.0001 confirms that subjects with comorbid conditions have direct influence on percentage variation on creatinine value but insignificant rise to term it as contrast induced nephropathy.

Conclusion

After a thorough evaluation of 158 patients with heterogenous clinical setting who has undergone contrast enhanced computed tomography with lowosmolar non-ionic intravenous contrast, we can conclude that incidence of contrast induced nephropathy among the general population is negligible and the use of lowosmolar non – ionic contrast is safe in such patients.

However, we would advise judicious use of intravenous lowosmolar non-ionic contrast in patients with associated comorbid conditions like Diabetes mellitus and hypertension, since we saw a mild but insignificant rise in serum creatinine values in such patients.

Utility of ultrasound elastography in evaluation of thyroid nodules and correlation with cytology

Vikrant Kanagaraju, S. Sukithra, N. Jayaprakash, B. Devanand

Department of Radiology, PSG Institute of Medical Sciences and Research, Coimbatore, Tamil Nadu, India

Abstract

Background: Ultrasound elastography (USE) has emerged as a potentially useful tool in the evaluation of thyroid nodules. The aim of this study was to assess the efficacy of elastography in differentiating benign from malignant thyroid nodules with fine-needle aspiration cytology (FNAC) analysis as reference standard.

Materials and Methods: This was a cross-sectional prospective study carried out at a tertiary care center in South India between May 2014 and March 2015. Consecutive patients with solid nodule in the thyroid gland on conventional ultrasound (US) underwent USE, followed by US-guided FNAC of the thyroid nodule. The findings of B-mode images and USE were correlated with cytology. Statistical analysis was performed using SPSS version 24. Descriptive statistics were presented as mean ± standard deviation. The diagnostic sensitivity, specificity, positive predictive value, and negative predictive value of USE were calculated.

Results: A total of sixty patients with sixty solid thyroid nodules were enrolled in the study. The mean age of the patients was 48.27 ± 16.10 years. About 83.3% were females. The frequency of benign nodules on cytopathologic analysis was 60% (n = 36). Seventy-five percent of the malignant lesions had irregular or poorly defined borders with lobulated margins on US. The sensitivity, specificity, positive predictive value, and negative predictive value of USE were 91.7%, 77.77%, 73.33%, and 93.3%, respectively, with FNAC as reference standard. Higher elastography scores were found to be significantly associated with malignant cytology (P = 0.0001).

Conclusion: Elastography, with its fairly high diagnostic accuracy and correlation with malignant cytology, can be an effective noninvasive adjunctive tool in distinguishing benign from malignant thyroid nodules.

INTRODUCTION

The prevalence of thyroid nodules which are clinically palpable is about 2%–6% in the general population.[1] Although majority of these nodules are benign, up to 7% can be malignant.[2,3]

On palpation, a hard or firm nature is associated with an increased risk of malignancy. However, palpation is a highly subjective method and its value is limited in patients with multinodular goiter or deep-seated nodules. Ultrasonography (USG) is the most commonly used imaging modality to diagnose thyroid nodules. The utility of

USG in differentiating benign from malignant lesions has been established by several studies.[4-6] However, no USG feature has been shown to have both high sensitivity and high specificity in detecting malignancy in thyroid nodules.[7] Elastography is a newly developed noninvasive dynamic imaging technique analogous to manual palpation. This technique uses ultrasound (US) to estimate tissue stiffness by measuring the degree of distortion under application of an external force.[8] Several studies have used US elastography (USE) for evaluation of thyroid disorders.[9-11]

Fine-needle aspiration cytology (FNAC) is an efficient tool in distinguishing benign nodules that can be managed conservatively from those with suspicious or malignant features that warrant further intervention. Limited data exist on the utility of elastography in differentiating benign from malignant lesions of the thyroid and its correlation with FNAC, especially from India. The aim of this study was to assess the efficacy of elastography in differentiating benign from malignant thyroid nodules with FNAC analysis as reference standard.

MATERIALS AND METHODS

This prospective study was carried out at a tertiary care center in South India between May 2014 and March 2015. Consecutive patients of either gender who were found to have thyroid swelling/goiter on clinical examination and referred for USG were considered. Only those with solid thyroid nodules at least 8 mm in size on conventional US were included in the study. Cystic lesions with no solid component, multinodular goiters with coalescent nodules, and nodules with eggshell calcification were excluded from the study. A large nodule involving more than 75% of thyroid lobe volume was also excluded because of inadequate normal thyroid tissue to be used as reference. The institutional review board approved the study protocol, and the protocol complied with the tenets of the Declaration of Helsinki. Informed consent was obtained from all participants.

With a patient in supine position and neck fully extended, B-mode US of the thyroid gland was performed with SIEMENS ACUSON S2000 machine using high-frequency probes 9 L4 and 14 L5. US features studied included echogenicity, regularity of borders, presence of halo, vascular pattern, and calcification. Thyroid imaging reporting and data system (TIRADS) scoring was used to categorize the lesions[12] [Table 1].

USE was performed with SIEMENS ACUSON S2000 at the same time as the B-mode examination. The probe was placed over the region such that the lesion is in the center of the image, holding the scan plane perpendicular to the skin surface. At least 5 mm of normal adjacent tissue was included to assess the lesion stiffness in relation to the average elasticity of surrounding tissue. Patients were asked to hold their breath and avoid swallowing during examination in order to minimize the motion of the thyroid gland. The elasticity images were obtained by appropriate compression, followed by decompression of the transducer. The images were displayed on split-screen mode with US grayscale images on the left and USE images on the right. Multiple frames were acquired, and the best-fit B mode-USE image pairs were selected for examination [Figures 1 and 2]. The targeted lesion was scored as 1–4, using strain elastographic scores proposed by Asteria *et al*.[9] [Table 2].

US-guided FNAC of the thyroid nodule was done using a 22G needle, and the lesion was aspirated at least twice with the freehand technique. The aspirated contents were expelled onto glass slides and immediately fixed with 95% ethyl alcohol. The slides were stained with modified Papanicolaou staining and examined under light microscopy. The cytological results were classified

Table 1: Thyroid image reporting and data system scoring of thyroid nodules

Category	Description
TIRADS 1	Normal thyroid gland
TIRADS 2	Benign conditions
TIRADS 3	Probably benign nodules (<5% malignant)
TIRADS 4	Suspicious nodules (5%-80% malignancy rate)
TIRADS 5	Probably malignant nodules (malignancy rate >80%)
TIRADS 6	Biopsy-proven malignant nodules

TIRADS – Thyroid image reporting and data system

Table 2: Asteria's criteria of scoring of thyroid nodules on elastography

Elasticity Score	Description
Score of 1	Elasticity in the entire examined area
Score of 2	Elasticity in a large part of the examined area
Score of 3	Stiffness in a large part of the examined area
Score of 4	Nodule without elasticity

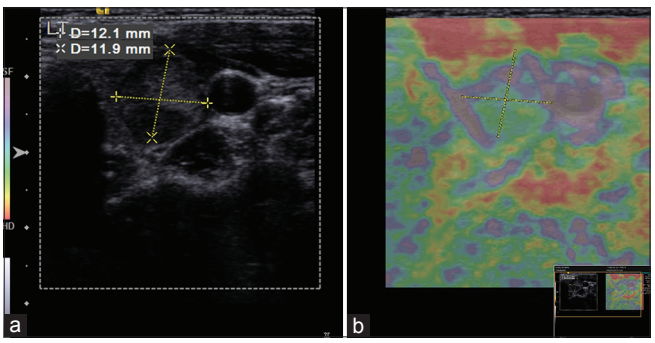

Figure 1: Thyroid nodule images obtained on conventional ultrasound (a) and ultrasound elastography with elasticity score 2 (b)

as benign, indeterminate/suspicious (follicular lesions), and malignant according to standard pathological criteria.

Statistical analysis

Statistical analysis was performed using the Statistical Package for the Social Sciences (SPSS, SPSS Inc., Chicago. IL, USA) version 24. Descriptive statistics were presented as mean ± standard deviation. Qualitative variables were presented in the form of frequency and percentages and compared using the Chi-square test. The diagnostic sensitivity, specificity, positive predictive value, and negative predictive value were calculated. Statistical significance was set at $P < 0.05$.

For statistical purposes, USE score of 2 was strongly predictive of a benign lesion and therefore considered sample negative for malignancy. Scores of 3 and 4 describing stiffness in a large part of the examined area and nodule without elasticity, respectively, were considered as positive for malignancy in our study. With regard to cytology, two groups were considered for evaluation: benign and malignant. Patients with fine-needle aspiration (FNA) reports of indeterminate/suspicious (follicular lesions) were also included in the malignant group for statistical purposes.

RESULTS

A total of sixty patients with sixty solid thyroid nodules were enrolled in the study. The age of the patients ranged from 19 to 85 years (mean: 48.27 ± 16.10 years). About 83.3% (n = 50) were female and 16.7% (n = 10) were male. The frequency of benign nodules on cytopathologic analysis was 60% (n = 36), whereas 40% (n = 24) were nonbenign (follicular lesions and malignant tumors). Of the 24 nonbenign thyroid nodules, 20 had been reported as papillary carcinoma, 2 as medullary carcinoma, and 2 as follicular neoplasm. Table 3 shows the presenting clinical features and cytologic diagnoses of patients with thyroid nodules.

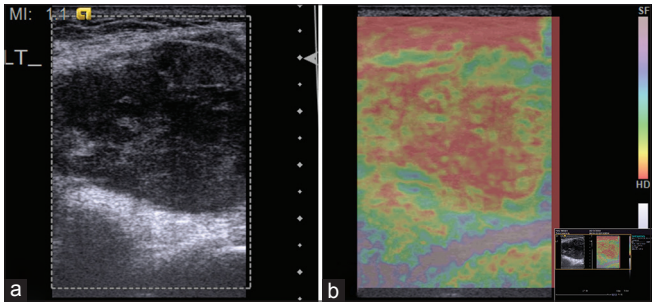

Figure 2: Heterogeneous nodule on conventional ultrasound (a) and ultrasound elastography with elasticity score 4 (b)

Seventy-five percent of the malignant lesions had irregular or poorly defined borders with lobulated margins on US and 68% had microcalcification. Seventy-seven percent of the benign nodules were hyperechoic. On TIRADS scoring, score of 2 was found in 24 cases, all benign lesions; score 3 in 14 cases, 8 benign and 6 malignant; score 4 in 12 cases, 4 benign and 8 malignant; and score 5 in 10 cases, all malignant lesions. Table 4 shows the correlation of USE scores and FNAC diagnoses of patients.

The sensitivity, specificity, positive predictive value, and negative predictive value of US elastography were 91.7%, 77.77%, 73.33%, and 93.3%, respectively, with FNAC as a reference standard [Table 5]. Higher elastography scores were found to be significantly associated with malignant cytology ($P = 0.0001$).

DISCUSSION

Thyroid nodules are common in the general population, and the reported prevalence varies depending on the identification method. Apart from serum markers and FNAC, USG plays an important role in the detection and evaluation of thyroid nodules. Being noninvasive conventional US provides information regarding the nodule dimensions, structure as well as parenchymal changes and is widely used to determine which nodules should be biopsied. Microcalcifications, hypoechogenicity,

Table 3: Clinical presentation of thyroid nodules

Clinical feature	Benign	Malignant	Total number of patients, *n* (%)
Neck swelling	26	2	28 (46.7)
Weight loss	2	8	10 (16.7)
Dysphagia	2	6	8 (13.3)
Pain	6	2	8 (13.3)
Hoarseness of voice	0	6	6 (10)

Table 4: Correlation of elastography scores and cytologic diagnoses of patients with thyroid nodules

Elastography score	Benign	Malignant	Total
2	28	2	30
3	8	2	10
4	-	20	20
Total	36	24	60

USE	Malignancy (positive on FNA)	Malignancy (negative on FNA)	Total
Positive	22 (true positive)	8 (false positive)	30
Negative	2 (false negative)	28 (true negative)	30
Total	24	36	60

FNA – Fine-needle aspiration; USE – Ultrasound elastography

irregular or microlobulated margins, taller than wide shape, and increased intranodular vascularity have been reported as independent risk factors for malignancy.[13,14] Although these features are characterized by high specificity, their positive predictive value is lowered by their relatively low sensitivity.[15]

USE is based on the principle that the softer parts of tissues deform easier than the harder parts, under compression, thereby allowing an objective determination of tissue consistency. Malignancy is often associated with changes in the mechanical properties of a tissue, and USE has been used to differentiate benign from malignant lesions in the breast, liver, and prostate.[16-18] The two general criteria for evaluating the efficacy of USE are elasticity scores and strain ratio. Although elastography has been suggested to be of great use as an adjunctive tool in the diagnosis of thyroid cancer, studies have reported conflicting evidence on its additional value in predicting thyroid malignancy.[19-21]

This study was planned to assess the efficacy of elastography in differentiating benign from malignant thyroid nodules with FNAC analysis as a reference standard. The mean age of presentation for benign nodules was 44.31 ± 14.28 years, whereas that for malignant lesions was 54.21 ± 17.13 years ($P = 0.018$) A majority of our cases diagnosed with thyroid nodules were females (83.3%). Thyroid nodules are reported to be four times more common in women than men, and their frequency increases with age and low iodine intake.[22] The female preponderance has been explained by the hormonal influences of estrogen and progesterone, as increasing nodule size and new nodule development have been demonstrated to be related to pregnancy and multiparity.[23]

Of the sixty nodules studied, 60% were benign ($n = 36$) and 40% ($n = 24$) were nonbenign. Of the 36 benign nodules, 26 were colloid nodules and 10 were adenomatoid nodules. The 24 nonbenign lesions included 20 papillary carcinomas, 2 medullary carcinomas, and 2 follicular neoplasms. The most common clinical presentation was painless mass in the neck which was encountered in almost 47% of the patients. Majority of the patients who presented with significant weight loss, dysphagia, and hoarseness of voice were found to have malignant lesions. Dysphagia, dysphonia, reports of rapid growth, male gender, prior head-and-neck irradiation, and presentation at extremes of age have been reported as significant elements in the patient's history, which increase the likelihood of malignancy.[24]

Our study found that 75% of malignant lesions had irregular or poorly defined borders with lobulated margins, whereas 68% of malignant lesions had microcalcification. Seventy-seven percent of the benign nodules were hyperechoic, whereas 23% were hypoechoic. None of the hyperechoic nodules was malignant. Although none of these US features is sufficient to differentiate benign lesions from malignant ones, studies have shown that a combination of at least two of the features is better helpful in pointing out a subset of lesions at high risk for malignancy.[25,26]

With regard to TIRADS score, all the nodules with TIRADS score of 2 ($n = 24$) had benign FNA characteristics, whereas all the patients with TIRADS score of 5 ($n = 10$) were found to have malignant lesions on FNA. Among TIRADS 3 lesions ($n = 14$), 57% were benign, and among TIRADS 4 lesions ($n = 12$), 33% were found to be benign on FNA.

On US elastography, score of 2 was found in 30 nodules, 28 benign and 2 malignant; score 3 in 10 cases, 8 benign and 2 malignant; and score 4 in 20 cases, all malignant. The sensitivity, specificity, positive predictive value, and negative predictive value of US elastography were 91.7%, 77.77%, 73.33%, and 93.3%, respectively, with FNAC as a reference standard.

The elastography scores of 3–4 were achieved in 22 of the 24 malignant nodules in our study. Among the 20 nodules with cytologic diagnosis of papillary carcinoma, 18 were correctly scored as malignant by USE, thus achieving 90% diagnostic accuracy in terms of confirming the malignant etiology. Only two nodules were incorrectly given a USE score of 2. Both of the two nodules with medullary carcinoma thyroid had been scored as malignant on USE (score 4). We had eight false-positive nodules (score 3) which can be attributed to the fibrotic changes and calcification that lead to hardness of the nodule under study.

Our observations are in line with that of Mehrotra *et al.* who have reported the sensitivity and specificity of USE for thyroid malignancy to be 90% and 79.6%, respectively.[27] Of the 147 nodules examined by USE and US-guided FNAC, 122 were nonneoplastic, 5 were benign neoplasm, 10 had indeterminate cytologies, and 10 had malignant neoplasms. The observed positive and negative predictive values were 24.3% and 99.1%, respectively. In contrast, we found the positive predictive value of elastography to be 73.3% in our study. This can be explained by the high prevalence of malignant lesions among our study population.

The sensitivity and specificity of elastography based on elastography scores have been reported to vary from

86% to 97% and 66%–100% from various studies.[8,9,28] The observed wide differences are due to the fact that these studies involve different groups of populations, referral bias (patients referred for FNAC/surgery), varied inclusion and exclusion criteria, different machines as well as criteria for USE scoring. A recent comprehensive meta-analysis to investigate the diagnostic value of qualitative elastography in distinguishing benign from malignant thyroid nodules included 20 studies involving 3973 thyroid nodules.[29] Pooled results of elastography have shown a summary sensitivity of 85% (95% confidence interval [CI], 79%–90%) and specificity of 80% (95% CI, 73%–86%). The respective pooled negative predictive and positive predictive values were 97% (95% CI, 94%–98%) and 40% (95% CI, 34%–48%), respectively.

Despite the potential limitations of USE such as intra/interobserver variability and nodule characteristics such as calcification and follicular carcinoma (which appears soft), USE is considered to be reliable in the diagnosis of benign nodules in view of the high negative predictive values observed in most of the studies including ours.

FNAC is an essential diagnostic modality in the evaluation of thyroid nodules and features in all the guidelines in patient management.[30] Although the use of FNAC in the evaluation of thyroid nodules provides reliable results, it is invasive and the potential for complications such as postprocedural hematoma, increased patient morbidity, cost, and possibility of nondiagnostic specimen does exist. Unnecessary/repeat FNACs and FNA-induced changes can result in false-positive results on thyroid cytology and false-negative results or understaging of the tumor on thyroid pathology.[31,32]

Higher elastography scores were found to be significantly associated with malignant cytology ($P = 0.0001$) in our study. Merino *et al*. have also noted a statistically significant association between elasticity scores and cytological results, suggesting that malignant nodules could be excluded by elastography.[33]

Limitations of our study include small sample size and the fact that observations are from a single center.

CONCLUSION

With scanty literature comparing elastography with FNAC available from this part of the world, our study highlights that elastography has a fairly high diagnostic accuracy and correlation with malignant cytology. It can be an effective noninvasive adjunctive tool in distinguishing benign from malignant thyroid nodules and reduce the burden of unnecessary invasive procedures.

Abstract

The aim of this article is to assess Tamil Nadu pediatric computed tomography (CT) diagnostic reference levels (DRLs) by collecting radiation dose data for the most commonly performed CT examinations. This work was performed for thirty CT scanners installed in various parts of the Tamil Nadu region. The patient cohort was divided into two age groups: <1 year, and 1–5 years. CT dose indices were measured using a 10 cm^3 pencil ion chamber with pediatric head and body polymethyl methacrylate phantoms. Dose data such as volumetric CT dose index ($CTDI_v$) and dose length product (DLP) on a minimum of twenty average-sized pediatric patients in each category were recorded to calculate a mean site $CTDI_v$ and DLP value. The rounded 75th percentile was used to calculate a pediatric DRL for each hospital, and then region by compiling all results. Data were collected for 3600 pediatric patients. Pediatric CT DRL for two age groups: <1 year ($CTDI_v$ and DLP of head [20 mGy, 352 mGy.cm], chest [7 mGy, 120 mGy.cm] and abdomen [12 mGy, 252 mGy.cm]), and 1–5 years ($CTDI_v$ and DLP of head [38 mGy, 505 mGy.cm], chest [8 mGy, 132 mGy.cm] and abdomen [14 mGy, 270 mGy.cm]) for select procedures have been calculated. Proposed pediatric DRLs of $CTDI_v$ and DLP for head procedure were lower, and for chest and abdomen procedures were higher than European pediatric DRLs for both age groups.

Key words: Diagnostic reference level, pediatric computed tomography, pediatric computed tomography diagnostic reference level, volumetric computed tomography dose index

Received on: 06-07-2016 **Review completed on: 30-10-2016** **Accepted on: 07-11-2016**

Introduction

Children are being referred for computed tomography (CT) scan due to the latter's speed, accuracy, flexibility, and accessibility. This has been mainly due to the introduction of fast spiral scanning, which obviates the need for sedation to keep children motionless, thereby permitting scans of younger or less cooperative children.[1] In the US, about 33% of all pediatric CT procedures are in children aged 10 or younger, with 17% of children aged five or younger.[2] At these ages, the organs and tissues are inherently more radiation sensitive to the oncogenic effects due to the larger quantity of cells that are separating and reproducing.[3-5] The International Commission on Radiological Protection (ICRP) states that children are 2–3 times more radiosensitive as compared to adult patients, due to the effect of cell division in developing organs and the longer anticipated lifetime for developing cancer cells.[6,7] The radiation-induced effects are also elevated in pediatric patients due to wider and enlarged cellular circulation of red bone marrow, and their higher postexposure life expectancy.[8,9] With this sharp radio-sensitivity now well documented, and to better inform radiographers about the significance of limiting the unwanted radiation dose to pediatric patients[10] the European Commission (EC) has, in its recommendations published in the year 2000, stressed the need for optimization of pediatric CT radiation dose.[11] The Food and Drug Administration (FDA) has also published related recommendations in 2002[12] about pediatric radiation dose optimization. While the use of CT scan for pediatric cases has increased unlike adult examination protocols, most of the times the exposure parameters used in

ABSTRACT

BACKGROUND

Excessive consumption of carbonated soft drink is detrimental to oral and general health and the popularity of the aerated drinks among adults has grown exponentially. This study aims at determining the prevalence of aerated drinks among students in PSG Institute of management. The focus of the study is mainly on the aerated drinks consumption pattern, frequency of consumption, reason and the following symptoms.

MATERIALS AND METHODS

The study was conducted using questionnaire. About 200 students in PSG Institute of Management were taken for the study and the answer to the questions were analysed.

RESULTS

The results showed that out of the total participants 93% reported consuming aerated drinks out of which 84% of participants were seen to consume aerated drink for a period of more than 3 years. About 55% of participants were found to have symptoms like sensitivity. About 41% of them were found to have anterior tooth discoloration and 47% of them were found to have bleeding gums. About 52% of them were found to have mouth dryness consuming aerated drinks. Hence, the participants who took larger quantity of aerated drinks for a longer period of time were found to have more than three symptoms of the study conducted (sensitivity, anterior tooth discoloration, bleeding gums and mouth dryness).

CONCLUSION

The above study clearly shows that there is an increase in proportion of consumption of aerated drinks among young adult, thus resulting in increased ill effect in the oral health.

BACKGROUND

The aerated drinks are being marketed for their taste, energy, refreshment and for hydration for which these products are not indented, popularity of these drinks among adults and adolescents has grown exponentially. Worryingly, they consume them socially as well as during physical activity. They are high in sugar and are acidic products; marketing ignores the potential harmful effect of these soft drinks.

Aerated soft drinks containing inherent acid and sugar have both acidogenic and cariogenic potential. Many studies showed a positive relationship between caries and dental erosion and the consumption of soft drinks.[1]

CC BY NC ND

Consumption of aerated drink for a longer period of the time found to have many potential oral and health hazards.

The aim of the study is to evaluate the prevalence of aerated drinks consumption among group of adult in PSG Institute of Management and to analyse the out coming symptoms like sensitivity, discoloration in the anterior teeth (rampant carries), mouth dryness and bleeding gums.

MATERIALS AND METHODS

A total number of 200 students in PSG Institute of Management were planned to be included in the study, out of which only 180 students gave their consent to participant in the study and completed the questionnaire. A time period of 45 minutes were given to the participant for completing the questionnaire. The questionnaire mainly focused on the consumption of the aerated drinks, quantity frequency period of consumption and the symptoms like sensitivity discoloration in the anterior teeth, bleeding gums, dryness of mouth and the participant dental visit.

After obtaining the result from the questionnaire, the participants were grouped as group I (250 mL), group II (500 mL), group III (750 mL) (all of them consuming the aerated drinks at least 250 mL once in a week).

The inclusive criteria of this study are the young healthy adult of age group between 18-23 years who consumed 250 mL of aerated drinks once in a week.

Exclusion criteria of this study are nondrinkers, occasional drinkers and participants who took less than 250 mL of aerated drinks per week. So, out of 180 students who participated in the study, only 136 of the participants were in the inclusion criteria and they were subjected to the statistical analysis.

RESULTS

The frequency of the parameters is summarised in terms of percentage, proportions, tabulated and illustrated as histograms.

Statistical Analysis

Rinse	18	3	1
>3 symptoms	19	41	23
Dental visits	17	19	4

Table 1

The statistical analysis of the study conducted states that 17% of the participants who took about 750 mL of aerated drinkers were found to be 100% positive for more than three of the symptoms considered (sensitivity, bleeding gums, mouth dryness, discoloration in the anterior teeth) than compared to the other two groups in the participants who consumed 250 mL, 32% of them were affected with more than three symptoms and in the 500 mL were 76%. The dia[2] shows that the participants with 250 mL consumption rinsed the mouth immediately hence preventing the drop in PH, hence less ill effects than compared to the other two groups. It is also clearly seen from dia[3] that the participant with 750 mL had less dental visit than compared to their counterparts.

DISCUSSION

Soft drinks have many potential health hazards .The inherent acid and sugar have both acidogenic and cariogenic potential resulting in dental caries and potential enamel erosion.[4] Most soft drinks contain one or more food acidulates; phosphoric and citric acid are common, but malic, tartaric and other organic acid also may be present.[5] The presence of these polybasic acid in beverages have ability to chelate calcium at higher PH, this mean that they can be very erosive to dental enamel.[2] In few cases, the slowly progressing caries suddenly may become rampant, which may be due to the result from frequent exposure to erosive acids.[3] Drinking method also has significant impact on dental erosion, holding the drink longer in the mouth lead to more pronounced PH drop in saliva.[6,7] When the pH level in mouth goes below 5.5 (i.e., the critical pH value), the acids begin to breakdown the enamel on teeth. The longer the teeth are exposed to a low salivary pH, the more likely the development of dental caries.[8] Statistically, frequency of consumption have shown significant differences in susceptibility to erosion, which appear to emerge over time with increase intake of acidic beverage.[9,10] In 60% of the soft drinks, caffeine is present as an flavour addictive.[11] Caffeine is a central nervous system stimulant with diuretic properties and also reduce salivary flow by direct effect upon the salivary gland through effect on the autonomous nervous system or through diuresis and dehydration.[12] Hence, with over time increase, intake of soft drink affect the salivary gland and decreases salivary secretion. The combination of sugar and caffeine may encourage frequent and perpetual pattern of consumption leading to early initiation and rapid progression of dental caries.[13] In rare cases, severe reduction in salivary secretion may also be seen, which in turn result in reduction in cleansing action leading to plaque formation ultimately leading to gingivitis.[14] The statistical analysis of the above conducted study clearly shows that increase in intake of aerated drink were seen to affect the oral health both directly and indirectly.

CONCLUSION

The above study proves that increase in proportion of consumption of aerated drink among young adult causes increased ill effect of oral health than compared to the nondrinkers resulting in discoloration, sensitivity, dental caries and gingivitis. This insist that all dental practitioners should educate their patient about the ill effect of aerated drinks on the teeth and should design health promotion initiatives with this in mind.

PREVALENCE OF DENTAL CARIES AMONG SCHOOL CHILDREN IN SULUR - COIMBATORE

Abhirami Kannan[1], Valli Govindarajan[2]

[1]Associate Professor, Department of Dental Surgery, PSG Institute of Medical Sciences and Research, Coimbatore.
[2]Senior Resident, Department of Dental Surgery, PSG Institute of Medical Sciences and Research, Coimbatore.

ABSTRACT

BACKGROUND

Dental caries is a universal health problem with involving the people globally of all regions and society. The agonising fact is that despite several efforts towards total eradication, dental caries is still prevalent. As the prevalence of dental caries is very high among school children and there is a paucity of such data in Coimbatore and the literature review does not reveal many such studies from this area, the study was conducted in the school going children in Sulur.

MATERIALS AND METHODS

All the students were screened visually using torch with the help of mouth mirror and probe and the observation recorded. A health screening camp was conducted for the students in private school, Sulur, February 20-25, 2017, by a team of doctors from PSG UHTC. A total of 1945 students were screened. The students health details have been entered in their health card and those requiring further evaluation have been counseled and the nursing staff at school has been requested to facilitate and guide for followup. All the students were screened visually using torch with the help of mouth mirror and probe and the observation recorded. All the students who were present in school during 20th to 25th were screened and considered as the inclusion criteria. The exclusion criteria were the absentees during this period. The students were made to sit in an ordinary chair in broad daylight facing away from the sunlight and examined in their school. Data were compiled in an excel worksheet and the percentage calculated.

RESULTS

A total of 1945 students were screened, of which, 541 students were found to have dental problems that is about 28% of the total screening done. The percentage of dental caries were found to be higher compared to other dental diseases like deep caries, malalignment, malocclusion and calculus. The percentage of dental caries was found to be higher in the females about 78% than the male for whom it was about 72%. The percentage of deep caries in female was 12% and male was 13%. The malocclusion in female 14% and 1% MFA (myofunctional appliance), male were about 15%. The percentage of calculus in female was 8% and male 13% and the follow up procedure for these conditions will be restoration, extraction, braces and MFA appliance and scaling.

CONCLUSION

The high prevalence rate shows further follow up and awareness among teachers, parents and students regarding dental caries and dental hygiene is needed. Awareness among students can be generated by the school teachers because they are role model for the students.

BACKGROUND

Oral health is an integral part of general health. In the developing countries like India, changing lifestyle and dietary pattern are distinctly expanding caries incidence. Dental caries is a disease with multifactorial cause. The incidence pattern of dental caries varies not only with age, sex, socioeconomic status, race, geographical location, food habits and oral hygiene practices, but also within the oral cavity. The seriousness and societal costs of dental caries in preschool children are enormous. The prevention of dental caries has long been considered as an important task for the health profession. Scientific research continues to make progress in identifying the best practices for diagnosing, treating and preventing dental caries.

ORIGINAL RESEARCH

'Comparison of TMA, STAINLESS STEEL and TIMOLIUM for friction, load deflection and surface characteristic"

Dr. K. Abhirami MDS.,

Associate Professor, PSG Institute of Medical Science & Research, Coimbatore.

Abstract:

OBJECTIVE

The present study aims at characterizing and comparing the mechanical property and surface characteristic of two arch wire alloys in orthodontics, stainless steel and TMA with newly introduced Timolium.

METHOD

An INSTRON 2366 testing machine was used for frictional characteristic and three points bend testing. Scanning electron microscope was used for surface evaluation and x-ray fluorescence for elemental analysis of Timolium wire specimen.

RESULT

Stainless steel was the strongest archwire alloy, and less friction at the archwire-bracket interface. TMA wires exhibited better load deflection characteristics with less stiffness than the other two wires. The surface of TMA appeared rough and exhibited very high values for friction at the archwire-bracket interface. Timolium appeared to be an alpha-beta titanium alloy composed of titanium, aluminum, and vanadium and intermediate in nature for all the parameters evaluated.

CONCLUSION

Timolium with its smooth surface, reduced friction and better strength can be considered as an introductive breakthrough in clinical orthodontic practice.

KEYWORDS

Friction, load deflection, scanning electron microscope, stainless steel, TMA, Timolium.

Introduction:

Gold alloy was one of the earliest orthodontic wire used .The gold wires have decreased usage in orthodontics because of their low yield strength and increasing costs. In 1940s austenitic stainless steel with adequate spring back, good formability, and moderate cost began to displace gold as primary alloy for orthodontic wires. Elgiloy, a chrome cobalt nickel alloy with excellent corrosion resistance was used. Nickel titanium alloy was introduced in orthodontics several years ago and find its application where deflection and low forces are required. These wires are not amenable to joining operations. With the introduction of b-titanium alloy distinctive features of good spring back, low force delivery, good formability, weld ability, high corrosion resistance, and excellent bio compatibility were available for orthodontist. The disadvantages are surface roughness and high friction. In 1995 a new TMA featuring dramatically reduced friction for a superior sliding mechanics was introduced by Burstone. Timolium ,a patented vanadium based high performance aerospace alloy, has been designed to produce a much smoother surface texture than other titanium molybdenum wires(TMA).Timolium as claimed by the manufactures has almost the same frictional resistance and half the stiffness of stainless steel making it ideal choice for finishing, aligning as well as leveling and torqueing through all phases of treatment.

MATERIALS AND METHOD

The following materials were used in the study

1. 0.016"x 0.022" stainless steel (ormco corporation Giendora CA) – 15 numbers.
2. 0.016"x0.022" TMA (ormco corporation Glendora CA) – 15 numbers.
3. 0.016"x0.022" Timolium (TP labs, Indiana polis IN) – 15 numbers.
4. 0.018" Edgewise canine brackets (American ortho.) – 45 numbers.
5. 0.010" ligature wires (ortho organizer).
6. Cold cure acrylic.
7. Stainless poles 5mm in diameter.
8. Instron machine with model number 2366.

METHOD

FRICTION ANALYSIS

In this study Tidy's (30) frictional test designs were used to stimulate canine retraction. The force acting on the surface of the tooth was simulated by single equivalent force acting at the center of resistance of the root. [27] . Four 0.018" slot edge wise bracket were fixed, at 8mm intervals with a 16mm space for a movable canine bracket at the center. A power arm of 10mm length from bracket slot was fixed at the base of each canine bracket. This distance was chosen according to Burstone finding relating to the location of center of resistance of canine. (3)

The wires stainless steel, titanium molibdinum and Timolium, were then evaluated for friction in the 0.018" slot edge wise brackets.

This jig assembly was mounted on to the lower jaw of instron machine. The canine bracket was then ligated to the test wires. The stainless steel ligatures 0.010" were initially fully tightened and then unwound by three turns; loose ligation was checked by rocking the brackets to confirm that there is play between both the spans of the bracket and the archwire.(21) the bracket was then moved over the archwire with the help of a 0.016"stainless steel wire which was suspended from a special jig which was attached to the upper jaw of the instron machine which was moved in the upward direction, at cross head speed of 5mm/min. In each test they were moved not less than 2.5mm across the central space and the load cell reading were recorded on the digital display.

The differences between load cell reading and load on the power arm thus represents the frictional resistance of the given material.

LOAD DEFLECTION ANALYSIS

The three point bending test was conducted as described by miura et al. (9)

A single bracket was attached on a steel pole, acting like a dental unit placed on a movable stage, so that the bracket span could be set at 14mm. the test wire was held in place with a ligature wire in the slot with a known quantity of force. This jig assembly was mounted on to the lower jaw of the instron machine.

A steel pole of 5mm in diameter was placed in an acrylic block, which was mounted on to the upper jaw of the instron machine. The steel pole which was attached to the upper jaw of instron machine was moved down so that mid portion of the wire segment was deflected to 2mm at the speed of 0.1mm/min under the pressure from the metal pole. The load cell reading in digital display was noted at 0.5mm, 1mm, 1.5mm and 2mm deflection.

The above tests were divided in to three groups comprising of 15 wires each.

Group 1 - 0.016"x0.022" stainless steel wires.

Group 2 - 0.016"x0.022" TMA wires.

Group 3 -0.016"x0.022" Timolium TM wires.

STATISTICAL ANALYSIS

Mean and standard deviation were estimated from the samples for each study group. The groups were subjected to one –way ANOVA to test the level of significance among the test groups. Multiple range tests by Tusky –HSD procedure was employed to identify the significant group if the p –value in the one- way ANOVA was significant.

In the present study, $p<0.05$ was considered as the level of significance.

SURFACE CHARASTERISTIC

In surface, characteristic study each wire was studied before and after sliding through the bracket with the help of a scanning electron microscope a 1cm specimen of each alloy wire was mounted and these wires were then scanned and viewed on the monitor at different magnification and representative micrographs (750 x) of the alloys were obtained.

RESULT

The result of the frictional resistance of the three wires which were analyzed in the study using instron testing machine are tabulated as follows (Table-1); and is graphically plotted in(chart -1)

Table-1

Frictional resistance between stainless steel, TMA, Timonium.

Group	Number of sample	Mean ± (grams)
I	15	203.2 ± 24.2
II	15	301.3 ± 27.5
III	15	222.5 ± 32.9

The above values were subjected to statistical analysis and tabulated as below (Table- 2)

Table-2

ONE-WAY ANOVA AND MRT

GROUP	ANOVA	Multiple range test
	P-Value	Significant group at 5%level
I	<0.001/(sig)	TMA VS STAINLESS STEEL
II		TMA VS TIMOLIUM
III		

- ANOVA test revealed a statistically significant difference among the three groups of the wires analyzed.
- Multiple range tests revealed a statistically significant difference between group-I and group-II and group-III.

The results of the three groups were analyzed for load deflection is tabulated as follows (Table 3); and are graphically represented in (chart 2).

Table-3

Load deflection between stainless steel, TMA and Timolium.

Group	Number of samples	Mean ± S. D (grams)
I	15	1576.3 ± 46.3
II	15	1189.3 ± 19.2
III	15	1319.6 ± 281

The above values were then subjected to statistical analysis and tabulated as below (Table 4)

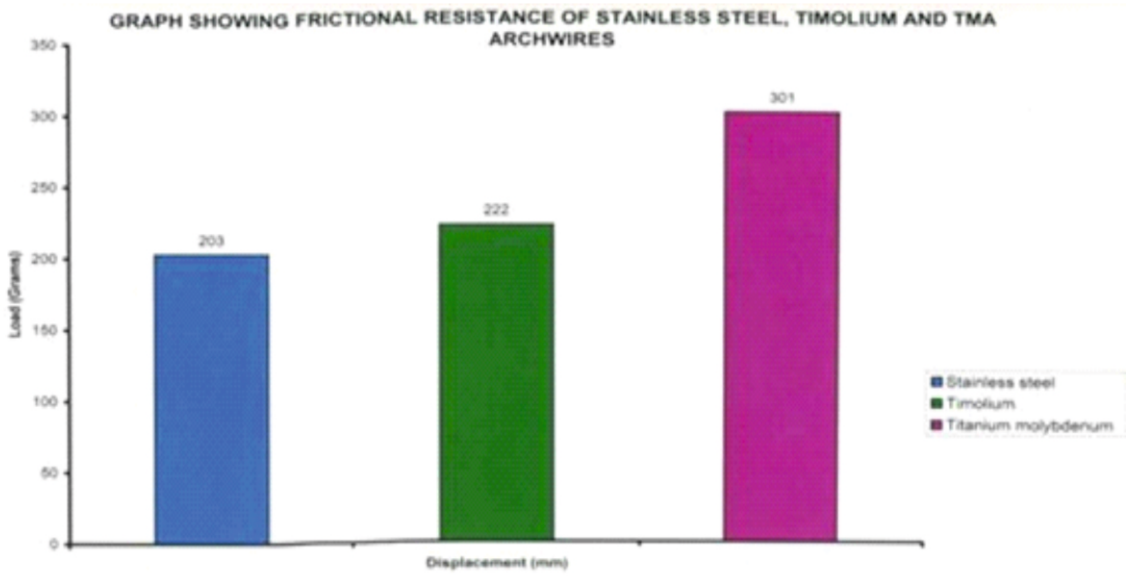

Table-4

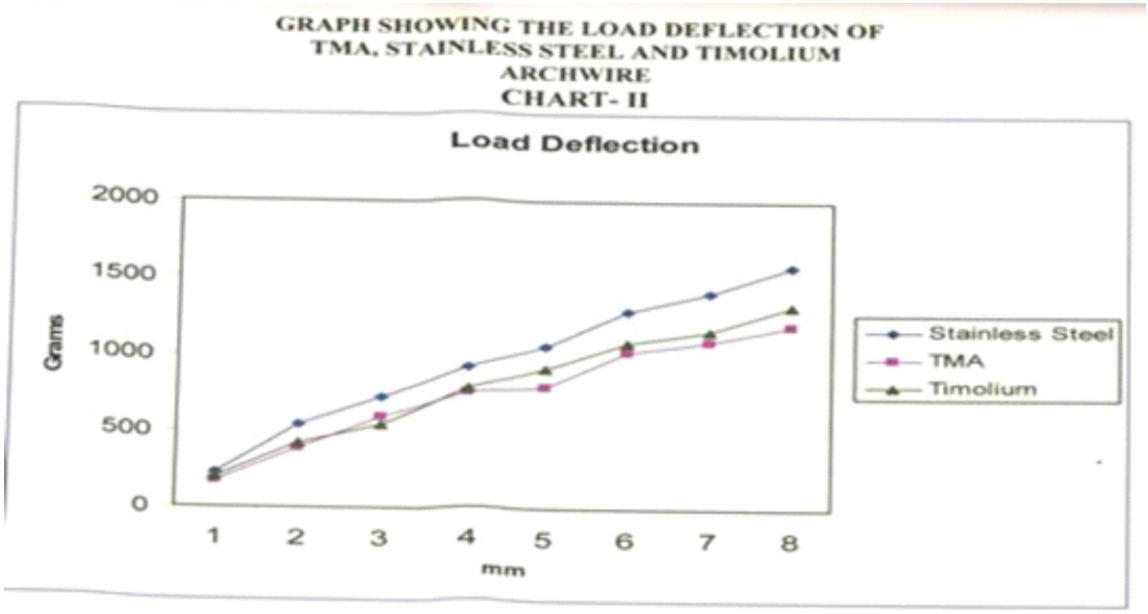
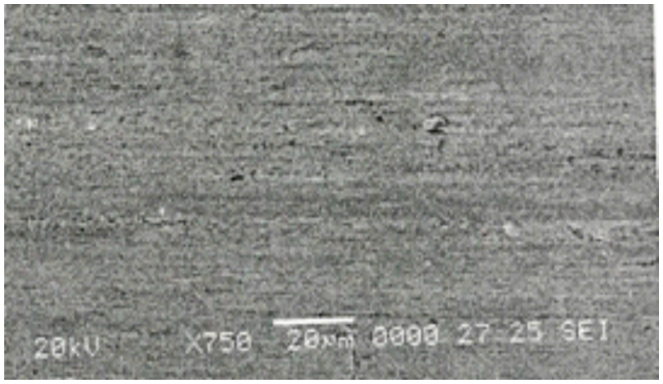


ONE-WAY ANOVA AND MRT

Group	ANOVA	Multiple range test
	P-Value	Significant group at 5%level
I	<0.0001/(Sig)	STAINLESS STEEL VS TMA
II		STAINLESS STEEL VS TIMOLIUM
III		TIMOLIUM VS TMA

- ANOVA test revealed a statistically significant difference among the three groups of wires analyzed.
- Multiple range tests revealed that there was a significant difference between Timolium and TMA wires.

All the three groups of wires which were



evaluated for the surface characteristic using scanning electron microscopy both before and after sliding of wire in the bracket, reveals that in

DISCUSSION

Characterization of arch wire alloy forms an initial step towards understanding arch wire behavior in biomechanical requirement of the clinical situation from the plethora of the material available.

Frictional force has long been an important consideration in orthodontic mechanotherapy. It is a well-known fact that any force needed to retract teeth must overcome friction. (13)

Friction is a function of the relative roughness of two surfaces in contact [23].

Both static and kinetic sliding friction arises in any orthodontic situation of intended displacement, overtime, of an arch wire through a bracket (or) a bracket along an arch wire. (1)

Profit (2000) (26) reported that 50 per cent of the force necessary to initiate tooth movement required to overcome the regarding force generated between brackets, arch wires and ligatures. This implies that only 50 percent of the force applied reaches the tooth and its supporting tissues. The absolute value for the optimum force required to produce "biological tooth movement" is extremely difficult to quantity and it has been demonstrated that increasing the force increases the rate of orthodontic tooth movement up to a point (Andreasn and Quevedo,(1970)(1); Frank and Nikolai,(1980)(8); Garner et al; (1986)(10), Beyond this point tooth movement fails thus, the concept of optimal force. (8)

Kinetic friction was measured rather than static friction because of the variable nature of the frictional process. The result shows that the frictional resistance of Timolium lies between stainless steel and TMA with range being close to that of stainless steel.

The present study clearly indicates a greater friction when TMA wires are used, with a mean value of 301.3 (±) 27.5 grams. The least friction arch wire with stainless steel, with a mean value of 203.2 (±) 32.9 grams.

The result of the study conducted by Cash et al., (2004)(5) is similar to the present study.

The study conducted by Garner et al., (1986)(10), Dresche et al., (1989)(7), Kusy and Whitley, Kapila et al.,(1990)(14), Angolkar et al., (1990),(2) is similar to the present study stating that beta titanium arch wires developed frictional forces greater than stainless steel.

Surface evaluation of an arch wire alloy is important because of its influence on working characteristic as well as working potential. (18) Scanning electron microscopic evaluation of surface characteristics revealed a smooth surface with horizontal lines for Timolium arch wires as in accordance to, pradeep babu[30] . Stainless Steel exhibited vertically oriented cracks, and TMA, a very rough surface as reported extensively in the literature [4, 3, 6].

A modified version of the three-point test by Miura et al(9) was performed to evaluate the load deflection properties, the most important parameter determining the biological nature of tooth movement.(4) The result indicated beta titanium with a mean of 1189.3 (±) 19.2 grams. Stainless steel was more rigid among three arch wire alloy with very high loading value and less spring back properties with a mean of 1576.3 (±) 46.3 grams. Timolium was intermediate in nature 1319.6 (±) 281 grams.

According to cristiane [33] , Oltjen et al., (1970)[22] , vijayalakshmi RD [34] Timolium possesses comparatively low stiffness, better strength and behave as an intermediate between stainless steel and TMA.

Elemental analysis of Timolium with the help of EDS revealed the alloy, with

combination of alpha and beta phase of titanium alloy, exhibits an unusual combination of strength and surface smoothness.

CONCLUSION

In the study performed shows that in frictional studies, Timolium has almost has the same surface friction as stainless steel, unlike TMA (Titanium molybdenum) which have much higher frictional characteristics. This reduced frictional property of the Timolium helps in efficient canine retraction.

Timolium has the half the stiffness midway between TMA and stainless Steel making it ideal choice for finishing, aligning as well as leveling and torqueing throughout all phases of treatment.

Timolium bends easily in "T" boots and" loops" because it has a higher stiffness than TMA and fewer surface defects.

Timolium with its smooth surface, reduced friction and better strength can be considered as an introductive breakthrough in clinical orthodontic practice.

Evaluation for prevalence of malocclusion among adults and need for orthodontic treatment: A cross sectional study

Dr. K Abhirami and Dr. G Valli

Abstract
Aim: The aim of this cross-sectional study was to find the percentage of prevalence of malocclusion and the type of occlusal trait from urban –rural population of age group 17-23 in a college in Coimbatore district.
Materials and Method: A descriptive cross -sectional study with purposive sampling method.
Statistical test used: Examinations were computerized and analyzed using statistical package for social science version 24. Chi square test was used for computing statistical significance.
Result: The difference in prevalence of malocclusion in college students from rural and urban area was significant with the prevalence being more in rural population.
Conclusion: Malocclusion is widely spread among young adult population with greater prevalence in students from rural area, with Angles class I to be the most predominant type of malocclusion. The type of occlusal trait in rural students was proclination and the urban students had maxillary anterior crowding.

Keywords: Crowding, malocclusion, over jet, overbite, prevalence

1. Introduction
In such a diverse country like India a large variation in prevalence of malocclusion exist in various regions of our country. The data on orthodontic awareness and treatment need is very scanty. Malocclusion is undoubtedly a public concern in young population that require the orthodontic treatment need in India. There is no record of the earlier reports to the prevalence of malocclusion, the occlusal trait and orthodontic treatment need in college going students of age 17-23 in Coimbatore district, Tamil Nadu state, India.
With the greater attention to aesthetics in recent years there is a notable increase in orthodontic treatment need in demand as a consequence of a higher perception rate of malocclusion [1, 2].
In a vast country like India there is a wide range of variation in the prevalence of malocclusion like 20.4% in Shimla city in Himachal Pradesh [3], 38.7% in Davangree Karnataka [4], 52% in Nalgonda Telengana [5], 66% in Jaipur [14], 80% in Ahmednagar in Maharashtra [6], 83.3% in Kozhikode district in kerela [7], 83.3% in Hyderabad in Telengana [8], 87.4% in Leh [9].
The aim of this study was to record prevalence of malocclusion and to define difference in occlusal trait in urban and rural population and the orthodontic treatment need.

2. Materials and Method
2.1. Study Design: Descriptive cross-sectional study. A health screening camp of dental, opthalmology and general medicine was conducted for students in a private college in Coimbatore from 22-1-2018 to 22-2-2018 and about 3500 students were screened by a team of doctors from PSGUHTC. Two examiners were involved in this research study, examiner A and examiner B. The study was carried out for a period of 28 days approximately examining 125 students per day. Demographic data including name, age, gender and permanent address of the candidate were recorded. The Inclusion criteria were subjects with permanent dentition, with no remaining deciduous dentition, subjects with age group of 17-23, Students present during the period of oral examination. Students with missing 1st molar, facial trauma, history of previous or ongoing orthodontic treatment were excluded from the study.

3. Ethical clearance
The study protocol was submitted to the institutional ethical committee [PSGIMSR] and clearance was obtained Project no: 18/205. July 30th 2018.

4. Training and calibration of examiner
Oral examination was performed by two trained and calibrated examiners. Before the survey, both the examiners and recording clerks were participated in a training and clinical calibration program in the department. Following this training, 10% of the children were examined by each of the two investigators to assess inter - examiner reliability and Kappa Values of 0. 87 and 0.88 were found respectively. There was good agreement between the examinations by the same examiner. The interview and examination of a single study subject took 3 to 4 minutes. Each subject was examined by a single examiner with aid of natural light. With head in natural position with a metallic ruler. Torch was used whenever required. This was measured to.5mm measurements, if unsure lower score was considered. The criterion was limited to occlusal anterior-posterior (A-P) relationship, crowding, over jet, overbite, midline diastema.[10]

5. Sample Design
Probability sampling method.

5.1. Sample size
Sample size was calculated with the reference to Mahajen *et al.* [16] using prevalence of malocclusion as 82%.
Sample size was calculated using formula n = $4xpq/d^2$ and found to be n= 103.

6. Method of registration
Sagital occlusal relationship was recorded using angles classification system as class I, II, III. According to occlusal relationship of 1st molar and other occlusal traits such as overjet, over bite based on the method of Bioerk *et al.* [11] for registration of Malocclusion in centric occlusion. Overbite was recorded as normal, followed by deep bite (>2/3) of lower incisors were covered by upper incisors) and open bite as no overlap (based on incisors overlap relation in the vertical dimension).over jet was recorded as normal (0-4mm),increased (>4mm) and deficient (<0mm),depending on the horizontal distance between the labial surface of the upper and lower incisors, and crowding was considered as present when there was over lapping of one tooth with respect to the other tooth.

7. Result
Prevalence of malocclusion in rural and urban population in a private college in south Indian population in Coimbatore district of age group 17-23 were taken for the study, the total sample size was 3313 students, out of which 1452 from rural area and 1861 were from urban area. The difference in prevalence of malocclusion in rural and urban students (88%vs82%) was significant statistically with (p =0.0001) (Table-1).

Table 1: Prevalence of Malocclusion in college students from urban - rural area

Occlusion	Rural		Urban		Total		P-Value
	n	%	n	%	n	%	
Normal	233	16.05	410	22.04	643	19.4	<0.0001*
Malocclusion	1219	83.95	1451	77.96	2670	80.5	
Total	1452	100	1861	100	3313	100	

(*P<0.05 significant, CI: 0.56-0.81)

The distribution of occlusal traits in urban and rural area: 19% had class I normal occlusion.16% of rural and 22% of urban population had class I normal occlusion with the statistically significant difference between rural and urban population (p=0.0001) class I sagittal occlusion was found in 85% of the subjects, class II in 11% and class III in 4% with the statistically significant difference (p=0.0001) between two groups. (Table-2)

Table 2: (AP relation) Prevalence of occlusal trait in college students from urban - rural area.

Occlusion	Rural						Urban						P-Value
	I		II		III		I		II		III		
A-P relation	n	%	n	%	n	%	n	%	n	%	n	%	<0.0001*
	1276	88	130	9	46	3	1526	82	251	13	84	5	

(*P<0.05 significant)

Normal over jet was seen in 43.5%, excessive in 33% and reduced in 23.5%. The difference between the urban and rural population was statistically significant (p=0.0001) with rural population having more of increased over jet. (Table-3)

Table 3: Prevalence of overjet in college students from urban - rural area.

Overjet	Urban		Rural		P-Value
	n	%	n	%	
Normal	763	41	668	56	<0.0001*
Excessive	539	29	537	37	
Reduced	559	301	247	17	

(*P<0.05 significant)

Normal overbite was seen in 55.5%, deep in 28.5% and reduced in 16% of total sample. The difference between urban and rural population was statistically significant (p=0.0001) with urban population having more of deep bite. (Table -4)

Table 4: Prevalence of overbite in college students from urban - rural area.

Overbite	Urban		Rural		P-value
	n	%	n	%	
Normal	911	49	908	62	<0.0001*
Excessive	688	37	287	20	
Reduced	262	14	257	18	

(*P<0.05 significant)

The frequency of crowding was 57.5%, urban population had 64% and rural had 51%. The difference between the urban and rural population was statistically significant (p=0.0001) with urban population having more of anterior crowding. (Table-5)

Table 5: Prevalence of Crowding in college students from urban - rural area.

Crowding	Urban		Rural		P-value
	n	%	n	%	
Present	1189	64	738	51	<0.0001*
Absent	672	56	714	49	

(*P<0.05 significant, CI 0.50 -0.67)

Midline diastema was present 17%, urban had 11%, rural had 23%. The difference between the urban and rural population was statistically significant (p=0.0001) with rural population having more of midline diastema. (Table-6)

Table 6: Prevalence of diastema in college students from urban - rural area.

Diastema	Urban		Rural		P-value
	n	%	n	%	
Present	207	11	334	23	<0.0001*
Absent	1654	89	1118	77	

(*P<0.05 significant, CI 1.96 – 2.89)

8. Discussion

Malocclusion has often been referred to as" disease of civilization" signifying that it is found (or at least reported) primarily in urbanized populations. This call for such studies involving the urban- rural population.

This cross-sectional study aims at finding the percentage of prevalence and type of malocclusion in students of age group 17-23 from urban and rural population in a college in Coimbatore district, Tamil Nadu state, India.

The prevalence of malocclusion in this study was to be around 84% which is in similar finding to by Ojass kumar *et al*. [8] Retna Kumari Narayanan *et al*. [7] Roopa Siddegowda *et al*. [15] Mahajen *et al*. [16].

In the present study prevalence of malocclusion was significant with increased overjet and midline diastema in rural area which is similar to the study conducted by Amit Rekhi *et al*. [19], who stated that rural population had midline diastema of 26.97% and increased overjet.

In the present study crowding was found to be the predominant type of malocclusion in urban population similar to the study conducted by Divakar karanth *et al*. [12] and Ravi Kumar Gudipaneni *et al*. [13].

In the present study class II type of malocclusion to be predominant in urban population similar to the study conducted by Kaur *et al*. [17], Dila Baz Khan *et al*. [18]

The most common type of malocclusion in this study was Angle's class I in both rural and urban population (88% and 82%) followed by crowding (51% and 64%). The least prevalent malocclusion was Angle's class III (3% and 5%). The result of the study regarding the most common type of malocclusion were in agreement with a study carried out by Patoli and Rashid [20] who reported Angle's Class I to be the most prevalent malocclusion (88.8%) followed by crowding (50%). However the result of this study were contradicted by Abu Alhaija *et al*. [21] who reported Angles class II as the most commonly occurring malocclusion.

This study is limited as it has only recorded malocclusion in age group 17-23 years which cannot be generalized to the entire population.

9. Conclusion

Malocclusion is wide spread in population examined at Coimbatore, India. Prevalence of malocclusion was more in rural population when compared with urban population. Crowded incisors were most common feature associated with class I malocclusion. In future further efforts should be made on a larger scale to obtain a base line data to find out the orthodontic treatment need.

Dental Health Status among College Students and the Treatment Needs

Abhirami K[1], Vallig[1], Karthikeyan MS[2]

[1]Department of Dental Surgery, PSGIMS and R, Coimbatore, India

[2]Department of Community Medicine, PSGIMS and R, Coimbatore, India

ABSTRACT

Aim: The aim of this cross-sectional study was to investigate the oral health status and normative need of college students both from urban –rural population of age group 17-23.

Materials and method: A descriptive cross-sectional study was done among 3312 college students belonging to urban –rural population of age group 17-23 in Coimbatore district, Tamil Nadu using purposive sampling method. Data entered in Microsoft excel sheet and analyzed using statistical package for social science (SPSS) version 24. Chi-square test was used for computing statistical significance

Result: Overall dental caries prevalence accounted to 70% (rural-72.12% urban-68.43%) with a mean DT of (1.14) in the rural population than urban population (1.09) and majority of the student's required one surface restoration. Periodontal status of the students as measured by community periodontal index (CPI) showed that majority of the student participant (32.66%) had calculus necessitating the need for oral prophylaxis, with the mean CPI index of (1.13) rural than (0.94) Urban.

Conclusion: In this study the dental caries prevalence and the periodontal problem was more in the rural population than the urban population with the one surface restoration and oral prophylaxis as the predominant treatment need.

Key words: College students, Oral health, Urban, Rural, Dental caries, Periodontal disease

INTRODUCTION

Oral diseases are the most common of the chronic diseases and are important in public health problems because of their prevalence, their impact on individuals, society, and the expense of their treatment [1]. On September 6, 2016, a new definition of oral health was approved by the FDI (World Dental Federation General Assembly) [2]. The new definition acknowledges the multifaceted nature and attributes of oral health. In developing countries were the resources are sparse it is of utmost importance to plan primordial preventive strategies rather than treating oral diseases and data regarding the prevalence of oral diseases gives us comprehensive picture to identify the target group and impart preventive modalities and there is a paucity of such data of this age group (17-23) in Coimbatore, Tamil Nadu, India.

College life is a crucial period of transition with personal responsibility. Students in this period can be targeted for preventing dental diseases and building future oral health [3] voluminous literature pertaining to oral health status of school children [4,5] is available, but data pertaining to young adults, especially to college students are sparse. Thus, analysing epidemiological data of age groups not customarily studied [world health organisation (WHO) index age groups] give the exact picture of the current oral health status and normative needs of the population. The aim of this study was to accesses the oral health status among and the normative needs among college students in Coimbatore in Tamil Nadu.

MATERIALS AND METHOD

Study Design: Descriptive cross-sectional

study. A health screening camp of dental, ophthalmology and general medicine was conducted for students in a private college in Coimbatore from 22-1-2018 to 22-2-2018 and about 3500 students were screened by a team of doctors from PSGUHTC. Two examiners were involved in this research study, examiner A and examiner B. The study was carried out for a period of 28 days approximately examining 125 students per day. Demographic data including name, age, gender, and permanent address of the candidate were recorded. The Inclusion criteria were subjects with permanent dentition, with no remaining deciduous dentition, subjects with age group of 17-23, Students present during the period of oral examination. The students taken for the study were 3312. The study protocol was submitted to the institutional ethical committee [PSGIMSR] and clearance was obtained Project proposal number-18/223 August 10th 2018.

Oral examination was performed by two trained and calibrated examiners. Before the survey, both the examiners and recording clerks were participated in a training and clinical calibration program in the department. Following this training, 10% of the students were examined by each of the two investigators to assess inter-examiner reliability and Kappa Values of 0. 87 and 0.88 were found, respectively. The interview and examination of a single study subject took 3 to 4 minutes. The study was done using probability sampling method and the sample size of calculated reference to Punitha et al. [6] using prevalence of caries as 36.7%. Sample size was calculated using formula $n=4 \times pq/d^2$ and found to be n=372.

Method of registration

Oral examination was done using the WHO Basic Oral Health Assessment [7] form with plane mouth mirror and WHO periodontal probe. Clinical examination was conducted using natural light with the participant sitting on a chair with a head rest. The examination was performed in a classroom. The examination area was arranged in such a way to allow one person at a time apart from the examiner and the recorder. The recorder was made to stand close to the examiner so that the instructions and the code could be easily heard, and the examiner could see that the findings were being recorded correctly. The data were coded and analyzed using the SPSS version 24 software the level of statistical significance was kept at $p<0.05$. The descriptive statistics were calculated. Chi-square test was used.

RESULT

A total of 3312 (urban-1888; 57%, rural -1424; 43%) participated in this study. The average DMFT among the target group was 1.92 with urban having DMFT score of 1.95 rural with 1.80 (Table 1).

In this study the highest score as measured by CPI showed that a total of 21.13% of the student had a bleeding as their highest score, 32.66% had calculus indicating the need for oral hygiene instruction and oral prophylaxis and 5.07% had a pocket of 4-5mm necessitating surgical interventions (Table 2). The community–wise distribution according to the highest score as measured by CPI showed that35.74% rural and 30.34% urban had calculus as the highest score.

Mean number of sextants with bleeding was higher in urban (0.21), whereas the mean number of sextants with calculus and shallow pocket was more in rural (0.35) compared to urban (0.30) (Table 3).

Association of CPI Index with community (urban/rural) shows that rural population has increased periodontal diseases than urban, and it is statistically significant $p < .000$ with 95% CI (0.255-0.121) (Table 4).

Loss of attachment according to the highest score showed that loss of attachment of 0-3mm was seen in 94.41%, 4-5mm in 3.38%, 6-8mm in 1.20% of the population (Table 5).

Mean number of sextants with score 1 was more in rural than urban (0.04; 0.02) (Table 6).

Association of Loss of attachment with community (urban/rural) shows that rural population has increased Loss of attachment than urban and it is statistically significant $p < .003$ with 95% CI (0.048-0.010) (Table 7).

Among the study participant 0.3% had prosthesis in the upper arch and 0.1% in the lower arch, out of which 0.3% had bridge denture and 0.1% had both bridge and partial denture.

DISCUSSION

Oral health is an essential component of general health and overall well-being of an individual. Oral cavity and its surrounding structures that are free of any diseases are indicative of good oral health. This not only makes a person look and feel good, it is equally relevant in maintaining oral function [8-10]. Oral disease is one of the most common public health issues worldwide with significant socio-economic impacts, and yet it is frequently neglected in public health policy [11].

Schools and colleges play an immense role in the growth of young minds not only for learning new information but also by having long-lasting effects [12]. In India despite improvements in infrastructure and dental manpower, oral health care remains to be neglected entity as it is not considered to be life threatening [13].

As there is no national level oral health policy and fee for services is still the most common mode of payment for dental service preventive strategies hold priority as the most economical way for improving oral health of the community. To advocate preventive measures, it is essential to assess the complete presence of disease burden in the community.

This cross-sectional study aims at finding the percentage and prevalence of dental caries, periodontal diseases in students of age group 17-23 from urban and rural population in a college in Coimbatore district, Tamil Nadu State, India.

Overall caries percentage in the study conducted by DharV et al. [14], Saravanan S et al. [15], Niyanta Joshi et al. [16], Farooqi FA et al. [17], Kumar S et al. [18] was found similar to the present study around 70%

The mean DMFT of the study conducted by theFarooqi et al. [17], Kumar et al. [18] is like the present study (1.94 ± 2.0) and (1.94).

The study conducted by Mohammed A.AL-Rafee et al. [19], Sriailapanan P, et al. [20], Soroye et al. [21], Sanadhya et al. [22], Akinyamoju et al. [23], showed rural population had more caries prevalence which is supporting to the present study.

The study conducted by Maserejian NN et al. [24], Patro et al. [25], David J et al [26] showed Urban population to have more Dental caries prevalence contradicting to the present study.

The study conducted by Kalsbeek H et al. [27] (24%) (Score-1), Hannan et al [28] (33.5%) (score-2) periodontal index was like the present study.

The study conducted by Arvidson et al. [29], Baiju et al. [30], Vadiakas et al. [31] concluded that rural population had more periodontal diseases than urban population like the present study.

The study conducted by Popoola et al. [32], Sane [33] had mean plaque index (1.12 ± 0.41) which was like the present study (1.13 ± 0.997). The study conducted by Zhang S et al. [34] showed that only 7% of the population had normal periodontium which was contradicting to the present study. The limitations of this study are inherent to cross-sectional studies, which do not allow establishing a relationship of cause and effect, and it only addresses the prevalence and severity of the disease without looking at sociodemographic variables such as parental education, economic status or family size. Furthermore, the current paper only reports the dental caries and the periodontal status and does not examine the oral hygiene practice or other individual reasons for the above dental morbidity.

CONCLUSIONS

The caries prevalence and the periodontal diseases severity were higher in students from rural areas than the students from the urban area. The DMFT index was higher in students from urban area than the students from rural area; this is because the FT value was higher in the urban area indicating the awareness and availability of dental care.Dental health care needs are high in rural areas than in urban areas.

RECOMMENDATION

It is recommended that continuous scientific monitoring, design, and effective implementation of preventive and restorative programs to be carried out by dental surgeons and included in national wide program like RBSK (RASHTRIYA BAL SWASTHYA KARYAKRAM).

ABSTRACT

Mucormycosis is a very aggressive, devastating opportunistic fungal infection commonly involving nasal, maxillary,orbital, and cerebral regions. In the second wave of the coronavirus disease 2019 (COVID-19) pandemic, a high frequency of mucormycosis infections has been seen because of the triad of COVID-19, systemic steroids, and preexisting diabetes mellitus. A patient might present with a simple mobile tooth/teeth with multiple gingival abscesses Necrotic bone could be seen in the palate. Blackish discoloration might be present in the oral mucosa. There might be extraoral swelling . If rhino-oculo cerebral mucormycosis is diagnosed, then there are two immediate treatment modalities to be followed. Both surgical and medical treatment are necessary. Surgical is thorough debridement of the necrotic tissue. To prevent the occurrence of mucormycosis, meticulous glycemic control and rational use of steroids and antibiotics for the shortest possible time with adequate attention toward the ventilators and tubing are necessary.

KEYWORDS: *COVID-19, dentistry, gingival abscesses, mucormycosis*

Mucormycosis is a very aggressive, devastating opportunistic fungal infection commonly involving nasal, maxillary,orbital, and cerebral regions. It is acquired primarily through inhalation of spores through the nasal route. It is a rapidly progressive fungal disorder and any delay in identification and management leads to high morbidity and mortality.

The fungus belongs to the order Mucorales and subphylum Mucormycotina and it is angioinvasive that causes occlusion of blood vessels, which leads to tissue necrosis. Other forms of clinical presentation are gastrointestinal, bone, and joint infection and pulmonary, cutaneous, and disseminated mucormycosis.

In the second wave of the coronavirus disease-2019 (COVID-19) pandemic, a high frequency of mucormycosis infections has been seen because of the triad of COVID-19, systemic steroids, and preexisting diabetes mellitus (DM). This could be due to any or all of the following reasons COVID 19 associated illness requiring high and prolonged steroid use leading to worsening of preexisting DM and immunosuppression; elevated ferritin leading to high iron load, acidosis, and endothelial damage and the use of multiple broad spectrum antibiotics to prevent or treat secondary infections.[1,2] Since India has the second-highest number of COVID-19 cases,[3] the second-highest number of DM

patients,[4] and the highest incidence of mucormycosis,[5] it is expected that mucormycosis will be seen in India in huge numbers, especially in COVID-19 patients.

Predisposing Factors

- Uncontrolled DM
- Concurrent/recently treated COVID-19
- Inappropriate use of steroids
- High doses of steroids
- Using for prolonged periods.
- Immunocompromised individuals
- Malignancy
- Transplant recipients.
- People under long-standing oxygen therapy
- Prolonged intensive care unit (ICU) stays
- People under mechanical ventilation
- Prolonged use of broad-spectrum antibiotics
- Nosocomial-contaminated dirty linen, ICU instruments, and materials - if not properly sterilized.

Clinical Presentation

A patient might present with a simple mobile tooth/teeth with multiple gingival abscesses [Figure 1]. Necrotic bone could be seen in the palate. Blackish discoloration might be present in the oral mucosa. There might be extraoral swelling [Figure 2]. We should not misdiagnose it as simple periodontitis or cellulitis if the patient is/was COVID positive and diabetic and was given steroids. Strongly suspect mucormycosis and evaluate the patient or refer to a higher center. The patient might have other symptoms such as headache, myalgia, and fever and nasal symptoms such as nasal discharge often bloody, brownish, or blackish. Diminished vision or proptosis might be present. There could be altered sensorium in case of cerebral involvement.

Figure 1: Multiple gingival abscesses in a diabetic patient who was coronavirus disease positive before 15 days and was given steroids (Picture Courtesy – Dr. S. Sanjeev Kumar, Ambur)

Diagnosis

Clinically, there will be necrotic bone with blackish eschar. Computerized tomography and/or magnetic resonance imaging might show erosion of bone involving nasal, paranasal sinuses, maxilla, ethmoid, and base of the skull. KOH smear will show the presence of nonseptate, ribbon-like hyphae (at least 6–16 μm wide) with obliteration of the vessels. On histopathological examination, we could find angioinvasion, coagulation necrosis, hemorrhagic infarction, infiltration by neutrophils, and perineural invasion. Fungal culture done with routine media between 30°C and 37°C might show grayish–black or cotton-white colony.[6]

Treatment Algorithm

If rhino–oculo cerebral mucormycosis is diagnosed, then there are two immediate treatment modalities to be followed. Both surgical treatment and medical treatment are necessary. Surgical is thorough debridement of the necrotic tissue. Functional endoscopic sinus surgery is done if there is nasal and paranasal sinus involvement without involving maxilla or palate or zygoma. If the maxilla is involved, then maxillectomy is done. If the orbit is involved, then orbital exenteration is done. If the frontal bone is involved, then debridement or cranialization is done. The osteomyelitic bone is removed and the necrotic tissue is debrided.

Medical treatment is with injection amphotericin B (1–1.5 mg/kg/day) or injection liposomal amphotericin B 5–10 mg/kg/day for 14–21 days.

Conclusion

As the disease is known to be really very aggressive, mortality is generally >50%.[7] The mortality increases

Figure 2: Extraoral swelling in a patient who is diabetic and was coronavirus disease positive before 20 days

[Downloaded free from http://www.jpbsonline.org on Saturday, December 18, 2021, IP: 103.224.34.2]

to an unbelievably high 80%, with an intracerebral involvement of the disease.[8] Larger studies are the need of the hour in mucormycosis in COVID-19 to know prognostic markers and outcomes.

Due to the rapid increase in cases of mucormycosis in COVID-19, there is an immense need to improve awareness among treating physicians and dentists about early diagnosis and treatment. There is marked variability in the frequency of mucormycosis cases reported in different regions in pre- and post-COVID times. A nationwide registry and larger studies could help in providing useful data. Abnormalities in the immune system in COVID-19, sensitivity patterns of fungus, and the reasons for the sudden surge in cases in the second wave of the pandemic need to be studied. To prevent the occurrence of mucormycosis, meticulous glycemic control, rational use of steroids and antibiotics for the shortest possible time with adequate attention toward the ventilators and tubing are necessary. The microbiologists should also monitor the ward, ICU, and hospital environment to account for fungal diseases and take regular swabs and culture them.

Declaration of patient consent

The authors certify that they have obtained all appropriate patient consent forms. In the form the patient(s) has/have given his/her/their consent for his/her/their images and other clinical information to be reported in the journal. The patients understand that their names and initials will not be published and due efforts will be made to conceal their identity, but anonymity cannot be guaranteed.

CASE REPORT

A Simple and Innovative Technique for Prosthetic Rehabilitation of Continuous Maxillary and Orbital Defect

[1]Yogesh Kumar, [2]Vinayak Bharate, [3]Dinesh Babu, [4]Chandralekha Verma

ABSTRACT

Orbital exenteration along with hemimaxillectomy for malignant tumor of maxilla usually results in continuous orbital and maxillary defect. A removable maxillofacial prosthesis with adequate retention and stability during functional movement along with good esthetics is the key for successful rehabilitation of such patients. This case report describes a novel and yet cost-effective method for retention of silicone orbital prosthesis using acrylic resin base attached to maxillary obturator using pin and socket of an electric plug which results in better retention of both the prosthesis.

Keywords: Continuous defect, Obturator, Orbital prosthesis.

INTRODUCTION

Surgical resection for orofacial malignancy is extremely debilitating in nature because of its deep psychological impact with severe disfigurement and functional impairment. It often results in communication between the oral and nasal cavity that causes difficulty in swallowing and speech, nasal regurgitation, and unesthetics facial appearance. Such defects are usually rehabilitated by a facial prosthesis to restore function and appearance along with an intraoral obturator to restore speech and swallowing.[1] Various methods used for retention of such prosthesis include spectacle frame,[2] anatomic retention using acrylic conformer relined by a soft liner,[3] adhesives,[4] stud attachments, magnets,[5] and osseointegrated implant.[6] With use of spectacle retained prosthesis, it becomes mandatory for the patient to wear spectacles during use of prosthesis. Limitations of adhesives include possible allergic reactions, decreased efficacy with use, and need for daily application and removal. Although osseointegrated implants may provide the most reliable prosthesis retention, additional surgeries, expenses, inadequate bone, and prior radiation to the area may contraindicate their use. Other means are use of magnets or buttons to attach orbital prosthesis with obturator.[7] Limitations of magnets include high cost, corrosion, and loss of magnetism with time. This case report describes an innovative technique for retention of silicone orbital prosthesis to maxillary obturator with use of pin and socket of an electric plug.

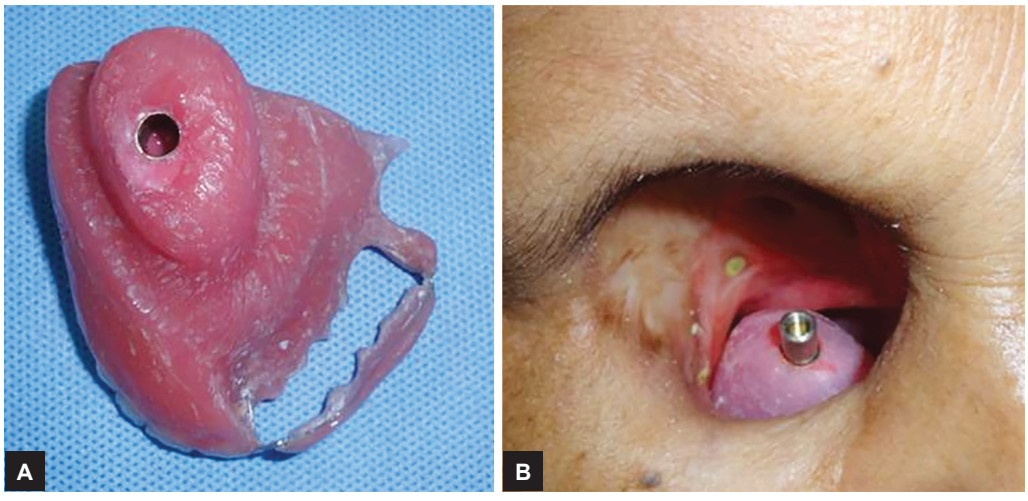
CASE REPORT



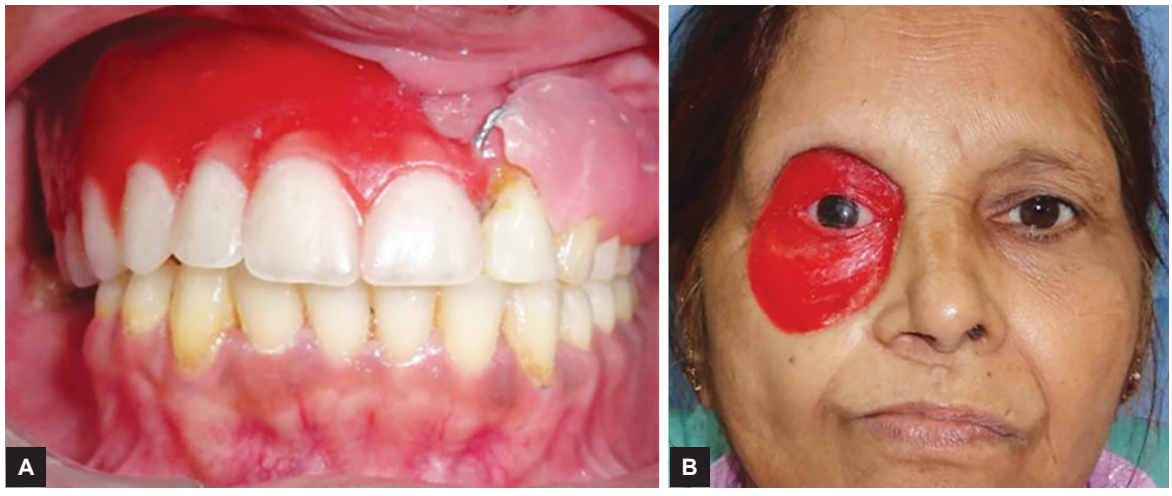
A 55-year-old female patient reported to the Department of Prosthodontics, CDER, AIIMS, New Delhi, with a chief complaint of missing right eye and regurgitation of food since last 3 months (Figs 1A and B). Patient had underwent orbital exenteration and hemimaxillectomy of the right side because of squamous cell carcinoma eroding the right orbital floor, posterior wall of maxilla, infratemporal fossa, right hard palate, medial wall of maxilla, right nasal cavity, and right ethmoidal air sinuses. This led to the formation of right orbital defect which was continuous with intraoral maxillary defect. For prosthetic rehabilitation of this patient, silicone orbital prosthesis attached to a hollow closed bulb obturator with the help of electric pin and socket was planned.

Impression Procedure for Obturator and Orbital Defect

Primary impression of intraoral maxillary defect was made with alginate and poured with dental stone (type III). Maxillary cast was then surveyed and undesirable undercuts were blocked. Custom tray was thus fabricated, border molding of the defect was done and final impression was made with light body addition silicone. On final working, model of obturator record base was fabricated, jaw relation was made followed by try in patient to check

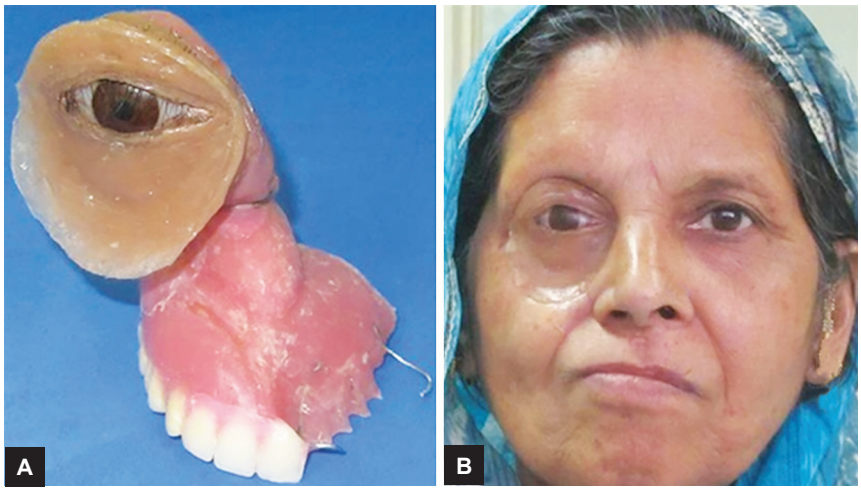
Figs 1A and B: Orbital defect and intraoral maxillary defect

Figs 2A and B: Intraoral maxillary obturator



esthetics and function. After try-in was completed, the orbital impression was made with trial denture in place covering the intraoral defect. Patient was draped for impression and extraoral marking was made on the face with indelible pencil so that it can replicate exact position of anatomical landmarks over the cast. Custom tray was fabricated with the help of impression compound with additional relief holes. Alginate was used as a primary impression material. Final impression of orbital defect was made with light body addition silicone with custom acrylic tray.

Attachment of Pin and Socket to Acrylic Conformer and Obturator



An acrylic conformer of orbital defect was fabricated and trial was made. To provide a mechanical undercut for the retention of orbital prosthesis, a 4 mm thick sprue wax was attached to the base of acrylic conformer. An obturator plate made of cold cure acrylic resin was also adjusted in patient's mouth. On the base of acrylic conformer, a pin of electric plug was attached and a corresponding socket was attached to the top of bulb of the maxillary obturator and fit of both the parts were checked for easy insertion and removal of prosthesis. Flasking, dewaxing, and packing with heat cure acrylic resin was carried out for both acrylic conformer and obturator. Processed heat cure bases were tried on the patient for accurate adaptation, retention, and stability during functional movements (Figs 2A and B).

Fabrication of Orbital Prosthesis

To replicate pupil-iris size, color, contour, and sclera shape of contralateral eye accurately, a customized ocular prosthesis was fabricated. Its final orientation was first refined on the working model with the help of recorded facial measurement and then tried on patients face. Missing structures like eyelids and associated anatomical structures were sculpted in modelling wax. Final completed wax pattern was tried on the patient face for evaluation of ocular orientation gaze, eyelid aperture, size, and volume

Figs 3A and B: Trial of obturator and orbital prosthesis

Figs 4A and B: Final silicone eye prosthesis and intraoral obturator

of sclera visible and prosthesis margin fit as compared to the contralateral eye (Figs 3A and B). Patient's opinion was also taken regarding the esthetics acceptability of prosthesis. This was followed by flasking, dewaxing, and packing in room temperature vulcanizing (RTV) silicone. Retrieved orbital prosthesis was characterized and was delivered to the patient with intraoral obturator in place (Figs 4A and B).

DISCUSSION

Surgical resection of the maxilla usually results in communication between the oral and nasal cavity that causes difficulty in swallowing, nasal regurgitation, unintelligible speech, and unesthetic appearance. Surgical reconstruction in such patient may add major financial burden and also has certain limitations, such as donor site morbidity, risk of recurrence, and compromise in esthetics. Therefore, prosthetic rehabilitation is usually preferred for such defects as it is quite inexpensive, allows for periodic examination and cleaning, and is also an alternative to surgery in medically compromised patients.

For rehabilitation of such patient, selection of biologically and functionally acceptable material for fabrication of prosthesis with economically feasible retentive aid should be used. For fabrication of orbital prosthesis, Factor II RTV silicone was used as it has better marginal adaptation, adequate edge strength, more lifelike appearance and better color stability as compared to other available material for maxillofacial prosthesis fabrication.[8] In present case, to retain the obturator and orbital prosthesis together economic and household electric pin and socket was used.

With the use of osseointegrated implant and magnets, a much better final outcome with improved retention and stability would have been achieved but this was not possible because of financial constraints. Advantages of this technique are adequate retention, economical, tissue tolerance, noninvasive, and comfort for use and wear.

CONCLUSION

Orbital exenteration along with hemimaxillectomy with an ablative surgery as a treatment procedure for malignant

tumor of maxilla resulting in continuous maxillary and orbital defect severely affects the vital functions, such as mastication, speech, swallowing, deglutition, and facial esthetics. For rehabilitation of such defects, removable maxillofacial prosthesis with adequate retention and stability during function along with good esthetics is necessary. A simple and economic attachment which provides adequate retention for both orbital and obturator prosthesis made up of a pin and socket of an electric plug, was used in this case.

Effect of denture soft liner on mandibular ridge resorption in complete denture wearers after 6 and 12 months of denture insertion: A prospective randomized clinical study

Dinesh Babu B, Veena Jain, Gunjan Pruthi, Nidhi Mangtani, Rajath S. Pillai[1]

Department of Prosthodontics, Centre for Dental Education and Research, All India Institute of Medical Sciences, New Delhi, India, [1]Department of Dentistry, Aarhus University, Aarhus, Denmark

Abstract

Purpose: Soft liners act as a cushion between the denture base and the residual ridge. Hence, it is important to study their effect on resorption of mandibular denture bearing area. Therefore, the purpose of this study was to evaluate the influence of soft denture liner on mandibular ridge resorption after 1 year in completely denture wearers.

Materials and Methods: Twenty-eight completely edentulous patients having age between 45 and 60 years with well-formed ridges in class I jaw relations were selected as per the inclusion and exclusion criterion. Randomization chart was used to enroll participants in experimental and control groups who were given mandibular dentures with and without soft denture liner, respectively. Vertical measurements were made on orthopantomograph and analyzed using Adobe Photoshop 7.0 software at five points, i.e., one at central incisor and two points at right and left first premolars and two in each first molar region.

Results: On application of repeated measures analysis of variance, both groups showed a significant change in bone height after denture delivery ($P < 0.05$). Intergroup comparison (Wilcoxon rank sum test) of bone height in different regions at various time intervals showed statistically significant difference in bone levels ($P < 0.05$) from baseline to 6 months and baseline to 12months ($P < 0.01$), while the difference was statistically not significant during 6 and 12 months' period.

Conclusion: The use of soft denture liner significantly reduces the residual ridge resorption in complete denture wearers as compared to conventional denture wearers (without denture liner) over a period of 1 year.

Keywords: Complete denture, edentulous ridge, residual ridge resorption, soft liner

INTRODUCTION

Residual ridge resorption is a chronic, progressive, irreversible, and disabling disease, and it has probably multifactorial origin.[1] Bone loss varies from patient to patient, but more significant changes occur in the mandibular arch. Tallgren[2] and Atwood and Coy[3] found

that the mean ratio of anterior maxillary to anterior mandibular (residual ridge reduction [RRR]) was 1:4. This is because mandibular ridge bears higher functional forces transmitted through the dentures than the maxillary ridge because of its smaller area and less advantageous shape of the lower basal seat.[4]

Residual ridge resorption, especially in the mandible, may affect denture stability and retention.[5,6] Gross resorption of the edentulous mandibular alveolar process over a period of time resulting in excessive loss of the denture bearing ridge and mostly the overlying thin and atrophic mucosa over it makes it more difficult to withstand the masticatory load.[7,8] The mucosa gets impinged between the sharp ridge and the denture resulting in severe pain and discomfort to the patient.[8]

The difficulties encountered in such patients during function can be reduced with the use of either implants or resilient denture liners.[5,6,9] Although implants have been reported as highly effective,[10] they are not a viable solution for all edentulous patients because of unfavorable underlying bone, relevant medical, psychological, and financial constraints.[11] On the other hand, treatment with the resilient denture liners has only few limitations, being the nonsurgical application procedure, and have low treatment cost. The flexibility, resiliency, and the shock absorbency of the resilient denture liner materials help in impact reduction and distribution of masticatory load to the ridge.[12-15]

The use of soft liners became popular in dentistry because they have many clinical advantages. These materials have the ability to help in healing of the inflamed mucosa,[16-18] distribute the functional load in the support area of the prostheses[19,20] and improve their adaptation and retention.[21] According to the literature, due to cushioning effect provided by soft liners, lesser amount of forces are transferred to the underlying bone during various functions as compared to one without soft liners.[13-15,22] This leads to a reduction in residual ridge resorption. Although the idea of the resilient liners was introduced several years ago, most of the studies were either laboratory[22] or clinical observations for their efficacy. As intraoral environment is the most precise testing, clinical studies are a must to draw definitive conclusions.[23] Currently, the literature is scanty regarding the evidence of effect resilient liners on residual ridge resorption in complete denture wearers. Therefore, this study was designed to evaluate the effect of soft denture liners on the mandibular ridge resorption in complete denture wearers till 1 year of their application.

MATERIALS AND METHODS

This clinical study was carried out in the Department of Prosthodontics, CDER, All India Institute of Medical Sciences, New Delhi after approval from institutional ethics committee (IESC/T-255/01.06.2012). A total number of 28 completely edentulous patients within the age group of 45–60 years following the inclusion criteria; edentulous patients for the last 6 months, having class I jaw relation, well-developed ridges with firm mucosa and no previous denture experience were selected to participate in the study. Patient suffering with any systemic disorder which may influence bone metabolism and having class II or class III jaw relationship were excluded. Participants were thoroughly informed about the whole procedure, need of follow-up visits, radiographs required, and written informed consent was obtained.

The sample size was calculated based on literature review[24] as two groups, parallel, repeated measures with resorption as the primary outcome variable measured at 6 months' and 12 months' postdenture insertion. Keeping in mind the possibility to have dropouts and to achieve 90% power with detectable difference at 95% confidence interval, 14 participants were enrolled in each of the two groups as per stratified (male/female) block randomization which was based on computer-generated numbers given by the statistician.

For participants in experimental group (n = 14, 7 males and 7 females), maxillary dentures were fabricated in heat cured acrylic resin (Travelon, Dentsply India, Mumbai, India) while mandibular denture was lined with heat cured acrylic denture soft liner (Permasoft, Dentsply International, West Philadelphia Street York, PA, USA) at the time of packing. Participants in control group (n = 14, 7 males and 7 females) were provided with conventional maxillary and mandibular complete dentures fabricated

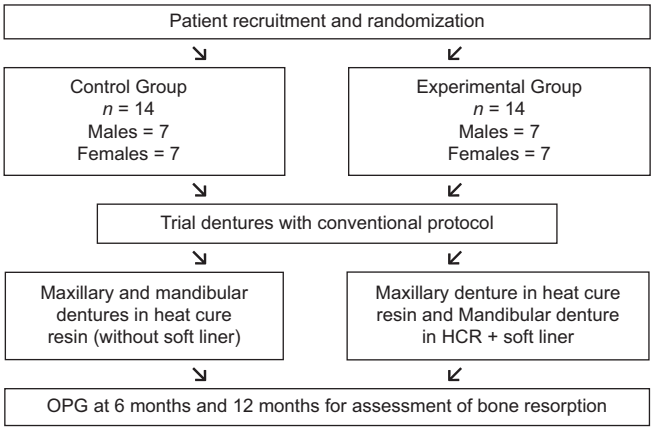

Figure 1: Flow chart of methodology

in heat cured acrylic resin (without soft liner) [Figure 1]. Bilateral balanced occlusal scheme was given in all the participants. The radiopaque markers were placed over the tooth surfaces in mandibular dentures after dewaxing at five different points (one in central incisor region and one in 1st premolar and 1st molar region on both sides) and secured in position with glue. Then the mold was packed in heat cured acrylic resin. Besides this, in experimental group, wax spacer of uniform two mm thickness was adapted over the mandibular cast and the remaining space was packed with heat cured acrylic resin. Wax spacer was replaced after trial closure with heat cured acrylic soft denture liner and denture was cured using the standard procedure. After processing, dentures were remounted for occlusal adjustment. Following this, dentures were finished, polished, and delivered to the participants.

For each participant, three panoramic radiographs (orthopantomogram [OPG]) were taken to assess the amount of bone resorption; immediately, at 6 months and at 12 months after denture insertion.

To assure the reproducibility between successive films, all the radiographs were taken on same machine (OPG machine details) by a trained radiographer using standard protocol and blinded about the use of soft denture liner. For the measurements, a reference plane was drawn touching the inferior border of the mandible. On this line, 90° tangents were drawn from the lower border of the radiopaque markers in five different regions; 2 in 1st premolar, 2 in 1st molar, and 1 in midline [Figure 2]. The distances from the radiopaque markers to the reference plane were measured with the help of Adobe Photoshop 7.0 (Adobe Systems, San Jose, CA, USA). All the measurements were performed by two independent and blinded examiners to minimize the operator-based bias and error. In case of different values, measurements were verified again.

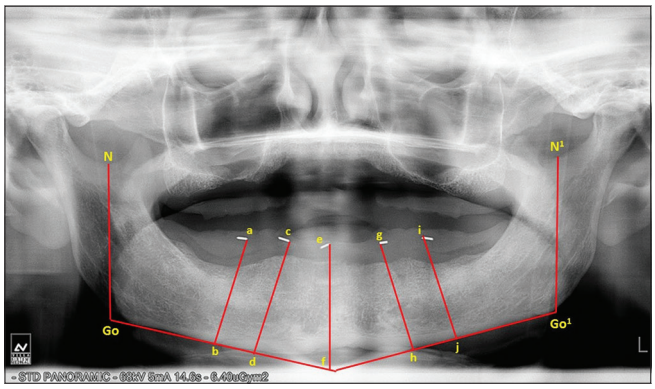

Figure 2: Orthopantomogram showing the measurement of bone height from the radiopaque marker to the reference point at the base of the mandible. Go and Go1 = mandibular right and left gonion, N and N1 = right and left mandibular notch, N-Go and N1-Go1 = fixed reference line, a, c, e, g, i = radiopaque markers

The magnification error for each participant was corrected by measuring the distance from the mandibular notch to the gonion on each radiograph. Measurements recorded immediately after denture insertions were considered as baseline values, and measurements made at 6 months and 12 months were adjusted according to the baseline radiograph.

The following equation represents an example of correction factor:

$$\text{Correction factor} = \frac{\text{Notch to gonion distance at denture insertion}}{\text{Notch to gonion after 6 months or 12 months}}$$

The values on each side were multiplied by the correction factor. To avoid any horizontal error, right and left sides of mandible were treated as separate and multiplied with respective factors.[24]

The data were analyzed using Statistical Package for Social Sciences (version 19, IBM, Chicago, IL, USA). Quantitative variables were assessed for approximate normality and summarized by mean and standard deviation. Wilcoxon rank-sum test was used to compare nonparametric variables in between the two groups. Within group change in the quantitative variables was assessed by repeated measure two-way analysis of variance followed by *post hoc* with Bonferroni test. In this study, the confidence interval was set at 95% and $P < 0.05$ was considered as statistically significant.

RESULTS

A total of 28 (14 male/14 female) participants with mean age of 53.93 ± 4.25 years were rehabilitated with maxillary and mandibular complete dentures. The mean mandibular bone height from radiopaque markers at five different points in the right posterior, anterior and left posterior regions to a reference plane in mandible was measured in both groups over a period of 12 months [Table 1]. The mean change in bone height in right posterior, anterior and left posterior region in control group from baseline to 12 months was 1.4 ± 0.14 mm (4.9%), 1.4 ± 0.2 mm (5.2%), and 1.7 ± 0.05 mm (5.9%) respectively and in experimental group, this was 0.7 ± 0.08 mm (2.3%), 0.6 ± 0.06 mm (2.5%), and 0.9 ± 0.08 mm (3.2%), respectively. Results showed decrease in bone height at

all time intervals in both groups, and the change was statistically significant ($P < 0.05$) [Table 2].

The comparison of bone height between the two groups in different regions at various time intervals showed significant difference in bone levels ($P < 0.05$) at baseline to 6 months and baseline to 12 months' period ($P < 0.01$), while the difference for 6 and 12 months' period was statistically not significant in right posterior ($P = 0.43$) and anterior region ($P = 0.16$) [Table 3].

DISCUSSION

Resorption of the residual ridge has been estimated with various radiographic techniques such as lateral cephalometric and panoramic radiographs. Panoramic radiography is widely used because an image of both the jaws can be produced on one film with a relatively lesser radiation exposure, and is common in routine examinations, especially for edentulous patients before the construction of complete dentures.[25-27] Magnification is one of the major problems with panoramic radiography. Larheim and Svanaes[28] investigated the precision of measurements of mandibular linear dimensions in panoramic radiographs and found that the variability of vertical measurements made from repeated panoramic radiographs is small when patients are properly positioned in the panoramic apparatus. According to Xie *et al*.,[29] if reference lines and measured points are located in the same vertical plane or in approximately the same plane as the teeth, variations in vertical measurements in the mandible and maxilla are within a small range.

Enlow *et al*.[30] described the distribution of surface fields of resorption and deposition in all parts of the edentulous mandible and stated that residual ridge resorption is usually more rapid in the premolar and molar region than the anterior region of the mandible, due to the lower position of the reversal line in the posterior region. Hence, it is especially important to record the resorption in anterior and posterior region of the mandible. The results of this study revealed statistically significant rate of RRR at all five reference points of measurement in mandible in all the participants. After 6 months of denture delivery, the bone loss ranged from 0.3 to 1.2 mm as compared to that during 6–12-month period (0.3–0.5 mm) in both groups in all the regions. According to Tallgren[2] and Kovacic *et al*.,[31] RRR was greater during the first few months after the tooth extraction than later. According to Karaagaçlioglu and Ozkan,[32] duration of edentulousness is one of the most important factor in contributing to the severity of mandibular bone loss. Mandibular resorption rate was greatest in the earlier stages of edentulism and slowed with the longevity of edentulism.[33]

Participants in the experimental group showed 50% lesser bone loss in all the three regions compared to the control group over a period of 12 months. After 1 year period, bone loss in experimental group ranged from 0.3 to 0.9 mm and in control group were 0.5–1.7 mm. Similar results were obtained by Elcharkawi and elMahdy[24] when comparing the bone loss in mandible after 6 months of denture delivery with and without soft liners. Lesser resorption with soft liner may be due to equal distribution of stresses under the denture and

*$P<0.05$ - statistically significant; Wilcoxon rank-sum test

lesser amount of force transmitted to underlying bone due to cushioning effect provided by viscoelastic property of soft liners.[13] Thus, the use of the resilient reliner material considerably minimized the stress in the alveolar bone and mucosa.[33-35] According to Lima *et al*.,[34] the thickness of the soft liner plays a significant role in the stress distribution especially in patient with thin mucosa, 2 mm thick soft liner relined denture shows lower stress distribution to bone as compared to denture with no soft liner or soft liner of variable thickness (0.5,1, 1.5, 2.5 mm). Taguchi *et al*.[36] stated that acrylic resilient liner material showed a higher viscoelastic behavior than silicone material after applying the stress, and have the ability of stress distribution or stress relaxation.

Contrary to this study, Al-Noori and Said[37] found no significant difference in bone resorption with and without soft liner in complete denture patients. This may be due to difference in the study design, i.e., their subjects were edentulous at least 1 year before denture delivery as compared to the present study in which patients were edentulous for 6 months only.

The main limitation of this study is the short study period. Cushioning effect of soft liner decreases over time; so they have to be replaced repeatedly.[38] Further studies can be carried out to evaluate the effect of different types of soft liner materials on ridge resorption and relining of complete dentures for patients with compromised ridges.

CONCLUSION

The use of complete denture with soft denture liner significantly reduces the residual ridge resorption as compared to the one without denture liner. Although acrylic denture liner bonds chemically to denture base, only problem that arises is the longevity of the denture liner and its long-term maintenance. The risk-benefit ratio should be analyzed before the use of this material.

Author Help: Online submission of the manuscripts

Articles can be submitted online from http://www.journalonweb.com. For online submission, the articles should be prepared in two files (first page file and article file). Images should be submitted separately.

1) **First Page File:**
Prepare the title page, covering letter, acknowledgement etc. using a word processor program. All information related to your identity should be included here. Use text/rtf/doc/pdf files. Do not zip the files.
2) **Article File:**
The main text of the article, beginning with the Abstract to References (including tables) should be in this file. Do not include any information (such as acknowledgement, your names in page headers etc.) in this file. Use text/rtf/doc/pdf files. Do not zip the files. Limit the file size to 1 MB. Do not incorporate images in the file. If file size is large, graphs can be submitted separately as images, without their being incorporated in the article file. This will reduce the size of the file.
3) **Images:**
Submit good quality color images. Each image should be less than 4096 kb (4 MB) in size. The size of the image can be reduced by decreasing the actual height and width of the images (keep up to about 6 inches and up to about 1800 x 1200 pixels). JPEG is the most suitable file format. The image quality should be good enough to judge the scientific value of the image. For the purpose of printing, always retain a good quality, high resolution image. This high resolution image should be sent to the editorial office at the time of sending a revised article.
4) **Legends:**
Legends for the figures/images should be included at the end of the article file.

AWARENESS OF ORAL HYGIENE AMONG PATIENTS ATTENDING DENTAL OUT PATIENT DEPARTMENT IN A TERTIARY HOSPITAL IN COIMBATORE –A CROSS SECTIONAL STUDY

Dr. Vinodha C* Senior Resident, PSG Institute of Medical Science and Research,Peelamedu, Coimbatore *Corresponding Author

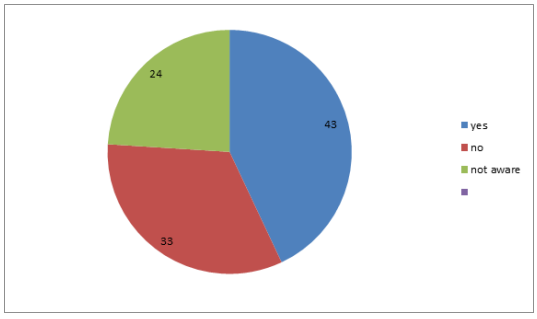
Dr. Arun K Simon Senior Lecturer, Sri Ramakrishna Dental College and Hospital, SNR College Road, Coimbatore

ABSTRACT

Periodontitis is one of the leading oral infections in India. Prevalence of periodontitis was 86% as per world oral health report in 2003 and has been ever increasing. Factors like neglected or under awareness of oral hygiene and oral hygiene, practices play a critical role in the pathogenesis of periodontitis .Moreover it is related to many systemic diseases. Present cross sectional study is done to evaluate the oral hygiene awareness and practices among patients attending dental OPD in PSG hospital, Coimbatore. The study is done to add on to the scientific base and to improve the awareness of oral hygiene and practices among Coimbatore population .The results show that though there is improvement in oral hygiene practices, awareness about oral prophylaxis and follow up is lacking among the study population.

Introduction

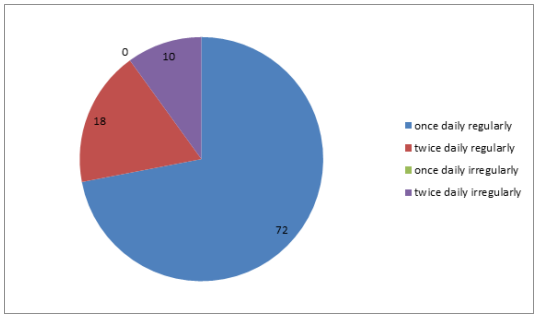
Health is wealth and oral health is window to overall health[1].In our country it is reported that awareness in oral hygiene for general wellbeing is under rated even in areas with adequate access to oral health care. Epidemiological studies suggest high prevalence of periodontitis from poor oral hygiene practices and calculus deposition[2]. Albandar in an overview concluded that subjects of Asian ethnicity had the third highest prevalence of periodontitis[3].



Periodontitis is one of the main inflammatory dental disease which is related to many systemic diseases bi-directionally like diabetes[4],cardiovascular disease[5],rheumatoid arthritis[6], alziemers disease[7,8],osteoporosis etc.[9][10].periodontal disease also leads to early tooth loss at an early age which leads to compromise in mastication and psychological problems in addition to affecting systemic health. Oral hygiene awareness is crucial as it aids towards effective plaque control, which is the corner stone to maintain periodontal health [11].Therefore, more efforts are needed to encourage greater use of preventive and therapeutic services. To achieve this goal, it is important to gain information regarding the awareness levels and values related to periodontal and gingival health. Literature on awareness of oral hygiene practices and aids among patients visiting dental clinics for treatment is negligible. This study is carried out with an aim to determine the oral hygiene status, knowledge about the practices and aids used in maintaining the oral hygiene among patients visiting dental outpatient department.

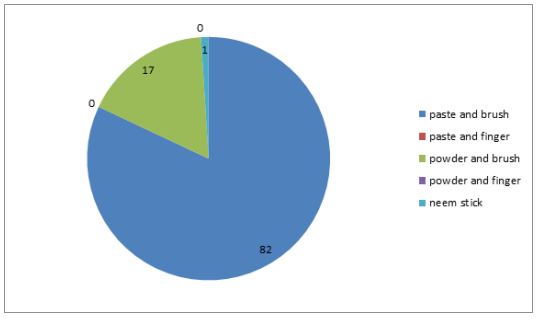
Methodology

Ethical clearance was obtained from the Institutional Board. Patients were selected randomly, Data was collected from 200 patients visiting dental out patient department after getting consent to participate in the survey. The inclusion criteria was patients above 18years and the exclusion criteria was medically compromised patients and those who did not consent to the survey. Questionnaire comprising 14 questions was used to collect the data. Questions relating to knowledge and attitude towards oral hygiene practices and aids were asked in face in face interview. Brushing techniques were explained to the patients as an attempt to improve the awareness about the oral hygiene habits. Completed questionnaire were then analyzed statistically to obtain the results in terms of percentage.



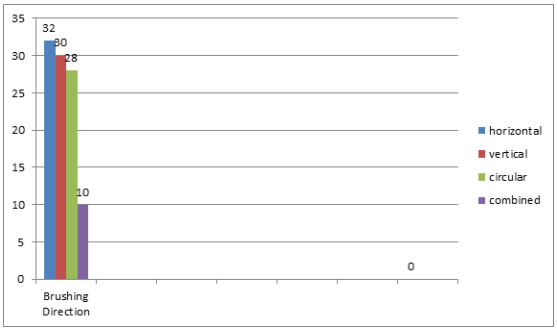
Results

Of the participants, 62% were male and 38% were female. About 43%feel oral health maintenance is important for general health, 33% do not agree and 24% were not aware of it[Figure1]



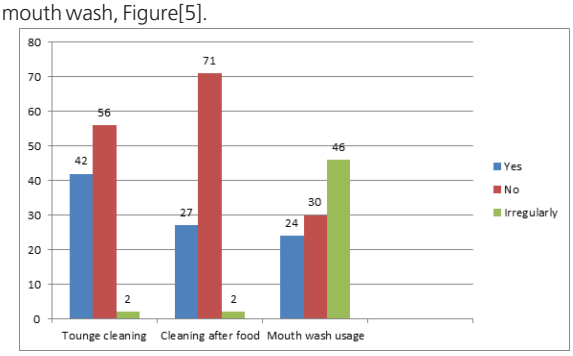
Figure[1] Oral health and general wellbeing

72% of people brush once regularly,18%brush twice regularly and 10% brush twice irregularly[Figure2]



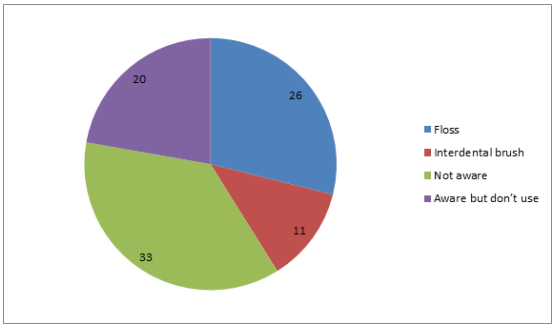
Figure[2]Brushing frequency

Paste and brush is used by 82% of people,17% use powder and brush and 1% used neem stick,figure[3].



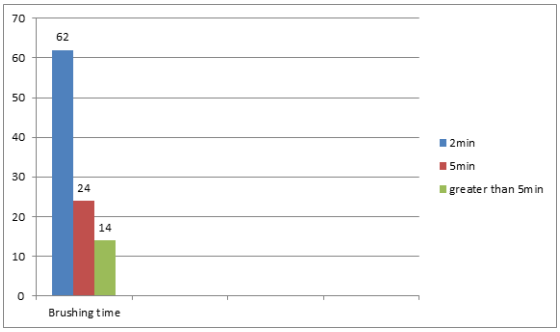
Figure[3] Frequency of population using brush and paste

About 32%of people use horizontal tooth brushing technique,30% use vertical brushing technique,28% use circular brushing technique and 10% use combined brushing techniques, figure[4].



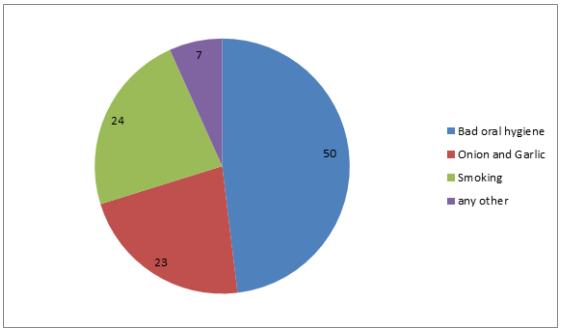
Figure[4] Brushing technique

Forty two percent of people clean their tongue daily and 56% of people don't and 2% clean irregularly ,figure[5]. Twenty seven percent of people clean their mouth after eating and 71% don't and 2% clean irregularly, Figure[5]. Twenty four percent of people use mouth wash regularly,46% use irregularly and 30% don't use mouth wash, Figure[5].



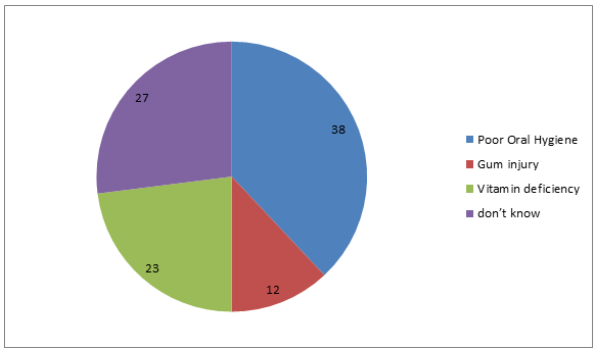
Figure[5] Frequency of tongue cleaning, cleaning after food intake and mouth wash usage

Regarding usage of interdental aids 26%use floss, 11%use interdental brush,43% are not aware if such aids and 20% are aware but don't use inter dental aids, Figure[6].



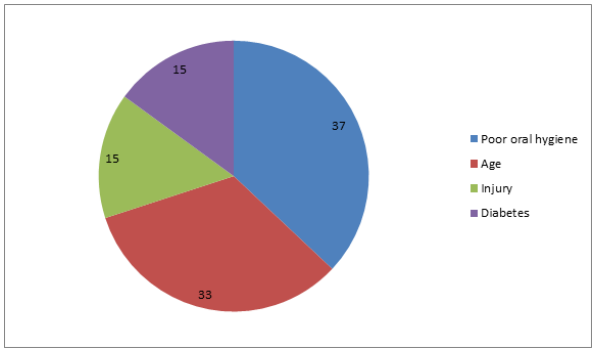
Figure[6] Percentage of people using interdental aids

Brushing time followed is 2min by 62%,5 minutes by 24 % and more than 5min by 14%,figure[7].



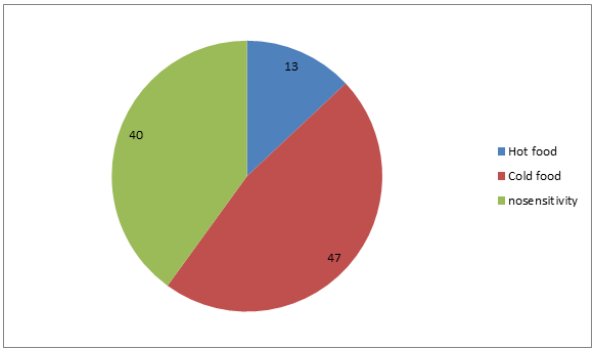
Figure[7] Brushing time percentage

Around 50%think bad oral hygiene is the cause for bad breath, 23% feel onion and garlic is the prime cause,20% feel it is because of smoking and 7% feel there is no specific reason, Figure[8].



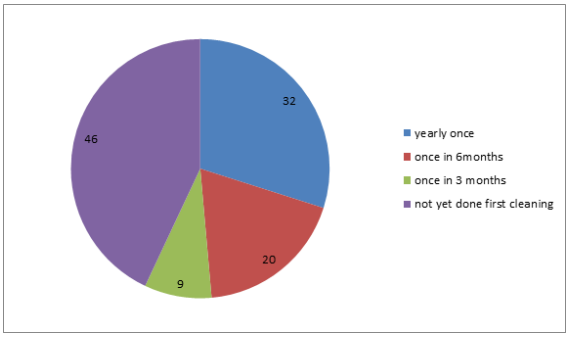
Figure[8] Frequency of people with bad breath

About 38% of people agree that poor oral hygiene is responsible for bleeding gums,12% say it is due to gum injury,23% say it is due to vitamin deficiency and 27% don't know the reason, Figure[9]



Figure[9] Percentage of people noticed gum bleeding

Loosening of teeth is due to poor oral hygiene say 37% of people, 33% say it is due to age,15% say it is due to injury and 15% agree the reason is diabetes, Figure[10].



Figure[10] Percentage of people with loosening of teeth

Hot food causes sensitivity in 13%,cold food causes sensitivity in 47% and 40% do not have sensitivity, Figure[11]

Figure[11] Percentage of people with tooth sensitivity

Oral prophylaxis is done by 32% of people once in a year ,13% of people do it once in 6months , 09% do it once in 3 months and 46% are yet to clean their teeth ,figure[12]

Figure[12] Percentage of people undergone oral prophylaxis

Discussion

Oral health is necessary for general wellbeing. Due to lack of awareness ,oral hygiene is ignored in India were the population is estimated to be more than 1.35billion.27% of this population live in urban area. The present study is conducted in tertiary care hospital dental department where a combined population from village and urban area come under one roof for various treatments. Among the study subjects,62% were literate and 38% were illiterate. For the illiterate subjects ,the questions were explained in their mother tongue and their answers were collected.

Forty three percent of subjects agreed that oral health is needed for overall health ,33% did not agree and 24% were not aware about the fact, Figure[1]. Our results shows that the level of awareness is much low compared to 60.4% in the study conducted by Sukhvinder et al in 2014[12].

Only 18% of subjects brushed twice daily,72 % brushes once daily and 10% brushes twice irregularly, Figure[2], which is also low compared to 58% of police recruits in a study by Dilip et al [13] but coincides with the study done by Kuppusamy VL et al where twice brushing was 17%[14].

Paste and brush was used by 82% of population which coincides with study done by Subha et al [15].Using tooth brush decreases the frequency of tooth wear Bhardwaj et al [16].Seventeen percent use powder for brushing which coincided with study by Sukhvinder[12] which again contribute to tooth wear, Figure[3].

Thirty-two percent used horizontal technique,30%used vertical method,28% used circular technique and 10% used combined technique. It is less when compared to study done by Zhu et al and Jain et al[17 ,18].Basically subjects were not very clear with the techniques existing for brushing. Awareness about the techniques if improved can reduce the tooth and periodontal diseases related to abrasion, Figure[4].

Only 32% clean their tongue regularly and 27% wash their mouth after food which is due to lack of awareness, Figure[6]. Thirty-seven percent of population use either dental floss or inter dental aid which is a huge transformation from 0% in study conducted by Hanaa M. Jamjoon in 2001[19]. This may related to the factors like oral health care media advertisements, Figure[6].

Around 62% brushes for 2 minutes,24% for 5minutes and 14% for more than 5minutes similar to study by Sukhvinder[16].Beneficial role of long brushing time for more than 2minutes in plaque removal is yet to be studied, figure[7].

More than 30% of study population agreed that poor oral hygiene is the reason for bad breath, bleeding gums and loosening of teeth which is similar to study by Ali et al[20] and MM Dayakar[21],Figure[8,9,10].

Mouth wash regular usage was 24% and irregular usage was 46% mainly as alternative for malodor, figure[11].Almost 50% agreed with cold food as the cause for sensitivity. The reason for sensitivity can be gum recession, caries, hypersensitivity which was not examined in the present study. About 46% of population are yet to do their first ever oral prophylaxis which is an alarming situation, Figure[12] . This study is similar to one by Peterson et al and Al Hussaini et al[22 and 23].This mind set of not reaching dentist for regular checkup and oral prophylaxis may be due to a generalized view that oral hygiene is separate entity from overall health in general population.

Limitation

Since the study is hospital based and only 200 subjects were involved, further studies involving general public and more involving population has to be carried out to further improvise our knowledge about oral hygiene practices. This will help to organize awareness programs at various levels to inbuilt the mindset that good oral hygiene is needed for overall wellbeing.

Conclusion

The results show that though usage of tooth brush and paste has increased, our general population are still reluctant about oral care, nearly 50% are yet to do their first ever oral prophylaxis. Awareness has to be created regarding regular dental visit and oral prophylaxis which can improve the life time of natural teeth and also help to reduce overall inflammatory reactions as periodontitis is related to many systemic diseases[1,4,5,6,7,8,9,10].Studies at various level and with different sample groups have to be conducted in India and compared in order to improvise our oral hygiene awareness and practice programs which will definitely improve oral health.

Abstract

The objective of dentists is to preserve teeth affected by either caries, trauma, or any other pathological condition. Teeth with deep carious lesions often require endodontic treatment to preserve their form and function. Sound knowledge of root canal anatomy, endodontic pathology, and proper treatment protocol are vital in endodontic treatment success. Currently, there has been an ongoing trend of case reports that highlight the presence of extra canals, which in turn, cautions the clinician to be more prudent. Any missed canal during root canal therapy is the common cause of treatment failure. This case report emphasizes the fact that proper understanding of pulp anatomy combined with the use of modern diagnostic aids and proper treatment protocol is essential for treatment success. This case report describes successful management of three rooted mandibular first molar with extra canals.

Categories: Pain Management, Dentistry, Anatomy
Keywords: mandibular first molar, additional canal, mid-mesial canal

Introduction

The success of endodontic therapy depends on the thorough elimination of infected pulp tissue, microorganisms, and complete three-dimensional sealing of the root canal space. Managing aberrant canals can be difficult, but inability or failure to identify extra canals can lead to treatment failure due to incomplete debridement of the root canal system. The clinician should thus have a thorough knowledge of not only the normal anatomy of the root canal system but possible root canal variations for successful endodontic treatment. Vertucci proposed a standardized method for classifying root canal anatomical variations and divided canal configuration into eight different types based on number of canals from orifices to apex [1]. Weine introduced a clinically significant classification (Type I to Type IV) of the root canal anatomy [2], and new additional canal types were also reported by Sert and Bayirli [3]. The earliest permanent posterior tooth to erupt, mandibular first molar, is most frequently involved in endodontic procedures. Mandibular first molar typically has two roots with the most prevalent root canal system configuration found in mesial and distal roots being Vertucci classification Type IV (two canals run separately from orifice to apex) and Type I (one canal runs from orifice to apex), respectively, but it is common to find other complexities with regard to number of root and root canals. This case report describes successful identification and management of three rooted mandibular first molar with six canals. Three canals were present in mesial root revealing Type XV Sert and Bayirli canal configuration, and the two distal roots

had Type II Vertucci canal configuration in one distal root and Type I Vertucci canal configuration in another.

Case Presentation

A 35-year-old male patient of South Indian origin reported with continuous throbbing pain in a lower left back tooth. The patient was referred by a general dentist who had performed emergency access opening to relieve acute pain in the left mandibular first molar, which was diagnosed with acute irreversible pulpitis one week prior. The patient had a non-contributory medical history. Clinical examination revealed that the left lower first molar (tooth # 36) had access opening done and restored with temporary cement, and the tooth was mildly tender on percussion. Tooth mobility and periodontal probing around the tooth was within physiologic limits. A thorough inspection and interpretation of the baseline intra-oral peri-apical radiograph (Figure *1*) was made at the time when the patient presented. The radiograph revealed an unclear view of the canal space as well as variation in the outline of the distal root contour, suggesting possibility of complex root anatomy. Based on history, clinical and radiographic examination, plan for completion of root canal treatment was decided.

FIGURE 1: Baseline digital radiograph

The tooth was anesthetized with an inferior alveolar nerve block using 2% lignocaine with 1:80,000 epinephrine (Lignox 2%, Indoco Remedies, Ltd.). Under rubber dam isolation, the temporary restoration was removed, and the pulpal floor was carefully examined with magnification loupe (3.5 x), and three canals (mesiobuccal, mesiolingual, distal canal) were easily identified.

Careful exploration using a DG16 Endodontic Explorer (Manipal Instruments, Manipal, Karnataka, India) was done along the groove connecting mesiobuccal and mesiolingual orifice, and a third mid-mesial canal was found. The distal canal was positioned a little buccally, indicating the possibility of an extra canal, and a dark line was observed between the distal

canal orifice and the distolingual corner of the pulp chamber floor. The conventional access was modified by extending the access cavity distolingually and a second distolingual canal orifice was detected. Exploration was carried out along the groove extending between distolingual and distobuccal canals, and an additional distobuccal canal was found. Thus, the pulpal floor revealed six distinct root canal orifices (Figure 2): three were detected mesially (mesiobuccal, middle mesial, and mesiolingual) and three distally.

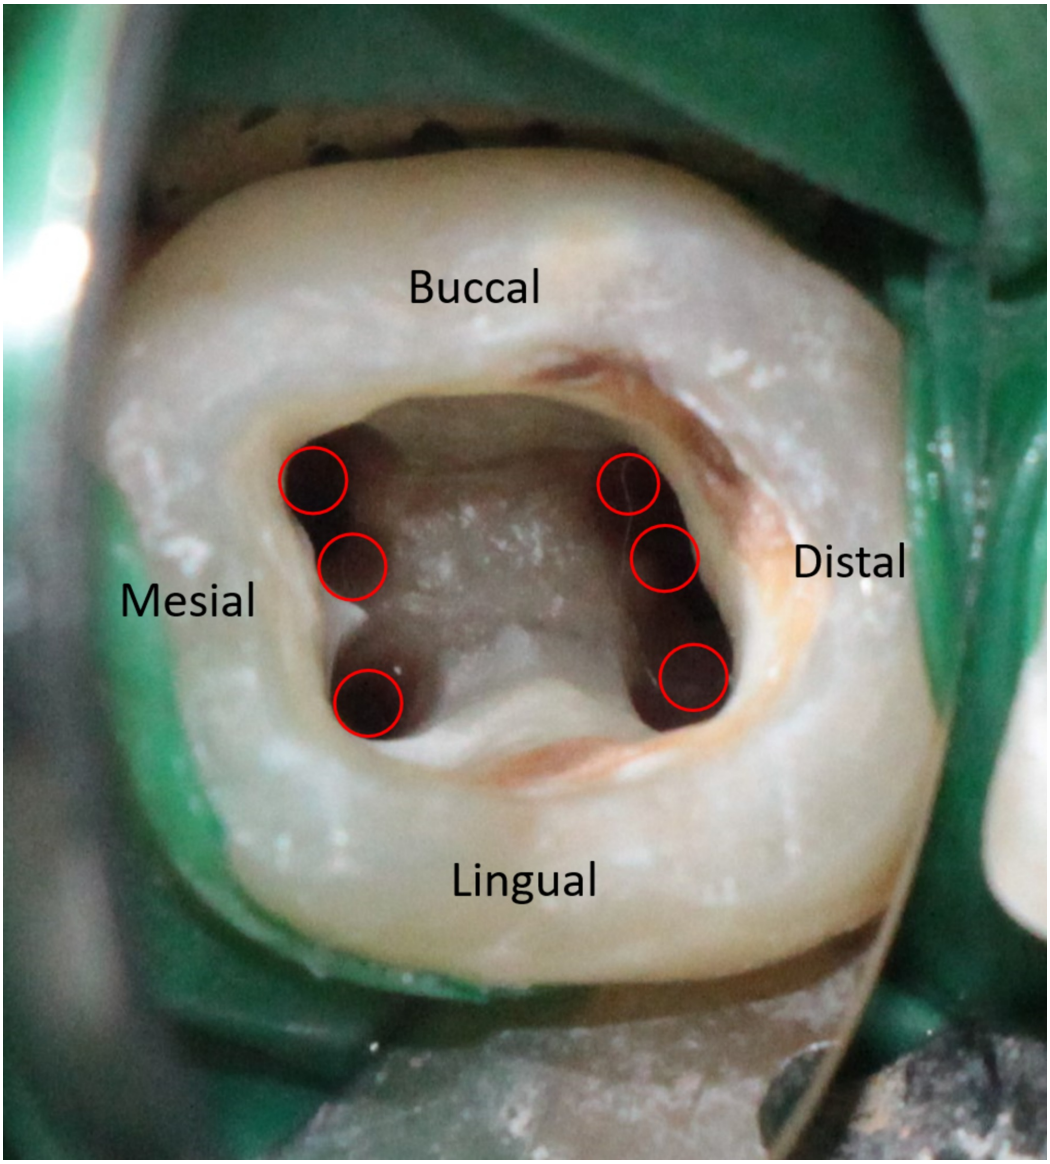

FIGURE 2: Access opening showing six distinct canal orifices

After canal identification and negotiation, coronal enlargement was done with the help of Ni-Ti ProTaper gold orifice shaper (SX; Dentsply, Maillefer, Ballaigues, Switzerland) to improve the straight-line access of canals. The working length was then determined by electronic apex locator (Root Zx II, J Morita, Japan) and was verified with a radiograph (Figure 3). Interpretation of working length radiograph confirmed the presence of an additional distolingual root. Of the six distinct root canal orifices detected, three were detected mesially (mesiobuccal, middle mesial, and mesiolingual), indicating the Type XV (3-2) Sert and Bayirli canal configuration, and two canals were present in distobuccal root (distobuccal 1 and distobuccal 2) with Type II Vertucci canal configuration, and one independent canal in distolingual root.

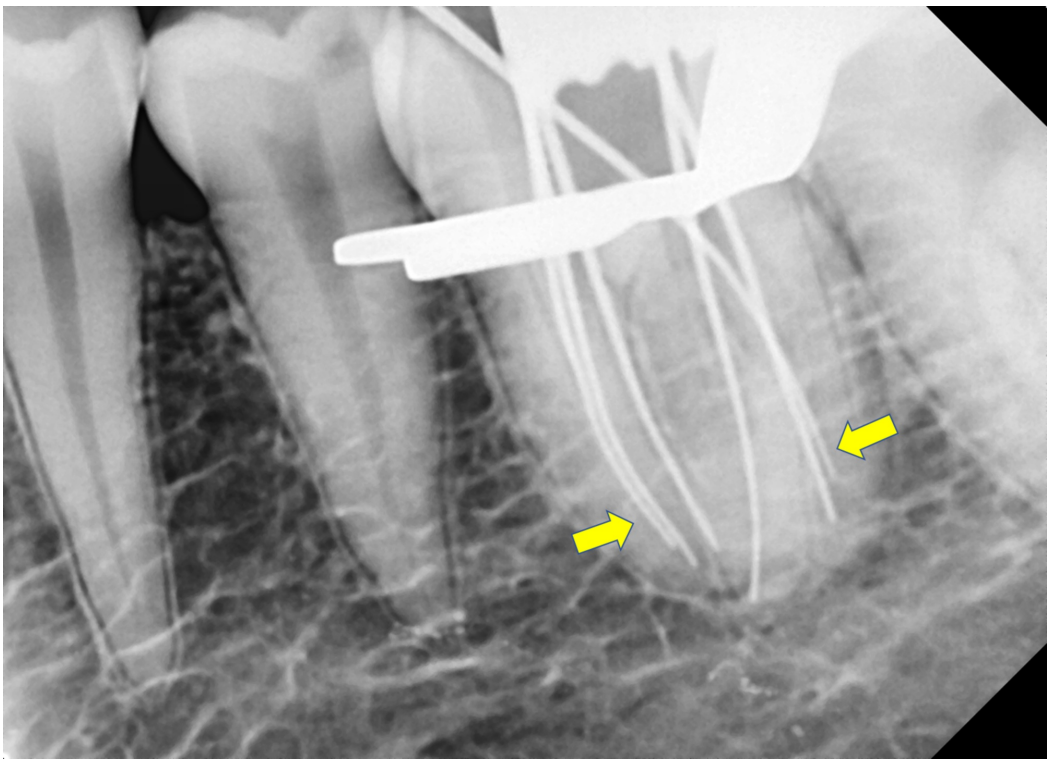

FIGURE 3: Working length radiograph showing six canals and extra distolingual root

Following working length determination, cleaning and shaping were done using Protaper Ni-Ti gold files using the crown down technique. All the instrumentation was performed with copious irrigation using 5.25% sodium hypochlorite and 17% ethylenediaminetetraacetic acid, alternatively. Irrigants were activated by sonic system (MM1500 Sonic Air, Micro Mega International, Besancon, France). Calcium hydroxide intracanal medicament (Vitapex, Neo-Dental International, Federal Way, WA) was placed in root canals, and access cavity was restored with temporary cement. At the second visit, after one week, calcium hydroxide medicament was removed, and a final rinse was done using sodium hypochlorite. Root canals were dried with absorbent points, and master cone was selected and positioned in respective canals, and radiograph was evaluated (Figure *4*). Canals were then obturated with warm vertical compaction technique, and calcium hydroxide-based sealer (Sealapex, Kerr Dental, Orange, CA) was used. Post-obturation X-ray was evaluated (Figure *5*), and at the six-month follow-up visit the patient was asymptomatic.

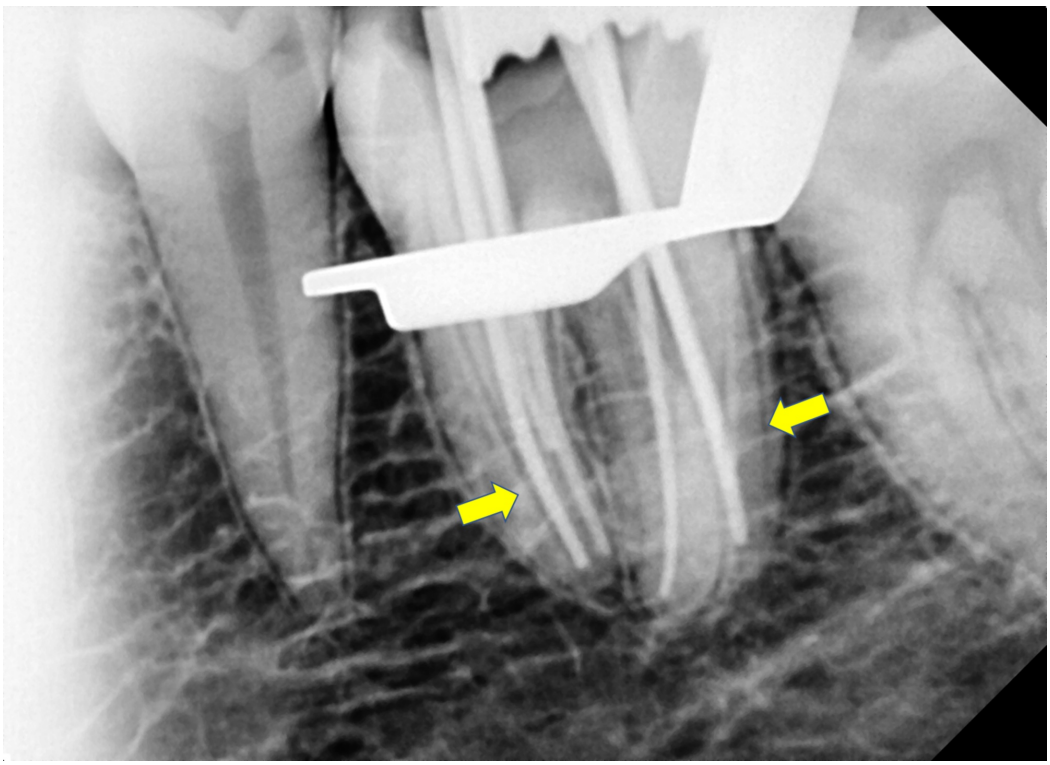

FIGURE 4: Master cone radiograph

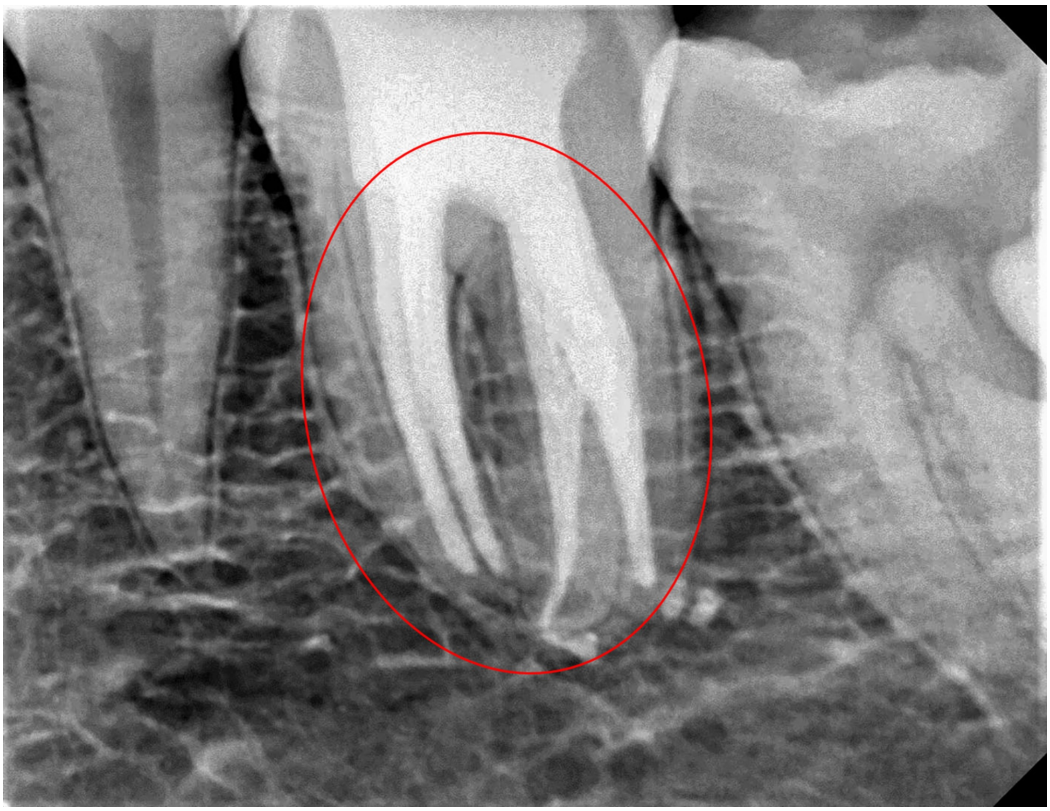

FIGURE 5: Post-obturation radiograph

Discussion

Various authors have reported the existence of mandibular first molar with additional root and extra canals [4,5]. Although preoperative radiograph has a key role in endodontic treatment, a minimum of two diagnostic periapical radiographs should be taken at different angulation for careful evaluation of the root canal morphology and to avoid chances of missing extra canals [6]. Krasner and Rankow proposed specific laws: the law of symmetry, the law of color change, and the laws of orifice location to locate canal orifices in an efficient manner [7]. Proper knowledge of root canal anatomy and its variations combined with use of various diagnostic aids such as spiral computed tomography, cone beam computed tomography, magnification devices, microscopes, performing sodium hypochlorite test will facilitate the identification of additional root and root canals.

The uniqueness of this case is the presence of six distinct root canal orifices and canals with extra distolingual root (radix entomolaris) in mandibular first molar. The mesial roots had canals with Type XV (3-2) as per Sert and Bayirli canal configurations, that is, the middle mesial canal merged with the mesiobuccal canal just above the apical third and exited through a common foramen. The mesiolingual canal was independent type with separate orifices and apical portal of exits.

In the distal root, distal buccal 1 and distobuccal 2 canal joined in its apical third having a mutual exit. The distolingual root had a separate canal. The presence of two distal roots is unusual but does occur. This additional root that can usually be found distolingually was first mentioned in literature by Carabelli and was called “radix entomolaris” [8]. A literature search showed that the prevalence of radix entomolaris in the mandibular first molar was reported to be 5.3% in the Indian population, 13.3% in South Indian by Chourasia et al. and Chandra et al., respectively [9,10]. Access cavity modifications are necessary (from triangle to rectangle or rhomboidal) to locate the additional canals in both mesial and distal roots. It has been reported that among the three-rooted mandibular first molars studied by the authors, the distolingual orifice was located 2.93 mm lingual to the distobuccal orifice, and the access form should be modified to a trapezoidal shape to expose all orifices [11].

Barker et al. and Vertucci and Williams first demonstrated the existence of a third root canal, in the mesial root of mandibular molars [12,13]. Since then, several authors have reported the existence of middle mesial canals. It has been hypothesized that the connective pulp tissue is likely to be compressed by the accumulation of secondary dentin during the growth of the root, which can, at times, form vertical walls, creating three independent mesial root canals [14]. Studies reveal that the incidence of negotiable middle mesial canals was found to be higher in younger patients [15,16]. In a clinical evaluation of 100 mandibular first and second molars, Pomeranz et al. found that 12 molars had mid-mesial canals in their mesial roots and classified them into three morphologic types as follows: fin, confluent, and independent, with the most prevalent anatomy being “fin” type [16]. However, Nosrat et al. reported that among the mandibular molar studied by the authors, 46.7% of teeth anatomy was confluent type, while Karapinar-Kazandag et al. found that in all the teeth studied by the authors, mid-mesial canal anatomy showed “confluent” anatomy [15,17]. The extra-mesial canal orifice found between the two main mesial canals is generally hidden by a dentinal projection of the pulp chamber wall, and this layer of dentin is differentiated from the pulp chamber floor by its lighter color. The mean diameter of mid-mesial canal orifice is reported to be 0.16 mm, which is three times less than the diameter of the two main orifices [18]. Enlargement of the middle mesial canal is more limited than for either the mesiobuccal or mesiolingual canal to avoid lateral perforation because the middle mesial canal is usually found in the narrowest portion mesiodistally of this root [16]. In addition, variation in location of the mid-mesial canal with respect to main canals has been reported by various authors. Karapinar-Kazandag et al. reported a higher number of additional mesial canals located closer to the mesiolingual canal in their study [17]. In a study

evaluating the frequency of middle mesial canals in a North Indian population, the authors found that among 258 mandibular first molars, in 67% of the cases the mid-mesial canal orifice was located in the middle of the mesiobuccal and mesiolingual canal orifices, 20% had the orifice closer to the mesiolingual canal, while the remaining 12% had the orifices located closer to the mesiobuccal canal [19]. Differences in observation by various authors may be attributed to difference in study methodology, population studied, and number of teeth included in the study.

The use of modern diagnostic tools can prevent an inadvertent search for extra canals that can lead to excessive removal of tooth structure and perforations. In this case report, use of magnification loupes aided in the proper detection of extra canals. In addition, proper treatment protocol was followed that led to success of endodontic treatment.

Conclusions

A thorough understanding of root canal anatomy is the key to successful root canal therapy. It is mandatory that clinicians should have a full understanding of the canal configuration and be aware of anatomical variations. Judicious interpretation of the radiographs, definite access preparation, and proper exploration of the pulp chamber under magnification, followed by proper cleaning and shaping of canals, are the fundamental prerequisites for a favorable outcome.

ABSTRACT

The aim of this study was to evaluate the surface tension values of established and potential endodontic sealers.Densities of zinc oxide eugenol ,AH Plus and Bioceramic sealers were calculated using pendant drop method.Surface tension was evaluated using rame hart goniometer with DROP image analyser software[Finn Knut Hansen1990-2006].The results show that surface tension of zinc oxide eugenol was the least followed by AH plus and Bioceramic sealer.Bioceramic sealer showed the highest surface tension of 47.8 Nm.From other studies it is known that bioceramic sealer has the highest dentinal tubular penetration.Various factors like dentin roughness,wetness,type of irrigant used,viscosity ,hydrophilicity of root canal sealers,temperature,dentinal tubule texture and density etc influence the penetration of sealers.Further studies are needed to evaluate the role of surface tension of root canal sealers as a potent influencer in dentinal tubule penetration for enodontic success.

KEYWORDS

surface tension, pendant drop, root canal sealers, goniometer.

INTRODUCTION

In endodontics the most commonly used filling method involves gutta percha with root canal sealers. Root canal sealers play a pivotal role in endodontic success by sealing the the void space between the core material and dentinal wall,effectively penetrationg and sealing the accessory canals and also acts as a lubricant thus preventing secondary infection[1].Various factors influence the dentinal tubule penetration and overall sealing scenario of root canal sealers like composition of the sealer,flow,bond strength,dentinal tubule diameter and orientation,rate of insertion of material[2], physiochemical properties of dentin [3,4,5].etc .An important factor influencing the flow ,wettability,adhesion and penetration of root canal sealer is the surface tension of the sealer.Surface tension is defined as 'the force between molecules that produces a tendency for the liquid surface area to decrease.This force tends to limit the adhesion and penetration ability of the liquid. It has inverse relationship with wettability[6,7] that is when the surface tansion is low,wettability will be high and inturn penetration and adhesion will be high. Having an array of endodontic sealers available in the market makes the decision for ideal sealer always difficult.Though many studies have been done on the various entities like sealer penetration,contact angle ,microleakage ,shrinkage,influence of irrigants,instruments used during biomechanical preparation,smear layer presence etc for the success of endodontic treatment.Evaluation of surface tension of sealers which influences the flow,wettability,penetration and adhesion have not yet been studied.

This study aims at finding the missing strength of sealers that is the surface tension among there endodontic sealers Zinc oxide eugenol (with grossman formula),AH plus Dentsply)and Bioceramic sealer(smart paste bio).Zinc oxide eugenol which the gold standard for sealer ,AH Plus which is near to gold standard in Resin based sealers and recently introduced calcium silico phosphate based bioceramic sealer(smart paste bio).Surface tension is evaluated to find out its influence in sealer penetration and adhesion to create an effective monoblock.

MATERIALS AND METHODS

Densitometer was used to determine the density of experimental sealers. Weight of 2ml syringe was calculated.sealers were mixed according to the manufacturers instructions and mass was calculated for 1ml of the sealer.density was calculated from the formula density=mass/volume.Surface tension was calculated using pendant drop method [figure 1]in rame harte goniometer [figure1.2]with DROP image analyser software.Fitting the drop to the shape method was used for surface tension calculation. Five values were taken for each sealer and mean of it was determined.

RESULTS

Mean value of surface tension as determined by rame hart goniometer using pendant drop method with DROP image analyser software is given in table1. The unit of surface tension is Nm/m.

DISCUSSION

Requirement for An ideal root canal sealer includes it being tacky which helps for good adhesion between it and the canal wall when set,creating a hermetic seal [8].Low surface tension decreases contact angle thereby increasing the wettability which inturn favours good sealer penetration and adhesion to dentinal tubules[9,10,11,12].

Surface tension is measured by pendent drop technique at room temperatures to nullify any discrepancy due to temperature.Geometry of a drop was analyzed optically using DROP image analyser software[Finn Knut Hansen 1990-2006].Pendent Drop method was used in the study because of high accuracy,ability to trace to national standards,apparatus cleanliness doesnot affect the measurement,small volume can be used to measure surface tension[13].

The reason for selecting Zinc oxide Eugenol sealer is that it is the gold standard still even with the introduction of a plethora of root canal selers. AH plus though has improved compostion still lacks the ability to create monoblock effect and the recently introduced bioceramic sealer has promising composition with setting in the presence of water .It is a known factor that dentinal tuble contains water and irrigants which we use also influence the adhesion of the sealer to the dentin.

From the results of this study,it is seen that Zinc oxide eugenol (25.13Nm/m)has low surface tension followed by AH Plus(33Nm/m) and Bioceramic sealer(47.8Nm/m).which inturn predicts the wetting and dentinal tuble penetration to be high for Zinc Oxide Eugenol followed by AH Plus and Bioceramic(Smart seal bio) sealers. studies done by Jardim Del Monaco R et al ,Wang Y et al reveal that Bioceramic sealers have better dentinal tubule penetration than AH PLUS sealer[14,15] ,while studies done by SK Arikalta et al say AH Plus has better dentinal tubule penetration and interfacial adaptation than Bioceramic sealer [16]while studies done by Afaf Al Hadad et al reveals equal Dentinal tubule Pentration[17].In the same way bioceramic sealer has superior wetting than AH plus sealer as studied by Jung-Hong Ha et al[20] .studies done by ss pawar et al,Srinidhi.V.Ballullaya et al state that bioceramic sealer has better adhesion and adaptation than AH plus and Zinc Oxide eugenol sealer [18,19]whereas studies done by Ola M Sakr et al state that bioceramic sealer has more dye leakage than AH 26 sealer[21].

Though the surface tension is low for Zinc Oxide Eugenol and AH Plus sealers,their sealer penetration adaptation,dye leakage are comparatively low than Bioceramic sealer.The reason for this variation may be the method of biomechanical preparation,dentin sirface roughness,dentin tubule orientation and diameter,irrigants

used,force of condensation etc.This study suggest for studies on surface tension of sealers to explore its role as a potential influencer in dentinal tubule penetration and adaptation which again is foremost for endodontic success.

Limitations

In all the studies mentioned as referrences,different bioceramic sealers from different companies were used .Therefore culminating the results under a broad category ,bioceramic sealers will result in false impact about the sealer.More studies have to be carried out on these sealers to find out the ideal root canal sealer.

Table 1.Surface Tension of experimental sealers in Nm/m

Sealer	Surface tension valuesNm/m
Zinc oxide eugenol	25.13
AH plus	33
Bioceramic	47.8

INVITRO COMPARATIVE EVALUATION OF CONTACT ANGLE OF THREE ROOT CANAL SEALERS

Dental Science

Dr vinodha Chandrasegaran Assistant Professor, Department Of Dental Surgery, PSG Institute Of Medical Science And Research

ABSTRACT

AIM: The aim of this study was to evaluate the contact angle of three endodontic sealers zinc oxide eugenol,AH plus [epoxy resin based] and bioceramic [calcium silico phosphate based] sealers.

METHODOLOGY: Working length of 21 samples of human mandibular premolars were determined followed by chemomechanical preparation. The specimens were then decoronated,split longitudinally, flattened, smoothened and stored in distilled water. Half of the dentin discs were treated with 5ml of 3%NaOCl followed by 17%EDTA and 2%chlorhexidinefor 1min each.The samples were air dried and divided into 3 groups based on the experimental sealers used. A total of 14 samples were assigned for each group with 7 samples per subgroup. In each sample 1drop [0.1 ml] of sealer was deposited and the contact angleat 0,5,10,15,20,25,30 seconds after the initial application of the sealers were recorded at room temperature.

RESULT: contact angle values were low for zinc oxide eugenol followed by AH Plus and Bioceramic sealer.

CONCLUSION: The present study revealed that lower contact angle along with smear layer removal enhanced the wettability of root canal sealers.

KEYWORDS

Wettability, Contact Angle, Smear Layer,dentin

INTRODUCTION

In endodontic practice, the success of root canal therapy mainly depends on the elimination of pathogenic microorganisms and their byproducts followed by three dimensional obturation of the root canal space.To achive this challenging task,a biologically acceptable solid or semisolid obturating material in conjuction with root canal sealers has been advocated in endodontic literatures.

Guttapercha is the most widely used core material for obturation till date. Its property of inertness,plasticity and solvent solubility have made it an ideal candidate for root canal filling. However it has a major disadvantage of not adhering to dentinal walls of the root canal space. This neccessiates the use of endodontic sealer mandatory[5,19]

Adhesion of root canal sealers is highly dependent on the wettablility of dentin .Wettability is a measure of surface reactivity or adhesiveness of substrate. It can be expressed interms of angle between the liquid drop and the plane surface of solid on which it rests .This angle is referred to as **contact angle** [4,10,12,14,22,32].Contact angle has inverse relationship with wettability,that is,the lower the contact angle,the greater the surface free energy and hence the greater the adhesion[8,12,32]

There are a number of factors which influence wettability of endodontic sealers.They are

1. The physiochemical properties of root dentin(surface free energy). [3,6,32]
2. The influence of irrigant solutions(sodium hypochlorite, EDTA,c hlorhexidineetc) that are used during the chemomechanical preparation.[2,26,32]
3. The dentin moisture condition and dentinal tubular density.[20]
4. Presence of smear layer due to biomechanical preparation ofroot canal.[17,29]
5. Hydrophobicity, Hydrophilicity, viscosity of sealers,film thic kness, obturation technique and the temperature at which the proc edure is performed.[3]

For good adhesion of root canal sealers,wettability[surface free energy] of dentin should be high and contact angle of sealers should be low.

Different endodontic sealers have different contact angle .In the present day, a plethora of sealers are made available in the market, one may find it difficult to choose a good sealer. [33]Every manufacturers claim that their product is the ideal one, but till date none of the sealers have proved to be the ideal except for a few which can come closer to be ideal.

The aim of this present study was to compare and evaluate the contact angle of three endodontic sealers zinc oxide eugenol,AH plus [epoxy resin based] and bioceramic [calcium silico phosphate based] sealers in the presence and absence of smear layer at 0,5,10,15,20,25,30 seconds after initial application of the sealers with goniometer.

MATERIALS AND METHODS

MATERIALS USED

SEALERS:

1. ZINC OXIDE EUGNOL SEALER (grossman formula)
2. AH PLUS SEALER(DENTSPLY)
3. BIOCERAMIC SEALER(SMART PASTE BIO)

IRRIGANTS:

Distilled water,3% sodium hypochlorite(PRIME DENTAL PROD UCTS),2% chlorhexidine(Asep-RC),17% EDTA (Den tm ark),2%sterile paper points(Dentsply)

ARMAMENTARIUM

carborundum disk,Laboratory Lathe (sugunas enterprises),Sand paper(3M ESPE.,1000 grit roughness),Glass slab ,Cement spatula,Plastic spatula,kfiles (MANI, INC.,size 15 – 45), Finger spreaders(MANI, INC.,size 15- 30),

SPECIAL EQUIPMENTS:

Goniometer(Easy Drop –KRUSS DSA 204)

SAMPLE SIZE

60decoronated human mandibular premolars were included in this study 21 decoronated human mandibular premolars were longitudinally sectioned to obtain 42 root dentin samples for contact angle measurement.

SAMPLE SELECTION

INCLUSION CRITERIA:

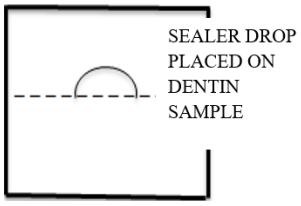
Single rooted mandibular premolars with single root canal, complete root formation and intact root surface.

EXCLUSION CRITERIA:

Teeth with root resorption , Root canal treated teeth , Teeth with root facture

STUDY METHOD

PREPARATION AND GROUPING OF THE SAMPLE FOR CONTACT ANGLE MEASUREMENT



From the stored collection of human mandibular premolars extracted for orthodontic purpose,21 samples were assigned for contact angle measurement. Working length was determined. Chemomechanical preparation of the specimens was done using k files till apical size 30,the specimens were irrigated with initial rinse protocol using 5ml of 3%NaOCl between each instrument,then the specimens were decoronated. The remaining root segments were then split longitudinally through the root canal in buccolingual direction using carborundum disk at low speed under water coolent.Buccal and lingual

surface of the samples were further flattened and smoothened using 1000 grit sand paper to obtain smooth and flat suface for contact angle measurement . The samples were then stored in distilled water until use. In one half of the specimens,canal space of the dentin sections were treated with the following irrigation protocol:5ml of 3%sodium hypochlorite followed by 5ml of 17%EDTA and5ml of 2%chlorhexidineas a final rinse. The dentin sections were rinsed with each irrigant solution for 1min.The samples were gently air dried before contact angle measurement.The samples were then divided into 3 groups based on the experimental sealers used. A total of 14 samples were assigned for each group with 7 samples per subgroup. The contact angles were measured at varied time intervals of 0,5,10, 15,2 0 ,25,30seconds in room temperature.
The groups were divided as follows

MEASUREMENT OF CONTACT ANGLE OF SEALERS ON DENTIN SURFACE

The samples were mounted flat on glass slab for measurement of contact angle.

In each sample 1drop [0.1 ml] of sealer [mixed as per manufacture instructions] was deposited on the dentin surface and then with help of software, images of the drop was captured and analysed to provide values of contact angles at time intervals of 0,5,10,15,20,25,30 seconds after the initial application of the sealers and the values were recorded.

STATISTICALANALYSIS

Kruskal - Wallis and Mann Whitney tests were used for intra and inter group analysis

CONACT ANGLE MEASUREMENT

The contact angle values(in degrees)were measured using goniometer.The observation revealed that the values decreased upto 30 seconds from the time of application in all the groups.

Table 1 shows the mean standard deviation Contact angle value in degrees for all the groups

Table 2 shows inter group p-value comparison for contact angle measurement in the presence of and after the removal of smear layer.
Table3 shows intra group p-value comparison for contact angle measurement.

DISCUSSION

For better penetration of sealer and adhesion into dentinal tubules, the wettability should be high. wettability of sealer is high when the contact angle formed by the sealer on the dentinal surface is low. The moisture content,temperature,the contents present in the dentinal tubules also influences the wettability and sealer penetration.[35]

In the current study contact angle of Zinc oxide eugenol,AH plus and bioceramic sealers were compared. Bioceramic sealer was compared with Zinc oxide eugenol and AH plus sealers because Zinc oxide eugenol sealer has been the gold standard for all the sealers and AH plus sealer is found to be a benchmark amongst the recently introduced resin based sealers.[33]

Middle third of root dentin is used in this study to measure contact angle ,as the dentin tubule density is high in this region.From the literature it is evident that the diameter of open dentinal tubules in the middle third of root dentin was large enough to promote deeper sealer penetration.[3,9,35]Additionally greater forces may be expected to be applied during lateral condensation in this part of dentin when compared to coronal and apical third of root dentin.[35]Apical third of the root section may not be ideal to perform the present study because it contains less tubules with smaller diameter and few of them frequently found obliterated.[3]

Irrigation regime used in this study was similarto the clinical situation as recommended by Zehnder 2006where intermittent rinse with saline was used between the irrigants -3%sodium hypochlorite,17%EDTA and2%Chlorhexidinegluconate.[2,26,32]

It has been proved in the literature that 3% sodium hypochlorite has antimicrobial activity and pulp dissolving capacity, hence it was recommended as a routine irrigant in the irrigation protocol.[1,25]Moreover it also has the collagen dissolving property which enhances the adhesion of smear layer to dentinal wall. Because of this reason subsequent irrigation with 17% EDTA, a chelating agent has been recommended to favour the removal of smear layer.[11,21,29]. Smear layer is defined as layer of irregular,amorphous microcrystalline and organic particle debris that is found on root canal walls and in dentinal tubules after root canal instrumentation.It was first described by Mc comb and smith in 1975. It has two layers,superficial layer and deep layer [smear plugs]where the material is packed into dentinal tubules .Smear layer if present will impede the sealer adhesion and penetration by decreasing the wettability of the sealers and also favoursmicroleakage contributing to endodontic treatment failure.[17]

Final rinse was carried out with2%Chlorhexidinegluconate, a cationic bisbiguanidebecause of its antimicrobial property that acts by abso rbing onto or disrupting the cell wall causing leakage of intracellular components[1], additionaly it exhibits substantivity in the root canal for some time after being used as final rinse[25].It was found from the previous studies that chlorhexidinegluconatewhen used as the final irrigant increases the surface free energy of dentin and this ensures better wetting,flow and penetration of theendodontic sealers[23].

From the literature search, it was observed that clinical significance of the precipitate (HEDTA)2(H2CHX)3formed by the interaction of EDTA with chlorhexidinehas not been established[23].From the wettability data obtained in the previous studies (de Assis,Bohn &Ilie),it was confirmed that this precipitate decreases the wettability effect of EDTA.In the current study dentin was irrigated with each irrigant for one minute[31].

The contact angle was measured for 30seconds (with 5 seconds interval) from the initial application of the sealer to dentin using sessile drop method[30].This represents the clinical time frame necessary to apply a freshly mixed sealer to the root canal wall prior to obturation (Bohn&Ilie 2014). It is worth mentioning here that contact angle measurement was carried out on a flat dried dentinal surface.Contact angle measurements require a solid surface with a clean,rigid and highly smooth surface[2,12].From the previous studies it is known that blot drying dentin with paper points lead to the formation of irregular fluid film on the dentinal surface making the measurement critical[16,20]. Therefore,in this study dentin discs were gentlyair dried to create a standard surface condition while maintaining the hydration in the deeper layers of dentin to facilitate the contact angle measurement.The dentin discs were not totally dessicatedas it is well known that on dessication, the exposed collagen matrix caneven collapse[24].

Any volumetric change could affect the contact angle value.To avoid this,sealer droplet volume was standardized with micropipette.0.1ml of the sealer was used to calculate the contact angle[8,13,15, 18,34].Room temperature was maintained at 25C during the measurement of contact angle in air conditioned room[22]..Roughness created by the instrumentation technique also influences the contact angle values[18,22].To prevent the influence of the instrument used during the canal preparation, dentin surfaces were smoothened using 1000 grit sand paper.

In the present study dentin sections treated with distilled water was used as control group because of the presence of smear layer in it.All the sealers were mixed individually according to manufactures instructions before the measurement.Contact angle was measured in the presence and absence of smear layer in all the groups. As the irrigation regime and time was standardized,it was expected that surface free energy of dentin is the same for all the groups and surface tension of the sealer has major influence on the contact values obtained[4,31].

The contact angle measurement decreased from the time of application to final measurement in all the groups(Table 1,2). This may be related

to the spreading and setting properties of the sealers used in the study[6].The inter and intra group comparison was highly significant expect for inter group comparison between zinc oxide eugenol and AH plus sealers at 10 and 15 seconds in the presence of smear layer. This may be attributed to the long working time of zinc oxide eugenol and AH plus sealers.

The contact angles measurement obtained in the current study reveals that zinc oxide eugenol has the least values followed by AHplus and Bioceramic sealer for both the test and control groups.From the values obtained (Table 1,2), it was clear that absence of smear layer in the test groups has favoured the wettability which was in accordance with the previous studies[8,12,22,28,35].The results were consistent with the surface tension values of the sealers.The contact angle of bioceramic sealer obtained in the study was high compared to other two experimental sealers which could be attributed to the viscosity and spreading properties of the sealers.

Bioceramic sealer sets in the presence of dentinal tubule fluid.It was also found that Bioceramic sealer exhibited better adaptation to dentinal walls . They produce non resorbable hydroxyapatite during setting reaction forming a chemical bond with dentin walls.This may be the cause for the better adaptation and penetration of bioceramic sealer over zinc oxide eugenol and AH plus sealers observed in the current study.

CONCLUSION

Within the limitations of this in-vitro study, it can be concludedthat:

1. Zinc oxide Eugenol sealer showed the lowest **contact angle values**followed by AH Plus and Bioceramic sealer(ZnoEu< AH plus <Bioceramic sealer).
2. For all the sealers, smear layer removal from the canal influenced the reduction of the contact angle

From the current study, it is evident that lower contact angle with smear layer removal improves the wettability of sealers on dentin substrate.The role of other factors like dentin moisture condition and roughness, obturation technique, viscosity, film thickness,capillary action of sealers etc which influence the wettability were not evaluated in the current study. Hence further clinical studies relating to the above factors are required for the identification of ideal sealer to achieve long term endodontic success.

ABSTRACT

AIM: This in vitro study was conducted to evaluate the lateral depth of penetration of zinc oxide eugenol (with grossman formula),AH Plus (Dentsply)and Bioceramic sealers(smart paste bio) into the dentinal tubules using confocal laser scanning microscope.

MATERIALS AND METHODS: Thirty nine recently extracted single-rooted mandibular premolars were taken. The working length was determined. Chemomechanical preparation done using k file to apical size 30. Between each instrument, the canal was irrigated with 5ml of 3%NaOCl.Three teeth were reserved as control and were not subjected to any procedure.In the rest of the samples, the canal were irrigated with 5ml of 3%sodium hypochlorite followed by 5ml of 17%EDTA and as a final rinse,5ml of 2%chlorhexidinewas used.Then the canals were dried with sterile paper points.The samples were divided into 3 groups (12 samples per group) based on the sealers used and were obturated with guttapercha cones using lateral condensation technique. All the sealers were mixed individualy with rhodamineB dye before obturation. Sections were prepared from middle third of the root for observation under confocal laser microscope

RESULTS: Bioceramic sealer(smart paste bio) resulted in greater sealer penetration into dentinal tubules compared to AH plus and zinc oxide eugenol sealers.

KEYWORDS

rhodamineB dye, sealer penetration, confocal laser scanning microscope

INTRODUCTION

Endodontic success is achieved by three dimensional hermetic seal in the main canal and the lateral dentinal tubules[1].In india most commonly used system to obturate root canal space is lateral condensation or the single cone technique.In both the techniques guttapercha is used with different root canal sealers available for obturation. Regardless of the obturation techniques gutta percha has no adhesive property[2]Good sealer penetration into the dentinal tubules with tight adaptation is therefore mandatory to prevent microleakage ,reinfection and aid in endodontic success[6,19,20].Various sealers exhibit different physiochemical properties which influences the penetration depth and interfacial adaptation[3].Untill today no endodontic sealer has proven to achieve all the properties of ideal endodontic sealer.In this study we have evaluated the penetration depth of Zinc oxide eugenol, AH plus(Dentsply) with newer endodontic sealer ,Bioceramic sealer(smart paste bio) under confocal laser scanning microscope.

METHODOLOGY

Thirty nine recently extracted single-rooted mandibular premolars were taken .The working length was determined. Chemomechanical preparation done using k file to apical size 30. Between each instrument, the canal was irrigated with 5ml of 3%NaOCl.Three teeth were reserved as control and were not subjected to any procedure.In the rest of the samples, the canal were irrigated with 5ml of 3%sodium hypochlorite followed by 5ml of 17%EDTA and as a final rinse, 5ml of 2%chlorhexidinewas used.Then the canals were dried with sterile paper points.The samples were divided into 3 groups (12 samples per group) based on the sealers used and were obturated with guttapercha cones using lateral condensation technique. All the sealers were mixed individualy with rhodamineB dye before obturation. Sections were prepared from middle third of the root for observation under confocal laser microscope .

The specimens were grouped as follows ,Group1:Zinc Oxide Eugenol sealer, Group 2:AH Plus sealer,Group3:Bioceramic sealer The samples were mounted flat on glass slab and viewed under confocal laser scanning microscope to determine the sealer penetration depth into the dentinal tubules [fig 1].

RESULTS

Sealer penetration depth was measured in micrometer using confocal laser microscope.The values are given in Table 1.

Table 2 shows the mean penetration depth of the experimental sealers.
Table 3 shows sealer penetration into dentinal tubules(inter group comparison)

STATISTICALANALYSIS

For sealer penetration measurement,One way analysis of difference (ANOVA) was used to study the overall mean within groups. The mean and standard deviation were calculated. The p- value showed significant difference among the groups [Table 3].

DISCUSSION

Quantification of sealer penetration depth was carried under confocal laser scanning microscope.

It has no special specimen processing step and the observations can be made close to normal conditions.Moreover CLSM works on noninvasive approach and has less potential to produce technique artifacts[18].CLSM offers a lot of advantage over SEM (scanning electron microscope), these include the ability to control depth of field, elimination or reduction of background information away from the focal plane (which leads to image degradation), and the capability to collect serial optical sections even from thick specimens[6]Scanning electron microscopic observation requires additional gold sputtering of the samples which is time consuming[18].

All the sealers were mixed according to the manufactures instructions and labeled with RhodamineB isothiocyanate fluorescent dye to facilitate the observation. Since there was no specific method devised to incorporate this dye into the dentinal sealers in the literature,[6,9]in this current study to maintain the standard amount of dye mixed,10 parts of sealer was manually mixed with 1 part of dye powder so that approximate concentration of 0.1% of the dye was obtained.The quantity of dye mixed with the sealer was negligiblethat it will not alter the physio chemical properties of sealer.[6,9]

Irrigation regime used in this study was similarto the clinical situation as recommended by Zehnder 2006where intermittent rinse with saline was used between the irrigants -3%sodium hypochlorite,17%EDTA and2%Chlorhexidinegluconate.[3,11,12,13]

Lateral compaction technique was used to obturate the samples as adding a core of laterally condensed guttapercha gives better control of obturation and helps to press the sealer into the dentinal tubules. [5,9,14,15] Three teeth served as negative control.The control teeth were neither irrigated with the standardised irrigation protocolnor obturated. Sections from the middle third of the root was used for observation in this study.[7,16]Cross section of the root was used in this study because in longitudinal sections overall penetration of the sealers into the dentinal tubules cannot be viewed.[10]

Zinc oxide eugenol and AHplus sealers showed a minimum penetration depth of 91.20um and 71.56 um and a maximum penetration depth of 257.55um and 158.66 um respectively. The penetration depth of Bioceramic sealer obtained from this study shows a minimum depth of 238.59um and a maximum depth of 409.67 um. The intra and inter group comparison was significant [Table3].

The results of the study show that the Bioceramic sealer has equal and highest penetration depth compared to other two sealers.Additional observation was that bioceramic sealer showed high penetration depth in all the samples.

Zinc oxide eugenol sealer showed deeper penetration (159.21±95.23 micrometer) than AH plus sealer (115.49±43.17micrometer) in contrast to previous studies by Chadha et al, Chandra et al and kokkas[5,6,8].In those studies it was reasoned out that capillary action played a major role in the deeper penetration of AH plus sealer.[5,6,8]White et al found that both Zinc oxide eugenol and AH plus sealer had equal penetration[6]. On the other hand, Vassiliadis et al in his landmark in vivo study on the penetration of zinc oxide eugenol sealer found that the sealer penetrated to a maximum of 900micrometer [14].Silicone oil being one of the components of AH plus sealer may be responsible for its hydrophobicity. This may give the possible explanation for the minimum penetration depth of AH plus sealer[5,15]. In thecase of zinc oxide eugenol sealer, its penetration was profoundly influenced by the filling technique,particle size and flow[10,15].Other possible reasons the different result between zinc oxide eugenol and AH plus sealer penetration depth in the current study may be possibly due to film thickness, flow and viscosity of the sealer mix used in the obturation[4,5].

Bioceramic sealer sets in the presence of dentinal tubule fluid.It was also found that Bioceramic sealer exhibited better adaptation to dentinal walls and penetration into dentin tubules (323.35±86.32 micrometer). This study results coincides with Roula El Hachem[17]. They produce non resorbable hydroxyapatite during setting reaction forming a chemical bond with dentin walls.This may be the cause for the better adaptation and penetration of bioceramic sealer over zinc oxide eugenol and AH plus sealers observed in the current study.

CONCLUSION

1. Bioceramic sealer displayed better tubular penetration followed by Zinc oxide Eugenol and AH Plus(Bioceramic sealer >ZnOEu> AH plus).
2. For all the sealers, smear layer removal from the canal increased the tubular penetration.

Table 1: sealer penetration depth into dentinal tubules in micrometer

Sample no	Group 1(zinc oxide eugenol sealer)	Group 2 (AH plus Sealer)	Group 3 (Bioceramic Sealer)
1.	97.36	87.44	264.67
2.	91.2	97.79	272.23
3.	94.08	84.62	238.59
4.	111.4	72.32	389.88
5.	110.61	71.56	296.57

Physiatrist's Assessment and Management of Diabetic Foot

Dr. V. Ramamoorthy

Professor and Head, Department of Physical Medicine and Rehabilitation, PSG Institute of Medical Sciences & Research, Coimbatore, Tamilnadu.

ABSTRACT

The incidence of diabetes is increasing day by day in India. By the year 2030, India will be the world capital of diabetes. Foot ulcerations, infections and Charcot neuropathic osteoarthropathy are three serious foot complications of diabetes mellitus that can too frequently lead to gangrene and lower limb amputation. Although not all foot complications can be prevented, dramatic reductions in their frequency have been achieved through the implementation of team approach to diabetic patient management. A multidisciplinary team approach is recommended for individuals with diabetic foot ulcers. Foot ulcers and wound care may require care by a podiatrist, orthopedic surgeon, vascular surgeon and physiatrist experienced in the management of individuals with diabetes. A Physiatrist is a medical doctor who specializes in physical medicine and rehabilitation. Physiatrists diagnose and treat both acute and chronic pain, and specialize in a variety of nonsurgical treatment for the musculoskeletal system. Initial screening for peripheral arterial disease (PAD) should include a history of claudication and an assessment of pedal pulse. Ankle brachial index (ABI) to be obtained in as many patients with PAD being asymptomatic. The neurologic examination recommended is designed to identify loss of protective sensation by simple clinical tests like use of a 10 G monofilament, tests of pinprick sensation, ankle reflex assessment, vibration testing using a 128HZ tuning fork and testing vibration perception threshold with a Biothesiometer. Patients with diabetes and high risk foot conditions should be educated about proper care of the foot and the selection of appropriate footwear. Plantar pressure is measured using podia scan and areas of high plantar pressure are identified. Footwear which offers pressure relief over these high plantar pressure areas is then prescribed. Interim footwear to be used by the patients who have forefoot and hind foot ulcers which require off loading the ulcer areas till the ulcer is healed.

Key words: Ankle brachial Index, Biothesiometry, Podia scan, Ideal diabetic footwear

INTRODUCTION

The incidence of diabetes is increasing day by day in India. In India, diabetic foot ulcers affect 15% of diabetics during their lifetime. Evidence from published literature shows 100,000 leg amputations are done per year due to diabetes related problems which results in an expense of approximately $1,960 for complete treatment of diabetic foot ulcers. Out of 62 million diabetics in India, 25% develop diabetic foot ulcers, of which 50% become infected, requiring hospitalization while 20% need amputation. Diabetic foot ulcers contribute to approximately 80% of all non-traumatic amputations in India, annually. [(1)]

The risk factors for the diabetic foot ulceration include vascular disease, peripheral neuropathy, limited joint mobility, foot deformities, abnormal foot pressures, minor trauma, history of ulceration or amputation, and impaired visual acuity. Early recognition and management of risk factors can prevent or delay adverse outcomes and the goal of the Physiatrist is to prevent limb loss among diabetics and maintain their quality of life.

FOOT CARE RECOMMENDATIONS [(2)]

- Perform a comprehensive foot evaluation at least annually to identify risk factors for ulcers and amputations.
- Patients with evidence of sensory loss or prior ulceration or amputation should have their feet inspected at every visit.
- Obtain a prior history of ulceration, amputation, Charcot foot, angioplasty or vascular surgery, cigarette smoking, retinopathy, and renal disease and assess current symptoms of neuropathy (pain, burning, numbness) and vascular disease (leg fatigue, claudication).
- The examination should include inspection of the skin, assessment of foot deformities, neurological assessment (10-g monofilament testing with at least one other assessment: pinprick, temperature, vibration), and vascular assessment including pulses in the legs and feet.
- Patients with symptoms of claudication or decreased or absent pedal pulses should be referred for ankle-brachial index and for further vascular assessment as appropriate.
- A multidisciplinary approach is recommended for individuals with foot ulcers and high-risk feet (e.g., dialysis patients and those with Charcot foot or prior ulcers or amputation).
- Refer patients who smoke or who have histories of prior lower-extremity complications, loss of protective sensation, structural abnormalities, or peripheral arterial disease to foot care specialists for ongoing preventive care and lifelong surveillance.
- Provide general preventive foot self-care education to all patients with diabetes.
- The use of specialized therapeutic footwear is recommended for high-risk patients with diabetes including those with severe neuropathy, foot deformities, or history of amputation.

VASCULAR EXAMINATION:

Peripheral vascular disease rarely leads to foot ulcerations directly. However, once ulceration develops, arterial insufficiency will result in prolonged healing and imparts an elevated risk for amputation. Vascular assessment would include inspection and assessment of pedal pulses. Initial screening for PAD should include a history of decreased walking speed, leg fatigue, claudication, and an assessment of the pedal pulses. Ankle-brachial index testing should be performed in patients with symptoms or signs of PAD. [(3)] The Ankle Brachial Index (ABI) is the ratio of the blood pressure in the lower legs to the blood pressure in the arms. Compared to the arm, lower blood pressure in the leg is an indication of blocked arteries (peripheral vascular disease). The ABI is calculated by dividing the systolic blood pressure at the ankle by the systolic blood pressures in the arm. The following can be used as a guide to interpreting results of ankle brachial index [(4)]

1. Normal ABI ranges from **1.0 — 1.4**
    a. Pressure is normally higher in the ankle than the arm.
2. Values **above 1.4** suggest a non compressible calcified vessel.
    a. In diabetic or elderly patients, the limb vessels may be fibrotic or calcified. In this case, the vessel may be resistant to collapse by the blood pressure cuff, and a signal may be heard at high cuff pressures. The persistence of a signal at a high pressure in these individuals results in an artifactually elevated blood pressure value.
3. A value **below 0.9** is considered diagnostic of PAD.
4. Values **less than 0.5** suggests severe PAD.
    a. Individuals with such severe disease may not have sufficient blood flow to heal a fracture or surgical wound; they should be considered for revascularization if they have a non-healing ulcer.

Figure 1: Interpretation of the Ankle Brachial Index

Refer patients with significant symptoms or a positive ABI for further vascular assessment and consider exercise, medications, and surgical options. Patients

with ABI 0.6 to 0.9 will be taught Buerger's exercise and prescribed vasodilators like Cilostazol 100 mg twice daily until symptoms improve. Cilostazol is a quinolinone derivative that inhibits specific cellular phosphadiesterases, which cause arterial vasodilation and inhibition of platelet function and makes it a valuable as a therapy of intermittent claudication and as a means of secondary prevention of stroke. [(5)] Patients with ABI 0.5 – 0.8 and below 0.5 to undergo non-invasive arterial studies like Doppler study and referred for revascularization procedures to prevent limb loss because arterial perfusion is a vital component for ulcer healing.

NEUROLOGICAL EXAMINATION:

The neurologic examination recommended is designed to identify loss of protective sensation (LOPS) rather than early neuropathy. The clinical examination to identify LOPS is simple and requires no expensive equipment. Five simple clinical tests (use of a 10-g monofilament, vibration testing using a 128-Hz tuning fork, tests of pinprick sensation, ankle reflex assessment, and testing vibration perception threshold with a biothesiometer), are considered useful in the diagnosis of LOPS in the diabetic foot.

Use of the vibration perception threshold (VPT) is a simple way of detecting large-fiber dysfunction, thus identifying individuals with diabetes at risk of ulceration. [(6-7)] The Bio-thesiometer is an instrument designed to measure simply and accurately the threshold of appreciation of vibration in human subjects. It is essentially an "electrical tuning fork" whose amplitude may be set to any predetermined level or whose amplitude may be gradually increased until the threshold of vibratory sensation is reached. The Bio-thesiometer is not only far superior to a tuning fork in accuracy, but will detect neurological changes that are not disclosed with a tuning fork. The results of the vibration perception threshold (VPT) testing are interpreted as follows: [(7)]

Table 1: Interpretation of vibration perception threshold values:

Vibration Pressure Threshold	Interpretation/ Grading for risk of developing foot ulcer
< 15 V	Normal
15 – 20 V	Mild
20 -25 V	Moderate
> 25 V	Severe

The risk of developing a neuropathic ulcer is much higher if a person has a Bio-thesiometer reading greater than 30-40 volts.

Patients with diabetes and high-risk foot conditions should be educated regarding their risk factors and appropriate management. Patients at risk should understand the implications of the LOPS, the importance of foot monitoring on a daily basis, the proper care of the foot, including nail and skin care, and the selection of appropriate footwear. Patients' understanding of these issues and their physical ability to conduct proper foot surveillance and care should be assessed. Patients with visual difficulties, physical constraints preventing movement, or cognitive problems that impair their ability to assess the condition of the foot and to institute appropriate responses will need other people, such as family members, to assist in their care. Patients who are found to have diabetic neuropathy are treated with antidepressants, anticonvulsants, topical agents, opiate analgesics and vitamin B12 supplementation.

PLANTAR PRESSURE MEASUREMENT:

High plantar foot pressure has been identified as a significant risk factor for ulcerations. A large number of studies have suggested that plantar pressures are high in people with diabetic peripheral neuropathy (DPN) and in people with a history of diabetic foot ulcers. [(8-17)] Measurement of these foot pressures is possible utilizing a variety of modalities. Several computerized systems can provide quantitative measurement of plantar foot pressure. These measurements are important in identifying areas of the foot at risk for ulceration and possibly in the evaluation of orthotic adjustments. Podia scan, which consists of

Harris mat, special scanner copier and printer, image analysis software and patient reporting software is not as sophisticated, but can provide a qualitative measurement of plantar foot pressures, both dynamic and static. When the patient steps over the Harris mat, greater local foot forces deposit more ink and detects the area of greatest concern for ulceration. Thus the Harris mat produces a weight bearing imprint of the foot and the podia scan produces qualitative multi color output and makes the pressure reading easier.

DIABETIC FOOTWEARS:

People with neuropathy or evidence of increased plantar pressure (e.g., erythema, warmth, callus, or measured pressure) may be adequately managed with well-fitted walking shoes or athletic shoes that cushion the feet and redistribute pressure. [(18)] Proper footwear is an important part of an overall treatment program for people with diabetes. Ideal diabetic footwear will relieve areas of excessive pressure, reduce shock and shear, accommodate, stabilize and support deformities and accommodate shoe inserts. There are two types of therapeutic shoes for diabetes. They are depth shoes and custom molded shoe. Depth shoe provides a minimum of 3/16" (4.7mm) of additional depth used to accommodate custom – molded or customized inserts. People with bony deformities (e.g., hammertoes, prominent metatarsal heads, bunions) may need extra-wide or depth shoes. Custom–molded shoe is constructed over a positive model/mold of a patient's foot. People with extreme bony deformities (e.g., Charcot foot) who cannot be accommodated with commercial therapeutic footwear may need custom-molded shoes. Footwear which are mass produced and then modified to fit an individual is called customized footwear. Medically indicated temporary footwear that permits ambulation and facilitates wound healing or post trauma recovery for the involved foot are called interim footwear. There are fore foot pressure relieving foot wear , hind foot pressure relieving footwear and rocker bottom footwear for relieving pressures at forefoot, hind foot and mid foot respectively.

PREVENTION:

The following are the important attributes of a foot ulcer prevention program undertaken within the framework of the multidisciplinary team.

- PODIATRIC CARE

Regular visits, examinations, and foot care
Risk assessment
Early detection and aggressive treatment of new lesions

- PROTECTIVE SHOES

Adequate room to protect from injury; well cushioned walking sneakers, extra depth, custom molded shoes
Special modifications as necessary

- PRESSURE REDUCTION

Cushioned insoles, custom orthoses, padded hosiery
Pressure measurements-computerized or Harris Mat

- PROPHYLACTIC SURGERY

Correct structural deformities- hammertoes, bunions, Charcot
Prevent recurrent ulcers over deformities
Intervene at appropriate time

- PREVENTIVE EDUCATION

Patient education – need for daily inspection and necessity for early intervention
Physician education – significant foot lesions, importance of regular foot examination, and current concepts of diabetic foot management.

CONCLUSION

Ulceration, infection, gangrene and lower extremity amputation are complications often encountered in patients with diabetes mellitus. These often result in extensive morbidity, repeated hospitalizations and mortality to the patient. All diabetic foot complications cannot be prevented but it is indeed possible to dramatically reduce their incidence through appropriate management and prevention program. The multidisciplinary team approach to diabetic foot disorders is the optimal method to achieve favorable rates of

limb salvage in the high risk diabetic patient. Foot care programs emphasizing preventive management can reduce the incidence of foot ulceration through modification of self car practices, appropriate evaluation of risk factors, and the formulation of treatment protocols aimed at early intervention, limb prevention and the prevention of new lesions. The physiatrist should play an integral role in this scheme, providing ongoing surveillance, education and management of new or impending lesions.

ABSTRACT

Background: Recent studies have shown that workers on the transport industry are more predisposed to cardiovascular morbidity and other health morbidities due to their improper diet and sedentary lifestyle. This study was aimed at assessing the common morbidity profile among the truck drivers and associated demographic and clinical parameters considered relevant to the development of cardiovascular disease.
Methods: This was a cross sectional study conducted among 175 truck drivers aged 18-60 years at the Walayar check post, Coimbatore, southern India. After getting informed consent, a detailed physical examination was conducted. Socio demographic information was also elicited.
Results: It was observed that 50% of the truck drivers were overweight and obese. Hypertensives were 41.1% and diabetics were 12%. About 27.4% had raised systolic blood pressure (BP) and 29.1% had raised diastolic BP. Low back pain was observed in 34.3%, hip pain in 24.6%, knee pain in 9.7%, shoulder pain in 5.4%, diminished vision in 4.6%, giddiness in 2.3% and hearing defects in 1.1% of the truck drivers.56.6% were current smokers and 66.3% were taking alcohol consumption more than 4 times a month. Older age was found to be a significant independent predictor [odds ratio OR 1.04 (95% CI 1.03-1.05)] for the total number of cardio vascular disease morbidities.
Conclusions: We observed a higher morbidity among the truck drivers and observed that periodic health appraisals are needed.

Keywords: Truck driver, Morbidity, Hypertension

INTRODUCTION

Non communicable diseases are considered as one of the major health and development challenges of 21st century. The social and economic effect of increased morbidity and mortality associated with cardiovascular disease is a great challenge that has to be encountered in these decades.[1,2] Recent studies done in other countries have shown that workers in the transport industry are more predisposed to cardiovascular morbidity due to their improper diet and sedentary behavior and unhealthy life styles. The commonly seen morbidities reported among truck drivers were diabetes mellitus, obesity, hypertension and heart disease.[3-6] However, most of the research done in India among the truck drivers, have focused only on their sexual health. To the extent of our knowledge, very few studies were done in India to assess other co morbidities like cardiovascular morbidity profile. Many studies done in other parts of the country have reported that professional truck drivers and other road transport professionals have a higher risk of ischemic heart disease.[7-9]

Objectives

Considering the importance of truck drivers to our country's economy, more studies are needed to assess their morbidity profile in general and associated risk factors. Considering the inherent risks associated with the profession of truck driving and scarcity of studies aimed at evaluating the cardiovascular risk of morbidity profile in their profession, this study was aimed to assess the morbidity profile among truck drivers in general and to assess the independent predictors of the total number of cardiovascular risk factors identified among them. Thus, this study focused on truck drivers, whose working conditions favor the development of a set of cardiovascular risk factors and simultaneously impose difficulties in accessing health care and adhering to life style changes that enhance quality of life. The results would provide important information to be used at personal and community level to develop strategies and actions targeted at the prevention of cardio vascular disease and the promotion of general health of these workers.

METHODS

Study design, setting and participants

A cross sectional study was conducted on 25th August 2016 among 175 truck drivers aged 18-70 years at the Walayar check post, Coimbatore, Southern India. Ethical clearance was obtained from Institute Human ethics committee, PSG IMS&R. We also got permission from highway transport authorities. The study was conducted at Walayar check post which is located on a national highway of South India on 23rd August 2016 between 10am to 4pm. Drivers who came with valid driving license for submission of documents at the check post and those who gave informed consent were included. A detailed physical examination was conducted. Socio demographic questions were also included. Truck drivers with known congenital heart disease and genetic disorders were excluded. The truck drivers who exhibited risk factors were informed about their condition and advised to attend health care services.

Variables and measurement

Demographic details were collected first followed by measurement of systolic and diastolic blood pressures using mercury sphygmomanometer, two times over a period of 10 minutes and the mean value was calculated. Digital weighing machine was used to measure weight nearest to 0.1 kg. Height was measured with bare foot nearest to 0.1 cm using calibrated stadiometer. Random blood sugar was also measured. The following criteria and definitions were used: family history of CVD: when the individual mentions the occurrence of heart disease in a first degree relative, history of chronic diseases: truck drivers were asked whether they had been previously been diagnosed with any chronic diseases and what medicines they were taking, subjects were considered physically active if they are performing aerobic (walking, biking, dancing and racing) or anaerobic activities (body building) at least 150 minutes in a week and moderately active if they do 10 to 150 minutes in a week and insufficient if they do less than 10 minutes in a week, subjects were considered active smokers if they use tobacco daily in any quantity or at quit smoking in the previous 12 months. Subjects were considered non-smokers if they had not used tobacco for the past 12 months. For determining the body mass index (BMI) the truck drivers were weighed (in kg) without shoes on a 150kg mechanical anthropometric scale and height in meter. The BMI levels were classified according to the WHO guidelines; subjects were normal if their BMI was 18.5-24.5 kg/m^2, overweight if their BMI was 25.0-29.9 kg/m^2.[11] Grade 1 obese if the BMI was 30.0-34.9kg/m^2, grade 2 obese if the BMI was 35.0-39.9 kg/m^2 and grade 3 obese if the BMI was ≥40.0 kg/m^2. Hypertension was defined as systolic blood pressure greater than or equal to 140 mm Hg or diastolic blood pressure greater than or equal to 90 mmHg. Self-reported history of previously known disease was also included.

Sample size

With an expected prevalence of hypertension as 45% and 20% allowable error of prevalence, the minimum sample size required for the study was 122.[1] With a non-response rate of 20%, the total sample required for this study was 153. A total 175 truck drivers were studied.

Statistical methods

Data were analyzed using SPSS 19.Initially data were analyzed descriptively. The categorical variables were represented by absolute frequencies. The numerical variables were summarized with averages, minima, maxima and standard deviations. The existence of association between two categorical variables was verified using Chi square test. Student t test was used to compare the averages of the numerical variables between the groups of two independent samples. Mean (SD) were calculated for continuous variables and percentages for categorical variables. 95% confidence interval was calculated for prevalence assuming normal approximation. As the total number of morbidity is expected to follow Poisson regression, we have initially checked this assumption by analyzing whether mean of the total number of CVD risk factors is approximately equal to variance using Kolmogrov Smirnov Z test. After observing the goodness of fit, Poisson regression model was performed to determine the independent predictors of the total number of cardiovascular risk factors of the truck drivers. This includes diabetes mellitus, hypertension and overweight including obesity. The independent predictors considered were age, smoking, alcohol consumption, family history of CVD and duration of physical activity. A significant level of 5% used for all statistical tests.

RESULTS

Descriptive data

Table 1 shows some characteristics among the 175 truck drivers studied. The population consist young adults with mean age of 39.38 years with a range of 22 years- 67 years. 50% of the subjects were aged 40 years and above, 137 (78.3%) were ever married, 112 (64%) had education only up to 10th standard, 56% were current smokers, 66.3% consume alcohol more than 4 times a month and 42% had family history of CVD.

Table 1: Baseline demographic characteristics (n=175).

Variable	%	Minimum	Maximum	Mean	Median
Age (years)		22	67	39.38	39.00
Physical activity (in minutes per week)		0	460	93.25	0.00
Weight (kg)		46	100	73.23	73.00
Height (cm)		144	185.50	169.55	170.00
Body mass index (kg/m^2)		16.90	36.13	25.47	24.96
Systolic blood pressure (mmHg)		70	190	127.80	130.00
Diastolic blood pressure (mmHg)		55	120	80.29	80.00
Family history of CVD	41.7				
Smoking	56.0				
Alcohol consumption	66.3				

Table 2: Morbidity profile observed.

	Number (n=175)	%
Hypertension	72	41.1
Diabetes	21	12
Overweight/ obesity	86	49.1
Low back pain	60	34.3
Hip pain	43	24.6
Knee pain	17	9.7
Shoulder pain	10	5.4
Diminished vision	8	4.6
Giddiness	4	2.3
Hearing defects	2	1.1

Table 3: Distribution of hypertension according to body mass index.

Hypertension	BMI≤ 25 kg/m^2 (n=89)		BMI 25-29.99 kg/m^2 (n=72)		BMI≥ 30 kg/m^2 (n=14)	
	N	%	N	%	N	%
Systolic only	18	20.2	25	34.7	5	35.7
Diastolic only	19	21.3	24	33.3	8	57.1
Systolic + diastolic	27	30.3	35	48.6	8	57.1
General hypertension	28	31.5	36	50.0	8	57.1

Table 4: Distribution of Study subjects based on systolic and diastolic blood pressure.

Classification	Cut point	Number	%
Optimal	SBP<120	28	16
Normal	SBP 120-129	40	22.9
High normal	SBP 130-139	59	33.7
Hypertension	SBP ≥140	48	27.4
Optimal	DBP<80	49	28
Normal	DBP 80-84	73	41.7
High normal	DBP 85-89	2	1.1
Hypertension	DBP ≥90	51	29.1

Outcome data

The analysis of the parameters obtained during the clinical evaluation shows that (Table 2), 41.1% were having hypertension, 34.3% were having low back pain, 24.6% were having hip pain and 12 5% were diabetes. It was observed that 41.1% were overweight (Table 3) and 8.05 were obese. It was also observed that 1 subject was underweight. It was also observed that the mean BMI (Table 1) of 25.47 kg/m^2 was found to be in the overweight range (25 kg/m^2-29.99 kg/m^2). We are observing an increasing trend in the blood pressure according to the increase in BMI (Table 4).

Table 5: Factors associated with the total number of morbidity using Poisson regression model.

Variable	Odds ratio	95% CI	P value
Higher age	1.03	1.02 -1.05	p<0.001
Positive family history	1.04	0.83 -1.30	0.69
Smoking	1.04	0.83 -1.34	1.32
Alcohol consumption	0.82	0.65	1.04
Physical activity	1.00	0.99 -1.00	1.00

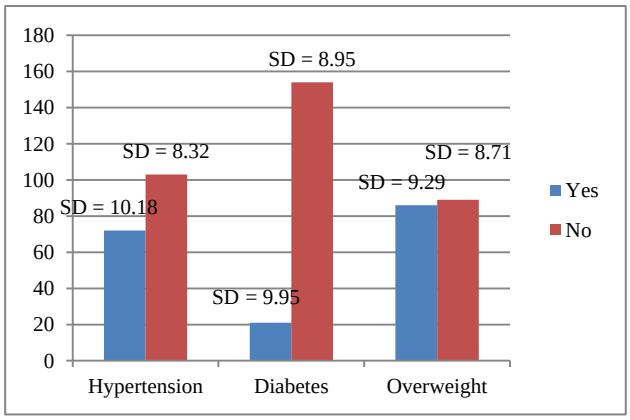

Figure 1: Mean (SD) of age (years) among cardio vascular disease morbidity.

In our study, 59 truck drivers (33.7%) were considered high normal and 48 truck drivers (27.4%) were hypertensive considering systolic blood pressure. Based on diastolic blood pressure, 2 drivers (1.1%) were considered as high normal and 51 drivers (29.1%) were hypertensive. The prevalence of overweight and diabetes were higher in this study population compared to the recent study at Hyderabad in the year 2014. The prevalence of hypertension was similar to the reported prevalence of Hyderabad.[10]

Main results

It was observed that the mean is approximately equal to variance. From the results from Kolmogov Smirnov test, it is concluded that the total number of morbidity follows Poisson distribution (z=0.665, p=0.768) and hence decided to Poisson regression analysis. On using Poisson regression model, Age was found as a significant independent predictor [OR 1.03 (95% CI 1.02-1.05)] for the total number of cardio vascular disease morbidity. It was also observed that mean age of truck drivers with risk factors were between 42.45 years to 46.95 years which is the most productive years putting them at risk of CVD morbidity (Table 5).

Other analyses

On further analysis it was observed that, a significant difference in the mean (SD) age of truck drivers between those who have hypertension 42.48 (10.18) compared with those who do not have hypertension 37.21 (8.32) (p<0.001). A similar difference in the age was observed for diabetes 46.95 (9.95) versus non diabetes 38.35 (8.95) (p<0.001) and for overweight and obesity 42.45 (9.29) versus others 36.41(8.71) (p<0.001).

DISCUSSION

The aim of the present study was to characterize a population of truck drivers with regard to demographic and clinical variables and the presence of cardiovascular risk factors. Our study highlights the need to retrospectively evaluate and systematize the presence of various risk factors in the population of long distance truck drivers. The main finding of our study is that truck drivers have a high prevalence of multiple factors that put them at high risk of cardiovascular events. This is an alarming prospect given the morbidity and mortality rates in the south Indian population and the risks these events pose to truck drivers and others who use roads.

Our study results showed that there is a high prevalence of behavioral risk factors such as overweight, obesity, hypertension, diabetes among the truck drivers and these risk factors were higher at older ages. A number of studies done on other parts other country have demonstrated that high prevalence of obesity among workers in the transport industry. According to Moreno et al., this category of workers in Brazil has a higher incidence of obesity, physical inactivity, inadequate diet, smoking habits, high levels of cholesterol and glycemia, hypertension, and obstructive sleep apnea in comparison to the general population in Brazil.[11,12] A study carried out in the United States involving more than 600 thousand workers found the highest prevalence of obesity to be among male employees who work as highway truck drivers.[13] A representative sample of the Australian in productive age compared ten different functional categories with regards to the risk of obesity and found that male employees of the transportation industry had a higher risk of overweight and obesity.[14] In our study, it was observed that nearly one third of the truck drivers were having low back pain (LBP). It has been pointed out by several studies that the factors leading occupational

LBP among truck drivers include exposure to vibration, repeatedly lifting heavy objects, strained postures, and sitting for work for many hours.[15] In a recent study conducted at Japan it was observed that 52.9% of the truck drivers were having LBP. Most drivers pointed out that vibration and road shock account for the LBP. Troup et al. noted that muscle fatigue due to mechanical stress such as road shock transmitted to the body and a restricted sitting posture contribute to truck drivers' LBP. From the viewpoint of prophylaxis, an improvement in the working condition is needed to reduce the incidence of drivers' LBP to some extent.

In this study we observed higher prevalence of hypertension among truck drivers. According to World Health Organization, systolic blood pressure greater than 115 mm Hg accounts 62% of cases of cardiovascular disease and 49% of cases of ischemic heart disease.[16] Moreover, arterial hypertension is one of the major risk factors of cerebro vascular accident. Many studies have also demonstrated an increase in the prevalence of systemic hypertension among professional drivers.[17,18]

In our study older age was found to be an independent predictor of the total cardiovascular morbidity profile life span. With aging, there is an increased acquisition of several CVD risk factors in an individual's life span. Several studies have shown that when age and other risk factors are used jointly to examine an individual's risk of CVD, it has been found that the contribution of age in the multivariate models may be a reflection of the intensity and duration of exposure to the traditional CVD risk factors.[19-23] Avoidance of these traditional risk factors at younger ages can reduce CVD risk associated with age per se.

People employed in the transport sector form a considerable workforce of our nation.[24-28] Intersectorial consideration between transport department and health department is needed to protect and provide health to transport employees. Thorough periodical medical examinations are to be conducted to these truck drivers and necessary steps are to be taken. In addition strict guidelines about diet are to be formulated to the truck drivers. In addition it is observed that the truck drivers must be educated at their younger age preferably early thirties to prevent overweight and obesity and thereby to reduce hypertension. Regular health education programs are to be conducted regarding various non-communicable diseases and attendance to such programs should be made compulsory. Strict guidelines about diet are to be formulated and implemented in all the eateries catering to the employees. Various recreational facilities, counseling centers with psychologists are to be established in all depots to help the employees cope with their stress.

Limitations

Our study has some limitations. First, this study does not allow the determination of causal associations since we used cross sectional study design. Another limitation of our study is that, we have not quantified the smoking and alcohol intake. Fasting blood sugar values were not studied. Because we were looking for a cluster of cardio vascular risk factors, another limitation of this study was the lack of measurements on lipid profiles or inflammatory markers.

CONCLUSION

In conclusion, we observed a higher morbidity among the truck drivers' ages. The data in the present study allow us to draw conclusion that truck drivers are highly vulnerable to developing CVD because of the high prevalence of variety of risk factors. Furthermore we must consider that the truck drivers we studied were adult men and that cardiovascular risk factors could decrease their maximum age and it affects their economy, the lives of the truck drivers and individuals who use the roads.

Recommendations and generalizability

More national studies are needed to look into what percentages of road traffic accidents involving human error and what percentages involve medical conditions involving cardiovascular conditions. Accordingly guidelines for the minimum standards required for fitness to drive those drivers with CVD. However, the driving restrictions may have disadvantage in the form of psychosocial effects on recipients and their family members. Instead, regular health education programs and appropriate healthcare action based on comprehensive public policies that focus on the truck drivers work environment and monitoring of these factors must be established at the national level. Accordingly various recreational facilities and counseling centers are to be established in highways for the truck drivers. Finally, intersectorial coordination between transport department and health department is needed to protect and promote health of transport employees.

ACKNOWLEDGEMENTS

The authors are deeply thankful to Dhanush M, and Prem Anand ES, medical interns helped us in conducting the study and in collecting clinical data. The authors are extremely thankful to Dr.SL Ravi Shankar, Professor and Head of the Department of Community Medicine, PSG Institute of Medical sciences and Research for his valuable guidance at various stages of the study. The authors are thankful to Mr. Abdul Navas, Regional Transport officer, Palghat for permitting us to do this study. We are thankful to Mr.vinod, Head of marketing and Mr. Sirajudeen for helping us to organize and conduct this study.

Funding: No funding sources
Conflict of interest: None declared
Ethical approval: The study was approved by the Institutional Ethics Committee of PSG Institute of Medical Sciences and Research

ABSTRACT

Background: Osteoarthritis (OA) is a degenerative joint disease and one of the major health problems that cause functional impairment and reduced quality of life. There is osteophyte formation remodeling of subarticular bone, ligamentous laxity, and synovial inflammation weakening of periarticular muscles. These changes may occur as a result of an imbalance in the equilibrium between the break down and repair of joint tissue. Hamstring tightness and quadriceps weakness are the major problems in osteoarthritis individuals. Tightness of hamstring muscle and quadriceps weakness can cause pain in patients with osteoarthritis. Stretching of hamstring and strengthening of quadriceps muscle can improve the pain and strength of the muscles around the knee joint. Retro walking can help in strengthening of the quadriceps muscles.
Methods: It was a Quasi experimental study with comparison between 2 groups consisting 30 participants (males and females) 15 in each group, with osteoarthritis. Group A received Hamstring stretch and quadriceps strengthening exercises and Group B received Retro walking, for 9 sessions, 3 days/week for a period of 3 weeks. Outcome measure was WOMAC and NRS measured before and after intervention.
Results: The results suggest that participants in Group B had significant improvement in NRS and WOMAC than Group A.
Conclusions: Both group A and group B showed significant results and displayed efficient improvement in decreasing pain and functional disability in patients with knee osteoarthritis.

Key words: Retro walking, Knee Osteoarthritis, Exercises, Pain and disability.

INTRODUCTION

Osteoarthritis (OA) is a non-inflammatory progressive disorder of movable joints, particularly weight bearing joints. Exact cause of OA is not known. However it is strongly believed that it occurs due to aging or wear and tear or degenerative changes in the joints. [1] Risk factors for OA knee includes age, gender, obesity, occupation, sports, osteoporosis, previous trauma, irregularity in joint surfaces, internal derangement, heredity, leisure and diseases leaving articular cartilage damage. [2] There is increased risk of development or progression of disease due to greater or uncontrolled loading on the joint; therefore, quadriceps strength needs to be considered in the study of knee OA. A reduced quadriceps strength has been shown to be associated with the presence of OA in the knee. [3]

The major symptoms present in osteoarthritis are pain and functional disability. [4] The knee is most common site for osteoarthritis with characteristic sign like pain, stiffness, tenderness, swelling, crepitus, and loss of movement, valgus or varus deformity, locking of the knee, on

auscultation of joint- scratching, crepitus and later on loud crackling sound. In addition, they have a lot of functional limitation when sitting and standing or going up and down stairs. [5, 6]

There is osteophyte formation remodeling of subarticular bone, ligamentous laxity, synovial inflammation and weakening of periarticular muscles. These changes may occur as a result of an imbalance in the equilibrium between the break down and repair of joint tissue.

According to Framingham study, among the individuals aged above 45 years the prevalence of radiographic knee OA was 19.2%, and in those above 80 years, it is 43.7%. [7] In rural India the incidence is 5.78% which is about 30% of all rheumatological problems. In India there is increased knee arthritis than western population. [8]

Management of knee arthritis is mainly concentrated on reducing pain, increasing joint ROM and improving extensor muscle strength, neglecting ligamentous and muscular tightening which affects lower limbs function and gait. The initial conservative management includes - Risk factor education of obesity, avoidance of ground level activities, Non steroidal anti inflammatory drugs, Intraarticular injections of sodium hyaluronate. The most surgical management done is total knee replacement in most advanced cases. [9]

Physiotherapy as the main choice of conservative management; which includes various strategies such as manual therapy, exercises, patellar taping and electrical modalities with or without thermal modalities as measures for pain reduction. [11] Recently, closed kinematic chain exercises have drawn much attention in the management of knee arthritis. [12] Studies suggest that these exercises are more effective and functional than the traditionally employed open kinematic chain exercises. [13] Closed kinematic chain exercises for knee joint can be incorporated in many ways; one of them is Retro‑walking. [12] Retro‑walking is walking backwards. [11] Since there is propulsion in backward direction and reversal of leg movement in Retro‑walking, different muscle activation patterns from those in forward walking are required. [14] Retrowalking significantly lowers peak patellofemoral joint compressive force and a significantly slower rate of loading has been found during backward walking. Consequently, trauma to the articular cartilage is reduced during retrowalking. [1] Retrowalking could be utilized as a mode of training during knee rehabilitation since excessive loading of the joint and overstretching of the ligaments are prevented whilst quadriceps strength. [15]

Strength of the quadriceps musculature is one of the intrinsic factors that have been shown to affect the knee joint functions. It is evident that lower extremity strength has a major role in knee joint shock attenuation during weight bearing activities. [10]

MATERIALS AND METHODS

The research design used for the study was Quasi experimental study with comparison between 2 groups. Participants received 9 sessions, 3 days per week for a period of 3 weeks. Each treatment session lasted for 30 minutes. Both male and female participants with a clinical diagnosis of unilateral or bilateral osteoarthritis of knee referred to department of PMR, from the department of orthopaedics, PSG Hospitals. The sample size was 30. Sample design was Convenience sampling. Selection Criteria used for this study was as follows- The inclusion criteria for the study:- Male and female participants, clinically diagnosed with osteoarthritis of knee by orthopaedician, Age more than 40 years, Participants having Pre test NRS score more than 5 score, Participants with unilateral or bilateral involvement of knee, Willingness to participate in the study. The exclusion criteria for the study were Participants with History of lower limb or spinal surgeries, Neurological disorder (motor and sensory loss), Pathologies related to hip, knee and

spine, Cardio vascular problems with increased heart rate, Other musculoskeletal disorders associated with knee joint, IT band, adductor muscle and sartorius muscle tightness.

The participants were screened from outpatient department of PMR department, after finding their suitability according to the inclusion and exclusion criteria, they were requested to participate in the study. The participants were briefed about the nature of study, the duration of intervention and the intervention being used in the language best understood by the participants. They were encouraged to clarify queries regarding the study, if any. An informed written consent form, previously approved by the Institutional Ethical Committee was then obtained from the participants. The demographic data was obtained and a detailed assessment of 30 participants was done on the basis of name, age, gender, height, weight, BMI, present chief complaints, past history, pain history, and medical history. Participants were subsequently allocated in a group according to the selection criteria. The outcome measures NRS and WOMAC were assessed before the intervention as given below;

- Pain was assessed with the help of Numerical Rating Scale, an 11-point numeric scale with 0 representing one pain extreme (e.g. "no pain") and 10 representing the other pain extreme (e.g. "pain as bad as you can imagine" and "worst pain imaginable"). [16]
- Physical function was assessed with the help of Western Ontario and McMaster Universities Osteoarthritis Index, is a widely used, proprietary set of standardized questionnaire used by health professionals to evaluate the condition of patients with osteoarthritis of the knee and hip, including pain, stiffness, and physical functioning of the joints. [17]

The two groups were as follows: Group A (Conventional Group) and Group B (Experimental Group). In group A Hamstring stretch and quadriceps strengthening with 5 seconds hold and a rest interval of 2 seconds for 10 repetitions for each exercise for a period of 3 weeks, 3 days per week was given. In group B retro walking with a rest (if need) for a period of 3 weeks, 3 days per week was given.

Procedure:

In Group A

Conventional Physiotherapy treatment for this group was given static quadriceps exercise, dynamic quadriceps exercise, straight leg raise, prone knee bending, and simple hamstring stretches, for 10 repetitions with 5 seconds hold followed by 2 seconds rest for each exercise for a period of 3 days per week for duration of 3 weeks. Home program for 2nd and 3rd week: same exercises.

In Group B

Procedure for retro walking: The participants initially were made to walk 4 steps retrowalk and were observed for any discomfort. If no discomfort then, participant was made to retrowalk for 10 minutes per session. The participants will be first familiarized with the retrowalking on flat surface (distance 20 meters) such that during retrowalking, the toes strike the ground first instead of the heel. Practice session was made for retrowalking with support of wall. The participants received retrowalking on flat surface (distance 20 meters) at their maximum pace with support of the wall for 10 minutes per session. The session included 4 minutes of retrowalking following 2 minutes of rest time and then again 4 minutes of retrowalking. The therapist was walking besides the participant. The protocol followed was retrowalking for 10 minutes, 3 days/ week for duration of 3 weeks. Home program for 2nd and 3rd week: same walking pattern.

Ethical clearance

The study followed the ethical standards of institutional human ethics committee, PSG IMS&R. [(Ref. no. PSG/IHEC/2018/ Appr/Exp/165) (project no.18/073)].

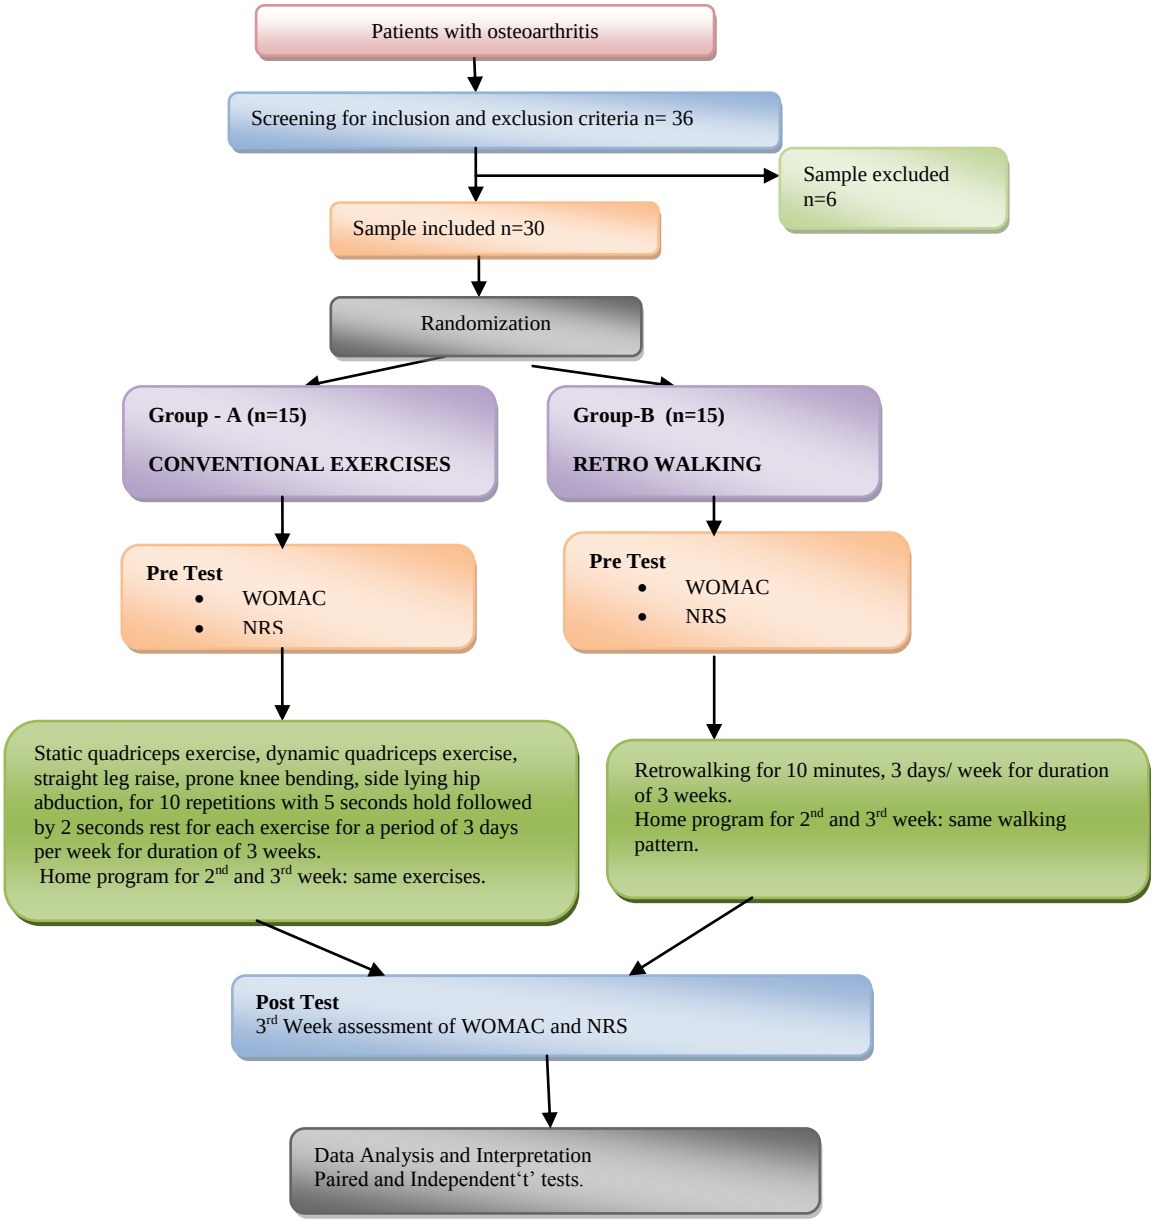

Fig.1 Flow chart representing the procedure of selection of participants

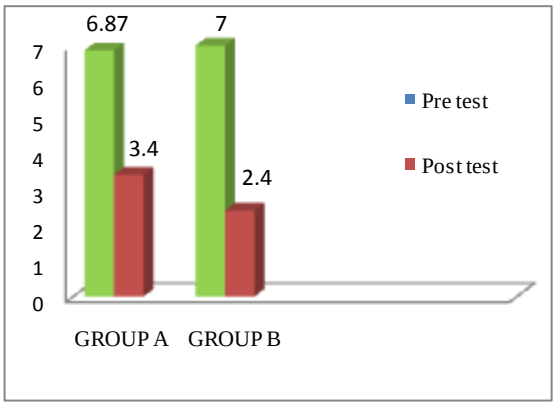
RESULTS

Study variables were done before starting physiotherapy sessions on both groups and at the end of the study, study variables include NRS and WOMAC.

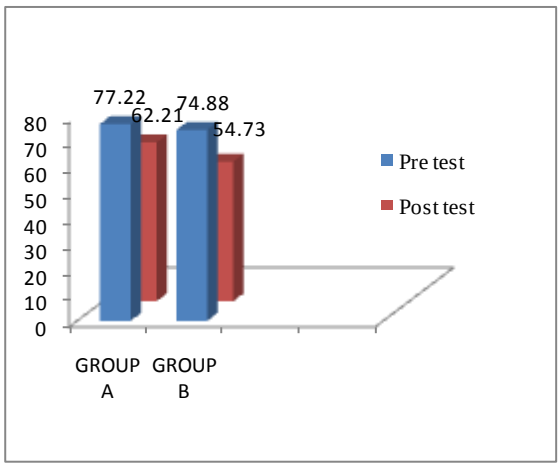


Data analysis: Statistical analysis was performed on the data obtained from 30 patients. Data was analyzed using Statistical Package for Social Sciences [SPSS] software [version 16.0]. Descriptive statistics for all outcome measures were expressed as mean, standard deviations and test of significance such as paired 't' test used for comparing data within each group and independent 't' test for comparing between the groups. Data was considered statistically significant with $p<0.05$ and highly significant with $p<0.01$.

Pre and post mean difference of pain (NRS) shows 3.47 ± 0.74 in group A and 4.60 ± 0.83 in group B. As $p<0.05$ there is significant difference between two groups.

Pre and post mean difference values of WOMAC shows 15.01 ± 4.51 in group A and 20.15 ± 5.29 in group B which shows a significant difference between two groups.

Table 1: Paired "t" test values for OA knee (NRS)



Group	Mean	Mean Difference	Standard Deviation	"t" Value	"p" Value
Group A Pre Test Post Test	 6.87 3.40	3.47	0.74	18.07	P<0.05
Group B Pre Test Post Test	 7.00 2.40	4.60	0.83	21.51	P<0.05

Graph 1: Mean values of NRS

Table 2: Paired "t "Test values for OA Knee (WOMAC)

Groups	Mean	Mean Difference	Standard Deviation	"t" Value	"p" Value
Group A Pre Test Post Test	 77.22 62.21	15.01	4.51	12.90	P<0.05
GROUP B PRE TEST POST TEST	 74.88 54.73	20.15	5.29	14.76	P<0.05

Graph 2: Mean values of WOMAC

Table 3: Independent "t" test for OA knee

Outcome Measures	Mean Difference	"t" Value	"p" Value
NPRS	1.00	4.33	P<0.05
WOMAC	7.49	4.53	P<0.05

DISCUSSION

The purpose of the study was to determine the effects of retro walking over conventional physiotherapy treatment in osteoarthritis of knee joint. According to many studies the backward walking increases the hamstring activation which generates reduced patello femoral and lower tibiofemoral compression load stress and ACL strain, and therefore backward walking reverses the shear forces in knee joint. [18] Results of the present study showed that retrowalking is more effective in reducing pain and disabilities as compared to conventional physiotherapy treatment.

Reduction of pain and disability was seen in both the groups. But a much better improvement was seen in group B. Despite the fact that patients in the group A performed conventional exercises to reduce pain and to improve physical function, changes were identified. The result of this study also suggests that retro walking positively influences pain and disability in the group B.

The outcome measures used for assessment were the Numerical pain Rating Scale (NRS) and the Western Ontario and

McMaster Arthritis Index (WOMAC). In the group B, the mean value for NRS was reduced at the end of 3rd week, showing a significant reduction in pain. The mean value for WOMAC was also reduced at the end of 3rd week, showing a significant reduction in pain, stiffness and disability.

CONCLUSION

Participants who underwent retrowalking showed significant reduction in pain, stiffness and disability at the end of the treatment period when compared to participants with conventional physiotherapy. Therefore, retrowalking can be considered beneficial reduction in pain, stiffness and disability in knee osteoarthritis individuals. The result of this study also suggests that retro walking positively influences pain and disability in group B.

Suggestions

- The study can be extended to large sample size.
- The duration of the study can be increased.
- Activities of daily living and recreational activities of patients were not taken into account. There were few dropouts that can be strategically improved in future.

ACKNOWLEDGEMENT

The author wants to thank all the patients for their participation in the study, PT Sherly, PT Divya Prabha, Physiotherapist, department of PMR, PSG Hospital, Coimbatore and PT Priyanka for their valuable support.

ABSTRACT

Background: Impaired balance is one of the most common problems in post stroke patients. Thus the subject may unable to maintain balance in sitting and standing or to move in weight bearing posture without loss of balance. Treatment focusing on balance impairment is important to achieve functional independence at the earliest following stroke.
Methodology: Quasi experimental design - pretest and posttest designs with two groups at Department of Physical Medicine & Rehabilitation, PSG Hospitals, Coimbatore, Tamil Nadu, India. A total of 30 stroke patients in the age group of 45 to 60 years who satisfied the selection criteria were randomly assigned into two groups. Group A received conventional therapy along with balance training using Swiss ball for 60 minutes/session and Group B received conventional therapy along with balance training on mat and stool for 60 minutes/session. Outcomes were measured with Berg balance scale.
Results: All participants in Group A and Group B showed significant improvement in Berg balance scale with a mean difference of 13.6 and 8.7 respectively, calculated 't' value using the paired test for group A and B were 39.3 and 15.9 ($P<0.05$) respectively. When comparing between the groups using independent 't' test, the Berg balance scale scores showed mean difference of 4.6 and 't' value of 5.4 ($P<0.05$)
Conclusion: This study revealed that there was a significant improvement in balance following balance training on Swiss ball than on bed and stool among hemi paretic patients.

Key Words: Swiss ball, Static balance, Dynamic balance, Berg Balance Scale

INTRODUCTION

Stroke is a rapidly developing clinical signs of focal cerebral dysfunction; lasting more than 24 hours or leading to death with no apparent cause other than the vascular origin. [1]

Balance is frequently disturbed following stroke with impairments in steadiness, symmetry and dynamic stability. [2] The automatic adjustment of muscle tension that occurs normally in preparation for and during a movement task, termed automatic postural tone is impaired in stroke patients. Thus the patient may lack ability to stabilize the proximal joints and trunk appropriately resulting in postural malalignment, impaired balance and risk of falling. Commonly problems may exist when reacting to a destabilizing external force or during self initiated movement. [3]

Patients with stroke typically demonstrate asymmetry with most of weight in sitting or standing shifted to non-paretic side. Hemiplegic subjects typically fall in

side of weakness. [4] They also have increase postural sway in standing. Balance problem during dressing activities increases the likelihood of stroke survivors having a fall.

In preface of stroke balance training is considered vital because it helps in achieving optimal posture, gait and thus can hasten the patients progression to near normal functional activities.

A cordial therapeutic intervention along with a good patient co-operation has led to early balance improvisation in patients. [5] Swiss ball therapy along with other physical therapy intervention will help in early regaining of balance when compared to conventional therapy interventions. [6, 7]

In this study we aimed at improving the balance through Swiss ball exercises along with other conventional balance training. So with the improvement of balance it's able to achieve a good and independent functional mobility, gait and ADL activities. The Berg Balance Scale is a used as an assessment tool to identify balance impairment. [8] Functional activities such as reaching, bending, transferring, and standing are evaluated on the test to evaluate balance.

METHODOLOGY

STUDY DESIGN

Pretest and posttest design with a comparison group – a quasi experimental study.

STUDY SETTING

Physiotherapy division, Department of Physical Medicine and Rehabilitation, PSG Hospitals

NUMBER OF SUBJECTS

A total of 30 hemiplegic participants who met inclusion criteria were randomly assigned into Experimental group (Group A – 15 subjects) and Control group (Group B – 15 subjects).

INCLUSION CRITERIA

Age: 45-60 years; Gender: male; Ischemic stroke for the first time; Functional balance grade – fair

EXCLUSION CRITERIA

Cognitive deficit; Bilateral cerebellar stroke; Sensory disorders; Cardiovascular system instability; Tumors and infections; Orthopedic conditions.

INSRTUMRNATION USED

Swiss Ball; Mattress; Couch; Stool; Bolsters; Balance board; Measuring tape.

OUTCOME MEASURES

Berg Balance Scale.

PROCEDURE

The purpose of the study was explained to the subjects, verbal description of all procedures and test was given to them and a written consent was obtained from the patients who fulfilled the inclusion and exclusion criteria and randomly assigned to two groups. An assessor who was blinded to the group allocation took the outcome measurements using Berg Balance Scale. Initial assessment was taken on the first day before therapy. Intervention was given to each group separately for a total of 10 sessions (5 sessions / week). Post assessment was taken after 10 sessions of physiotherapy treatment using the same outcome measure. Comparison of pretest and posttest values within the group and between the groups was done finally.

INTERVENTION

The subjects in the experimental group (Group A) received conventional therapy along with balance training using Swiss ball for 60 minutes per session, the subjects in control group (Group - B) received conventional therapy and balance training activities on mat and stool. Exercises performed by both the groups are given in figure 1.

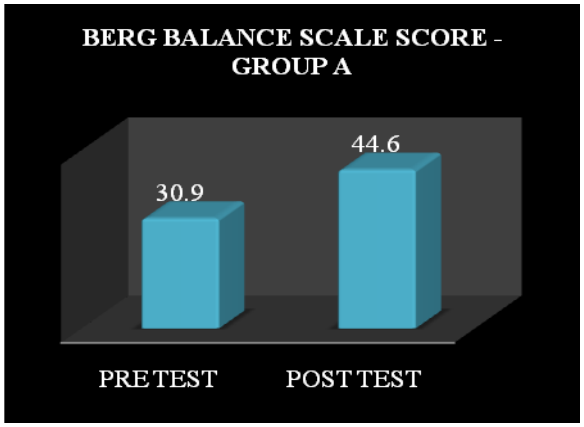
DATA ANALYSES

Paired 't' test was used to find the difference within the group between pre and post intervention scores in the outcome measure. Independent 't' test was used to find the difference between the groups in the outcome measure. The statistical significance for this study was set as $p < 0.05$.

Figure 1: Illustrates treatment protocol

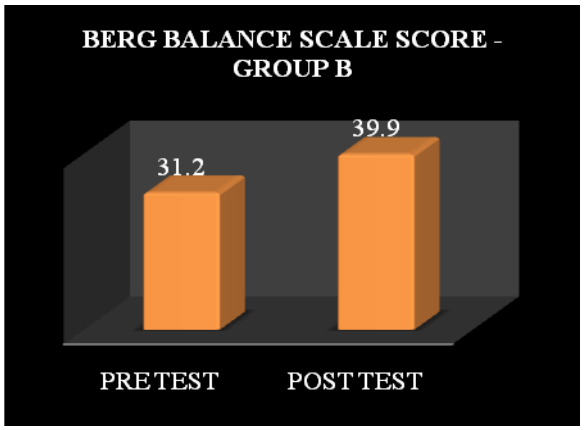
CONVENTIONAL PHYSICAL THERAPY
Normalization of muscle tone: Slow sustained stretching for biceps and wrist flexors, hamstrings and calf muscles; Weight bearing activities in forearm supported prone lying, prone kneeling, half kneeling, sitting and standing. Range of Motion exercises: Passive and active assisted exercises for the affected upper and lower limb - 15 repetitions each exercises.
GROUP A (Balance training using swiss ball)
Supine lying position: Pelvic bridging bilateral and unilateral; lower trunk rotation; lower limb flexion and extension. Sitting position: Static sitting balance training - patients should sit on the ball and have both feet touch the floor with hips, knees and ankles at 90-90-90 degree position and can work on achievement of an upright erect posture; Trunk forward and lateral reach; Upper and lower trunk flexion-extension and lateral flexion activities; Marching activities; Trunk rotation and PNF chopping and lifting activities. 15 repetitions each activities.
GROUP B (Balance training using mat and stool):
Supine lying position: Pelvic bridging bilateral and unilateral; lower trunk rotation; lower limb flexion and extension. Sitting position: Static sitting balance training - patients should sit on the stool and have both feet touch the floor with hips, knees and ankles at 90-90-90 degree position and can work on achievement of an upright erect posture; Trunk forward and lateral reach; Upper and lower trunk flexion-extension and lateral flexion activities; Marching activities; Trunk rotation and PNF chopping and lifting activities. 15 repetitions each activities.

RESULTS



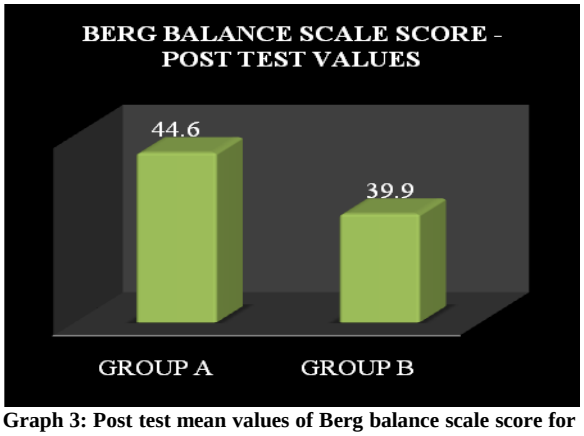
The aim of the study is to find out whether balance training using Swiss ball when given along with conventional balance training improves balance in all day activities among post stroke patients. As shown in Table 1, all participants in group A&B, showed significant improvement in Berg balance scale score with a mean difference of 13.6 and 8.7 respectively. The calculated 't' value by using the Paired 't' test for group A&B were 39.3 and 15.9 respectively which was greater than the table 't' value of 2.14; $p<0.05$. This shows that there is a significant improvement in balance in both the groups. As shown in Table 2, when comparing the groups using Independent 't' test, Berg balance scale score showed mean difference of 4.7 and the 't' value of 7.5;$P<0.05$, which was greater than the table 't' value of 2.04. This results shows that there is a statistically significant improvement in group A which underwent balance training using Swiss ball along with conventional balance training.

Table 1: Mean, mean difference and Paired 't' test values for Berg balance scale of groups A&B.



Groups	Means	Mean difference	't' value	'p' value
Group A				
Pre test	30.9	13.6	39.3	p < 0.05
Post test	44.6			
Group B				
Pre test	31.2	8.7	15.9	p < 0.05
Post test	39.9			

Table 2: Mean difference and Independent "t" Test values for Berg balance scale of groups A&B.



Outcome measure	Mean difference	't' value	'p' value
Berg balance scale	4.6	5.4	p < 0.05

Graph 1: Pre test and post test mean values of Berg balance scale score for group – A.

DISCUSSION

In stroke patients who can able to walk, the majority of falls were reported only during walking, an activity that requires dynamic and reactive balance for example turning, transferring, and stair climbing because of reduced balance.

Conventional physical therapy uses only traditional balance training protocols on a stable surface that is less demanding for the post stroke patients to improve balance, but the stroke participants need more of balance to prevent the fall related complications.

The Swiss ball, as a movable surface, provides the patient with some uncertainty in terms of stability. A sudden movement of the ball requires the patient to be able to make a quick, unanticipated postural response, to realign the centre of gravity in relation the base of support. Swiss ball stimulates body's natural motor reflex and encourages body to react as a whole integrated unit by increasing the muscle recruitment, thereby increasing the efficiency of the muscles for effective postural mechanism.

A significant improvement in balance the experimental group (balance training using Swiss ball) is due to the postural perturbation provided by the movement of the Swiss ball to which the trunk muscles responded reactively in order to maintain the desired postural stability.

Duncan et. al., (2009) in his study has stated that activity of the trunk muscle was greater when exercises are performed on a Swiss ball than in exercises performed on stable surface in healthy adults. [6] Karthik Babu et. al., (2011) in their study found that there was a significant improvement in lateral flexion of trunk when trained with Swiss ball than in plinth. The results were similar to our findings that balance improvement in Swiss ball training is much significant than conventional balance training. [9]

In Berg balance scale the components such as trunk rotation, turning and placing alternate step on stool scores improved much in Swiss ball training group than the conventional balance training group. This is due to the fact that with Swiss ball therapy coordination improved much more because of perturbations on unstable surface resulted in greater muscle recruitment.

CONCLUSION

The intent of this study was to find out the effect of Swiss ball therapy in balance rehabilitation of hemiplegic stroke participants. From the results of this study we can state that Swiss ball when administered along with conventional physical therapy will be more effective in improving balance.

ABSTRACT

Background and Purpose: Electrical stimulation has been used in clinical practice to accelerate wound healing for which positive results have been reported in clinical studies. The Purpose of the case report is to document the clinical effects of application of microcurrent stimulation in healing of pressure ulcer in a chronic bedridden patient. **Case Description:** The Patient was a 53 year old male who was diagnosed to have Cerebro vascular accident with Intraventricular hemorrhage and subsequent hydrocephalus underwent external ventricular drainage and Ventriculo peritoneal shunting before one year. Current evaluation demonstrated primary impairments of muscle weakness in right upper and lower limbs associated with activity limitation of bed mobility and ambulation. The patient also had secondary impairments of grade IV pressure ulcer in the sacral region. A plan of care was developed to focus on the management of primary and secondary impairments along with application of microcurrent electrical stimulation for management of pressure ulcer. **Outcomes:** The patient had benefits with significant reduction in the surface area of the pressure ulcer following 8 weeks of microcurrent stimulation. The Pressure Ulcer Scale for Healing (PUSH) showed a significant change from a score of 15 at week one, to a score of 6 at the end of 8 weeks. **Discussion:** Pressure ulcers are one of the most common issues in the elderly and immobile individuals, which constitute a major psychological and physiological burden with reduced quality of life. Among the treatment options, this research report focuses on the beneficial effects of Microcurrent electrical stimulation, based on its results in pain control, edema control and wound healing.

INTRODUCTION

Microcurrent therapy (MCT) is a form of low-intensity, direct current that delivers monophasic or biphasic pulsed micro amperage currents across the skin, below the sensation threshold which is a novel treatment for different pain disorders and wounds (Koopman, 2009). It has been used to regenerate the internal bioelectrical activity of injured tissues and has been consistent with that of endogenous currents that act at the cellular level. Application of microcurrent can influence the behaviour of cells involved in healing processes such as migration, proliferation and production of proteins and cytokines. At the tissue level, it can promote angiogenesis, neural sprouting and increase the rate of tissue synthesis (Poltawski, 2009). Microcurrent therapy results in accelerated healing of wounds compared with sham therapy.

Corresponding author: **Subash Palanisamy,**

Sufficient literature has reported positive outcomes as the result of application of microcurrent therapy in a range of pain syndromes, venous ulcers and open wounds. In this case report we have provided description about application effects of microcurrent therapy for healing of pressure ulcer wounds. A pressure ulcer, also known as pressure sore, decubitus ulcer, or bedsore, is defined as a localized injury to the skin and/ or underlying tissue occurring most often over a bony prominence and caused by pressure, shear, or friction forces alone or in combination. Pressure ulcers represent a major burden to patients and caretakers and have a detrimental effect on patients' quality of life (Grey, 2006). Pressure ulcers are classified into four categories: Stage I describes intact skin with nonblanchable erythema; Stage II pressure ulcers have partial-thickness skin damage with possible blister formation, but no subcutaneous tissues visible; Stage III pressure ulcers have full-thickness skin loss with subcutaneous fat exposed but no muscles, bones, or tendons visible; Stage IV pressure ulcers have tissue loss with exposure of muscles, bones, tendons, or vital organs (Dealey, 2006).

Pressure ulcer prevention aims to eliminate or reduce factors that predispose a person to pressure ulcer development. Strategies commonly used include other than regular risk assessment, use of special pressure relieving support surfaces, regular repositioning and turning, local skin care, nutrition support, removal of necrotic tissue, prevention of skin maceration, control of infections, which encourages soft tissue repair (Reddy, 2006). The purpose of the case report is to identify the effects of application of microcurrent therapy along with routine care for healing of pressure ulcer.

CASE DESCRIPTION: The patient was a 53 years old male who had been present with systemic hypertension over a period of 1 year, diagnosed to have an episode of cerebro vascular accident – interventricular hemorrhage, intracerebral hemorrhage and a subsequent episode of hydrocephalus before 1 year. He subsequently underwent conservative management for CVA and surgical treatment for hydrocephalus with external ventricular drainage followed by ventriculo peritoneal shunting performed by a neurosurgeon. The Patient underwent post surgical care and inpatient rehabilitation for a period of 85 days and was discharged to home from a tertiary care hospital. After a period of 6 months, the patient was admitted for provision of rehabilitation care. During that time, patient is confined to bed with complaints of weakness of muscles of both upper and lower extremities, decreased bed mobility, pressure ulcer in the sacral region and was completely dependent for performing activities of daily living (ADL). A review of systems demonstrated normal higher mental functions along with impairments in motor, sensory and integumentary functions. He had severe neurological impairments with a score of 40/56 in Scandinavian Stroke Scale (SSS), had modified dependence in functional activities with a score of 80/126 on the Functional Independent Measure (FIM).

Integumentary system examination revealed that the patient has grade IV pressure ulcer in the sacral region – Full thickness skin and tissue loss with exposure of muscles, tendons, bones and vital organs. The pressure ulcer scale for healing (PUSH tool) is a commonly used tool developed by the NPUAP, which grades pressure ulcers based on size of wound, wound bed tissue type, and exudate amount.(6)The pressure ulcer scale for healing (PUSH tool) Version 3.0 was used to assess the extent of ulcer. The patient had a PUSH score of 15 initially with a score of 10 in the Length X Width component as the wound had a total surface area of 46 cm^2, a score of 2 in the exudates component with moderate amount of exudate and a score of 3 in the tissue type component with slough tissues.

Intervention: The patient underwent regular physiotherapy treatment with short term goals to improve voluntary motor control, bed mobility and transfers, long term goals being set towards improvement of locomotor ability and independent activities of daily living. For the treatment of pressure ulcer, regular positioning care and saline dressing were the primary treatment choice along with application of microcurrent therapy. An intelect combination therapy unit was used to deliver microcurrents through reusable carbon-impregnated silicon rubber electrodes, with intensity within range of 20 – 50μA and negative polarity. The electrodes are placed such that it covers the surface area of the wound. The patient received microcurrent therapy for a duration of 20 minutes per session per day, six days a week for eight weeks. The patient underwent positioning care with regular change of position for every 2 hours and wound care with saline dressing for two times a day. During the course of treatment, the patient did not have/report any adverse events.

Table 1. Pressure Ulcer Scale for Healing (PUSH) weekly scores

Variables	On Initial Assessment	2nd week	4th week	6th week	8th week
Length X width	10	9	8	7	5
Exudate amount	2	1	1	0	0
Tissue type	3	3	3	2	1
PUSH total score	15	13	12	9	6

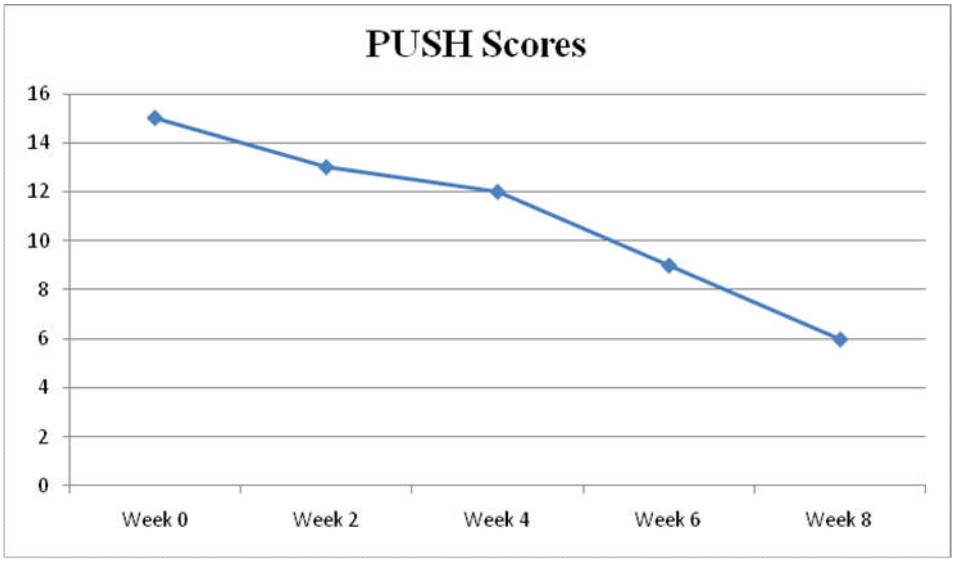

Figure 1. Graphical representation of PUSH scores monitored weekly

Outcome Measures

The pressure ulcer scale for healing (PUSH tool) Version 3.0 was used to assess the healing of ulcer. The PUSH model provides an accurate, simple, and clinically useful way to measure progress toward wound healing. Assessment of the ulcer characteristics include surface area, exudate amount (none, light, moderate, and heavy), and surface appearance (necrotic tissue, slough, granulation tissue, epithelial tissue, and closed). Each parameter is scored, and the sum of the three yields a total wound status score.

RESULTS

The pressure ulcer wound was monitored every week with PUSH score. At the end of six weeks of application of microcurrent electrical stimulation, the following results were obtained: (i) reduction in the wound surface area from the initial size of 46 cm^2 to 2.5 cm^2, ii) the exudates from the wound were completely absent, iii) Wound was completely covered with epithelial tissue from the initial stages of slough tissue. The findings resulted in a change of total PUSH score from 15 at day 1 to a score of 6 at the end of eight weeks.[1]

DISCUSSION

In this case report, we have reported the effects of microcurrent electrical stimulation on healing of pressure ulcer in an individual with severe mobility impairments. Previous studies have documented that adequate mobility is one of the efficient strategy in the process of healing of pressure ulcer.(5)To accelerate wound healing process in an individual with impaired mobility, the intervention strategies such as utilisation of pressure relieving support surfaces, adequate nutrition, wound care and regular positioning care is alone inadequate. In scenarios where endogenous healing has failed or healing has become obsolete, adjunct use of microcurrent therapy which is the transcutaneous delivery of miniature pulsating current that mimics the currents generated in the body at the cellular level, also known to stimulate cellular physiology and growth may be favorable (7)[2.]

Along with the use of conventional saline dressing and regular positioning, microcurrent therapy have resulted in reduction in wound surface area, improvement in tissue healing and growth in the wound site, demonstrated by a gradual decrease in the PUSH score through the weeks. At the end of eight weeks of microcurrent application, the total PUSH score had shown a change of 9 points from the time of initial assessment, a magnitude of change of 60%. The wound surface area has been reduced by 94%, with a change from initial size of 46cm^2 to 2.6 cm^2 at the end of eight weeks. Microcurrent application have been identified to physiologically help in re-establishment of tissue bio-electricity by imitating endogenous electrical signals that can guide cellular behavior and the proposed mechanisms of galvanotaxis which is attraction of positively/negatively charged cells towards the opposite pole of an electric field, thereby increasing transportation, cell migration, proliferation and synthesis of new tissue which are essential in the healing process (8,9).

Experimental studies involving the use of microcurrent electrical stimulation in larger specific population targeting wound healing are suggested. Therefore, the microcurrent electrical stimulation is considered an alternative for wound treatment specifically with in those with failed natural healing, reparation difficulties, devitalized tissue like pressure, diabetic, stasis and arterial ulcers.

Conclusion

These results indicate that microcurrent therapy has a positive effect in healing of pressure ulcers and it is preferable because of its easy application, acceleration in the healing and low cost.

Conflict of Interest: Ethical approval has been obtained for the case report from the Institute of Human ethics committee, PSG Institute of Medical Sciences and Research.

Physiatrist's Management of Diabetic Foot Ulcer

V. Ramamoorthy

Professor and Head, Department of Physical Medicine and Rehabilitation, PSG IMS&R Hospitals, Coimbatore, Tamilnadu.

ABSTRACT

Diabetes is a metabolic disease that affects multiple systems. Even within the nervous system the manifestations of this disease can be wide and varied. Foot disorders are a main source of morbidity and a leading cause of hospitalization for person with diabetes mellitus. Ulceration, infection, gangrene and amputation are significant complications of diabetes. Although not all foot complications can be prevented, dramatic reductions in their frequency have been obtained through the implementation of multidisciplinary team approach to patient management. The objectives of diagnosis and treatment of diabetic foot sequelae center around maintaining the patient as an ambulatory, productive member of society or returning the patient to that state as quickly and safely as possible. This may at any time require the expertise of a number of different specialists on the diabetic foot care team and a Physiatrist is one among them. The physiatrist by virtue of his or her training is uniquely suited to serve as a primary member of a multidisciplinary team for the management of diabetic foot disorders and able to recognize impending diabetic foot complications. Total Contact Cast is considered the Gold standard to assist healing for active diabetic ulcerations by providing weight (pressure) redistribution and friction/shear control. Multiple randomized controlled clinical studies have been conducted which illustrate that the majority of diabetic foot ulcers heal with the use of TCC in a mean time of 35-52 days for 85-95% of patients.

Keywords: Diabetes mellitus, Diabetic Ulcer, Total contact cast

INTRODUCTION

Patients with diabetes are prone to multiple complications such as diabetic foot ulcer. Diabetic foot ulcer is a common complication of diabetes that has shown an increasing trend over previous decades. In total, it is estimated that 15% of patients with diabetes will suffer from diabetic foot ulcer during their lifetime. [1] Although accurate figures are difficult to obtain for the prevalence of diabetic foot ulcer, the prevalence of this complication ranges from 4%-27%. [2-4]

To date, diabetic foot ulcer is considered as a major source of morbidity and a leading cause of hospitalization in patients with diabetes. It is estimated that approximately 20% of hospital admissions among patients with diabetes are the result of diabetic foot ulcer. [5] Indeed, diabetic foot ulcer can lead to infection, gangrene, amputation, and even death if necessary care is not provided. [6] On the other hand, once diabetic foot ulcer has developed, there is an increased risk of ulcer progression that may ultimately lead to amputation. Overall, the rate of lower limb amputation in patients with DM is 15 times higher than patients without diabetes. It is estimated that approximately 50% - 70% of all lower limb amputations are due to diabetic foot ulcer. [1] In addition, it is reported that every 30 second one leg is amputated due to diabetic foot ulcer in worldwide. [2]

Foot ulceration is the most common single precursor to lower extremity amputations among persons with diabetes. As a result of neuropathy, the foot can become deformed. This happens through two routes of reasons. The first is that the neuropathy causes paralysis of small muscles of foot, which result in clawing of the toes. Clawing of the toes causes prominence of the metatarsal heads in the

bottom of the foot as well as the knuckles on the dorsum of top of the foot. The neuropathy also causes diminished sensation. As the prominent metatarsal heads on the plantar aspect of the foot are subjected to increased pressure because of diminished sensation, the skin will begin to hypertrophy and become callused. The callused skin can be subjected to shear forces. The forces will cause a separation between the layers of the skin, which will fill with fluid, which can then become contaminated and infected. The pressure can also cause primary breakdown of the skin in these areas and the result is a foot ulcer. Once the initial breakdown and contamination occurs, the foot then can go on to significant problems of infection. Thus increased biomechanical stress is one of the most important pathways leading to ulceration in patients with neuropathic and neuroischemic foot ulcers.

Traditionally, diabetic foot ulcers are treated with regular dressings with frequent debridement with minimal weight bearing on the affected foot. The key element of any treatment program designed to heal these wounds is effective reduction in pressure (offloading). Offloading of the wound is one of the key elements in treating diabetic foot ulcers. Several offloading devices are available, such as walkers, half shoes, orthoses, felted foam and the total contact casting (TCC). Though offloading can be achieved by several orthotics, most of these are removable and strict compliance is not achieved thus reducing their effectiveness.

TOTAL CONTACT CASTING:

TCC is a casting technique that is used to heal diabetic foot ulcers. The cast is used to heal diabetic foot ulcers by distributing weight along the entire plantar aspect of the foot. It is applied in such a way as to intimately contact the exact contour of the foot. Hence the designation "Total Contact Cast". By relieving the bony prominent areas of pressure, the ulcers are permitted to heal if the cast is applied in such a way that the patient can remain ambulatory during the treatment of the ulcer.

Pressure is expressed in terms of force or pounds over the area per square inch. Therefore, if the weight-bearing area is enlarged the pressure per unit of weight bearing area diminished. In this way the pressure area is enlarged and the pressure per unit of the weight bearing area is diminished. So the pressure which has been concentrated on the bony prominences is distributed over the entire plantar aspect of the foot, allowing reversal of the mechanism that caused the ulcer to occur. Total Contact Cast minimizes ground reactive pressure and shear (friction), eliminates the propulsive phase of gait, shortens stride length, allows for healing while ambulating and forces patient compliance.

Total contact cast has the advantage that it cannot be easily removed by the patient and limits activity which promotes rapid healing of ulcers. When correctly applied, it has proven not only to interrupt the chain of events in the pathogenic pathway that produces ulceration but it also changes the histology of the ulcer shifting it from a chronic inflammatory state to a more evoluting condition. [7] Healing of ulcers using TCC takes approximately 6-8 weeks, during which the cast is replaced on a weekly basis. The cast is removed when complete healing is achieved, after which is recommended that the diabetic patient wear specially designed shoes that will relieve pressure over the ulcer healed area.

CAST APPLICATION:

Application of the cast should be as quick and smooth as possible to avoid lamination and thus weakening of the cast. The patient is kept in prone position. Placing the patient prone is the easiest way to apply the cast. Also the patient is more comfortable as he/she will not get cramps in the thigh or hip. The prone position allows the assistant to hold the appropriate position of the foot to the leg, usually ninety degrees to the leg. This position also allows the gastro-soleus complex to shift proximally

on the leg thereby removing their bulk allowing for the cast to fit more snugly. The cast should end at the widest point of the calf and should not end the cast at the knee level as this could impinge the common peroneal nerve.

Table 1: Materials required for Total Contact Casting (TCC)

Materials required	
3" or 4" stockinette 1- 1 " tape Adhesive felt- 4" wide x 20-30" long 3" or 4" webril 1-3" roll plaster casting tape 2-4" rolls plaster casting tape 1-2" roll synthetic casting tape 1-3" roll synthetic casting tape 2-4" rolls synthetic casting tape	1 walking heel Silicone (clear-site) protectors Foam toe protectors Precut plywood foot plate

PROCEDURE:

Total contact casting is a precise procedure that requires skillful application. The ulcer is debrided in standard fashion and if a dressing has to be applied, it is held in position with one inch paper tape. Circumferential dressings are not recommended. The patient is placed in the prone position. Bony prominences, the posterior heel and achilles tendon are padded. One fourth inch adhesive felt is applied to the leg and foot starting anteriorly on the tibial tuberosity crossing the ankle, ending on the dorsum of the foot. Stockinet is placed from the toes to just below the knee. One to two inches are left past the toes, folded dorsally and held in position with one-inch tape. Folds are created at the ankle and the excess material is cut away and the ends of the stockinet are taped with one inch tape. One fourth inch foam is placed over the toes and past the metatarsophalangeal joints dorsally and plantarly to protect the toes and limit MPJ tendonous motion. The assistant stands lateral to the extremity and holds the foot 90 degrees to the leg while the knee is flexed 90 degrees. One thin roll of webril is snugly placed over the foot and leg with minimal overlap. One or two rolls of plaster rolls are placed from the distal aspect of the toes ending just below the fibular head. The toes should be fully covered with the plaster so that they do not move once the cast dries. A 5" x 30" splint double folded at the distal 1/3 is now applied plantarly from the toes ending posteriorly on the leg. The precut plywood is placed on the plantar aspect of the foot. It should at least meet the entire plantar aspect of the foot. Multiple precut 3" to 4" pieces of plaster material are used to fill voids in areas where the foot does not meet the wood so that absolutely no rocking of the wood on the foot is noted. Four-inch synthetic rolls are used to cover the foot and leg. The walking heel is centered in the middle of the foot in a line just distal to the long axis of the tibia. The foot and leg are held in this position for a minimum of 5 minutes to allow the cast to dry. The patient may now be placed in the supine position and sits for another 20 minutes while the cast dries. It is preferred to maintain non weight bearing for 24 hours until the cast sets up well. The cast is changed as often as necessary but at least weekly to check for healing and other ulcer formation. [8]

INDICATIONS FOR TCC:

The patient must be non-infected, have an adequate blood supply to heal (ABI >0.7) and the ulcer must be Wagner Grade I or II.

CONTRA INDICATIONS FOR TCC:

Acute infection, severe ischemia, claustrophobia, Wagner Grade III or IV ulcers and wounds that are probe to bone, tendon or capsule.

DISADVANTAGES:

Although a TCC seems a highly attractive offloading modality, several disadvantages have been reported: new ulcers may occur, daily wound care is not possible, mobility is impaired, costs may be relatively high, and specialized staff seems necessary. [9] The TCC technique is not very effective in reducing elevated plantar pressures at the heel region. In some cases the ulcer may not heal during cast treatment (cast failure). In case of prolonged casting, joint rigidity and muscular atrophy have been documented. [10]

CONCLUSION

Diabetic foot ulcer healing may be delayed if the ulcer is subjected to constant pressure while walking. Total contact casting provides optimal wound healing conditions by ensuring that the ulcer is not further traumatized and also prevents the development of new ulcers in the bony prominences of the foot. Hence TCC is an excellent procedure for healing diabetic foot ulcers. The Physiatrist plays an integral role in the management of new or impending diabetic foot lesions.

Effectiveness of Intense Sensory Motor Stimulation on Improving Functional Recovery in Post Stroke Individuals

V. Ramamoorthy

Professor and Head, Department of Physical Medicine and Rehabilitation, PSG IMS&R Hospitals, Coimbatore, Tamilnadu.

ABSTRACT

Introduction: Rehabilitation measures help to restore lost activities, improve quality of life and decrease the long term economic cost of stroke. Realistic goal setting, interdisciplinary team approach and the active participation of both patient and family members are important for the success of stroke rehabilitation. The primary objective of this study is to investigate the effects of intense sensory motor stimulation, given in the form of electrical stimulation, massage and re-education exercise programme, in augmenting recovery in stroke patients.
Methods: A prospective single group pre and post test study design was conducted with a total of 29 hemiparetic patients who provided informed consent. All the participants received the therapeutic measures of electrical stimulation, massage and re-education exercises including gait training and ADL retraining until discharge. The Neurological and Functional recovery were measured using Scandinavian Stroke Scale score (SSS) and Functional Independence Measure score (FIM) respectively.
Results: An Analysis of variance 'F' Value of 37.31 and 43.94 which are significant at 0.01 level shows that there is a significant difference between scores at admission, discharge and follow up in SSS and FIM scores respectively. The Pearson correlation coefficient 'r' value of 0.62, 0.81 and 0.97 at three time periods suggests that a moderate to strong negative correlation exists between SSS and FIM scores which are significant at 0.01 levels.
Conclusion: A significant level of neurological and functional recovery was obtained in the study group during the time of discharge and in the follow up period indicative of effectiveness of intense sensory motor stimulation in augmenting motor recovery in stroke patients.

Keywords: Sensory Motor Stimulation, Functional Recovery, Stroke Patients

INTRODUCTION

Stroke is the most disabling chronic condition. The prevalence rate for hemiplegia in South India was reported to be 56.9 per 10000. [1,2] WHO defined stroke as "rapidly developed clinical signs of focal or global disturbance of cerebral function; lasting more than 24 hours; leading to death with no apparent cause other than vascular origin". [3] The 24 hours threshold in the definition excludes transient ischemic attacks (TIA). Modern advances in stroke research aid better management of stroke patients. In the past, recovery from motor deficit after a stroke was a puzzling scientific question. Now it has been found out that, neuronal organization, dynamic changes in the somatotopia of primary motor cortex, recruitment of remote motor cortices, and participation of associative cortices are clearly part of rearrangement process. [4] It is likely that such mechanisms represent the basis of clinical recovery of stroke patients.

Rehabilitation measures help to restore lost activities, improve quality of life and decrease the long term economic cost of stroke. [5] Realistic goal setting,

interdisciplinary team approach and active participation of both patient and family members are important for the success of stroke rehabilitation. [6] It is desirable to start rehabilitation programmes to stroke patients once they are medically stable. [7] Various programmes of treatment, for patients with motor control problems, were developed in the past based on neurophysiological and developmental research of the time as well as careful observation of the responses made by patients when being handled.

Review of literature shows that there will be natural, spontaneous neurological recovery after stroke. The mechanism to explain recovery is neuroplasticity. Brain plasticity is the ability of the nervous system to modify its structural and functional organization. The two most plausible forms of plasticity are collateral sprouting of new synaptic connections and unmasking of previously latent functional pathways. [8] Experimental evidence indicates that plasticity can be altered by several external conditions, including pharmacological agents, electrical stimulation and environmental stimulation. [9]

A comprehensive critical review of medical literature reveals that rehabilitation interventions have variable relationships with functional outcome after stroke. 1) Increased functional skills on admission to rehabilitation, early initiation of rehabilitation services, and rehabilitation in an interdisciplinary setting after stroke appear to have strong relationship with improved functional outcome at hospital discharge and follow-up. 2) The use of specialized type of therapy services and greater intensity of therapy services appear to have a weak relationship with improved functional outcome at hospital discharge and follow-up. 3) The current literature is too limited to allow an assessment of the relationship of specific types of non-inpatient rehabilitation services after stroke and functional outcome. [10-12]

Current stroke rehabilitation practice throughout the world is based on a number of approaches that were developed independently by several pioneers in the 1950's. Prior to the 1950's the physical treatment of the patients following stroke focused on encouraging the patients to use the unaffected side of the body to compensate for the disabilities of the affected side. The affected limbs were not a prime focus for treatment.

During the 1950's a number of new physiotherapy approaches emerged. These were developed by practitioners who were dissatisfied with the results of practice at the time and were interested in treating the paresis resulting from stroke. The work of many of these pioneers e.g. Bobath [1969], Brunnstrom[1961, 1970], Knott & Voss [1968] and Rood [1969] remains influential today. They developed their programmes primarily from observation and experience. Some of the approaches were associated with neuro physiological concepts current at that time; but others were developed observation alone and then a suitable theory was adapted to explain the effects.

Thus, several different physiotherapy approaches are used in the management of the patients who have suffered a stroke but these approaches are mutually exclusive and a rarely delivered in the uniform purist manner. The theoretical basis of the individual approaches remains unsubstantiated. All of the approaches aim to improve motor control and all of them demand that the therapist has a specialized training in the individual concept.

Many different electrical stimulation applications have been explored since the pioneering work of Liberson et al on foot drop. [13] So in this study electrical stimulation is used to augment motor recovery in patients being rehabilitated after acute stroke, in addition to olive oil massage, and re-education exercise programme.

The primary objective of the study is to investigate the effects of intense sensory motor stimulation, given in the form of electrical stimulation, massage and re-education exercise programme, in

augmenting recovery in stroke patients. The secondary objective of the study is to investigate the relationship between neurological and functional recovery in stroke patients.

METHODS

DESIGN

A prospective single group pre and post test study design. A total of 29 hemiparetic patients admitted to Government Institute of Rehabilitation Medicine, Chennai Medical college, Chennai were recruited. The participants received the intervention until they were discharged.

PARTICIPANTS

All stroke patients who were admitted to the Government Institute of Rehabilitation Medicine, Chennai Medical College, Chennai were screened and recruited on providing consent. No specific selection criteria with reference to age, side, and severity of paralysis, aphasia, neglect, incontinence and cognitive function were applied. But stroke cases of longer duration were not included in this study. On admission to the rehabilitation facility, age, and gender were documented for each patient as were the type and side of the cerebral lesion. The duration between stroke onset and rehabilitation were also recorded.

INTERVENTION

A) ELECTRICAL STIMULATION

The muscles stimulated in the upper limb are deltoid, supraspinatus, biceps, triceps, common flexors of forearm, common extensors of forearm, intrinsic muscle of hand. The muscles stimulated in the lower limb are Gluteus maximus, Quadriceps and Tibialis anterior. Each muscle is stimulated for 10 minutes. The active electrode is kept over the motor point of the muscle to be stimulated. The reference electrode is kept over the nearby bony point. An Electrical Stimulator which provides faradic current with a pulse width of 300 ms, intensity of 100 v and a frequency of 50Hz was used. The muscle contraction/relaxation time ratio is set at 5/10 sec. The patients received electrical stimulation daily for a duration of 1 ½ - 2 hours. [14-18]

B) MASSAGE AND RANGE OF MOTION EXERCISES

After electrical stimulation, olive oil massage was done to the affected upper and lower limbs. Effleurage or stroking massage involves lightly running the hand over the skin. This was performed with either superficial or deep pressure and provides different effects depending on the depth of treatment. Deep stroking involves mechanical effects and should be performed with continuous contact of the hands from distal to proximal on the extremities, the back, or the neck. Once the proximal extent is reached the hands can be drawn back to the distal position applying light contact or no contact at al. [19]

Then PROM exercises were done to the affected upper and lower extremities to prevent the occurrence of joint contracture. Once the patient developed volitional movement, strengthening programme was instituted with optimal movement pattern. ADL training to the upper limbs and gait training to the lower limbs were also administered.

OUTCOME MEASURES

After thorough neurological examination, CT brain was done to confirm the diagnosis. Then the neurological status was assessed using Scandinavian Stroke Scale score [20] and functional status was evaluated using Functional Independence Measure score. [21] Then the treatment programme was started. Outcomes were assessed in every two weeks. The patients were followed up to 6 months.

STATISTICAL ANALYSIS

To analyze the data, two types of statistical techniques are used. They are descriptive statistics and inferential statistics. The averages of baseline characteristics were calculated using mean and standard deviation. One way ANOVA was used to analyse the differences in neurological recovery and functional recovery at three different time periods

(admission, discharge and follow up). Paired‘t’ test was used to identify the difference in the scores between admission, discharge and follow up. The relationship between functional recovery and neurological recovery at the time of admission, discharge and follow up were assessed using Pearson correlation coefficient ‘r’.

RESULTS

The descriptive statistics of the mean scores of Scandinavian Stroke Scale (SSS) and Functional Independence Measure (FIM) is represented in Table 1. In both measures, the scores on admission is found to be less when compared to those at discharge and follow up. The standard deviation also seems to be within the normal limits. It does not skew very much. So this distribution can be considered as normal distribution.

Table 1 The mean and standard deviation of Scandinavian Stroke Scale (SSS) scores and Functional Independence Measure (FIM) scores of stroke patients at different stages

S.no	Stages	No. of cases	SSS Mean ± SD	FIM Mean ± SD
1	On admission	29	32.82 ±9.16	75.79 ± 19.22
2	On discharge	29	47.9 ± 7.068	105.17 ± 12.75
3	On follow up	29	53.13 ± 6.85	115.37 ± 12.00

An Analysis of variance results to identify the difference in the SSS scores at admission, discharge and follow up, shows that the F value 37.31 found to be significant at 0.01 level indicates, that stroke level of different stages are significantly different from one another. The mean scores of SSS increased from 32.82 ±9.16 on admission to a score of 47.9 ± 7.06 at discharge and increased further on follow up to a score of 53.13 ± 6.85. Similarly ANOVA results of FIM scores shows that the F value of 43.94 which is significant at 0.01 level reveals that, there is significant difference in the functional independence levels among the three levels. The mean score ascends from 75.79 ± 19.22 at the time of admission to 105.17 ± 12.75 at the time of discharge and to a score of 115.37 ± 12.00 at follow-up. Both the scores show an improvement in the order of follow-up > discharge > admission.

Table 2 ANOVA results of Scandinavian Stroke Scale scores in different time periods of stroke patients is shown below

S. No	Source of variations	Sum of squares	DF	Mean square	F	Level of significance “p”
1.	Between groups	6269.63	2	3134.81		
2.	Within groups	5366.27	84	63.88	37.31	>0.01

Table 3 ANOVA results of Functional Independence Measure scores of stroke patients at different levels

S. No	Source of variations	Sum of squares	DF	Mean square	F	Level of significance “p”
1.	Between groups	24499.13	2	12249.56		
2.	Within groups	23415.73	84	278.75	43.94	>0.01

To identify whether there is any statistically important difference exists between the time of admission and discharge, discharge and follow up, student‘t’ test was used. Between admission and discharge, the SSS scores had ‘t’ value 6.79 which reveals that the difference is significant. Similarly the FIM scores had ‘t’ value 6.87 which is significant at 0.01 level indicates that the patients have significantly improved at discharge.

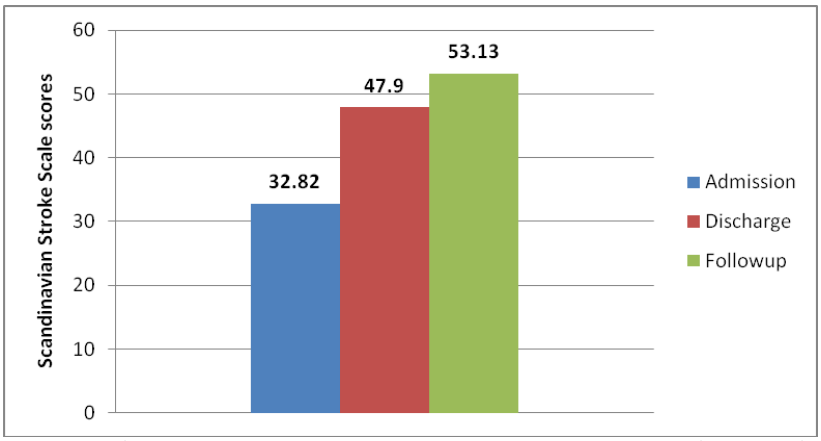

Table 4 The mean, standard deviation and ‘t’ value of Scandinavian Stroke Scale scores and Functional Independence Measure scores on admission and discharge

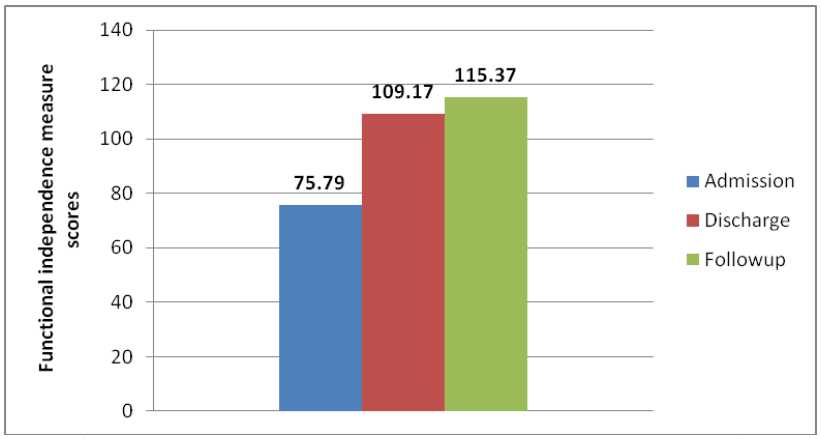
S. No	Outcome	On admission Mean ± SD	On discharge Mean ± SD	‘t’ value	‘p’ value
1.	SSS	32.82 ± 9.16	47.90 ± 7.68	6.79	>0.01
2.	FIM	75.79 ± 19.22	109.17± 12.75	6.87	>0.01



On comparison of scores between discharge and admission, both SSS and FIM scores were found to show a statistically significant difference among them with 't' values of 9.58 and 9.42 respectively. Hence the scores of SSS and FIM differed significantly between three time periods of evaluation.

Table 5 The mean, standard deviation and 't' value of Scandinavian Stroke Scale scores and Functional Independence Measure scores on admission and follow up

S. No	Outcome	On admission Mean ± SD	On follow up Mean ± SD	't' value	'p' value
1.	SSS	32.82 ± 9.16	53.13 ± 6.85	9.58	>0.01
2.	FIM	75.79 ± 19.22	115.37± 12.00	9.42	>0.01

Graph 1: Representation of Scandinavian stroke scale scores on admission, discharge and follow up of stroke patients

Graph 2: Representation of Functional Independence Measure scores on admission, discharge and follow up of stroke patients

Since the stroke level has got direct effects on the motor functions, the Pearson Correlation Coefficient was used to identify the relationship between the magnitude of the stroke and the level of functional independency at the time of admission, at the time of discharge and at the time of follow up.

Table 7 Correlation coefficient 'r' between Scandinavian Stroke Scale score and Functional Independence Measure score on admission, discharge and follow up

	On Admission	On Discharge	On Follow up
Correlation coefficient 'r' between SSS and FIM scores	0.62	0.81	0.97
Level of Significance	p>0.01	p>0.01	p>0.01

Based on the strength of correlation coefficient, the 'r' value of 0.62 between the scores at the time of admission and 'r' value of 0.81 at the time of discharge and 'r' value of 0.97 at the time of follow-up which are significant at 0.01 level indicate that a moderate to strong negative correlation exists between SSS and FIM scores. The above correlation

coefficient value suggests that, when the severity of stroke level increases, the functional independence level significantly decreases. Whereas, when there is improvement of the stroke status, the functional independence level will also increase significantly.
Since the total number of cases in certain conditions is found to be less, the non parametric tests were used to analyze the data. The percentage was calculated for each condition and the same was discussed.

Table 8 Shows the rate neurological recovery [SSS score] and functional recovery [FIM score] in cases of stroke at different levels of brain

S. No	Topography	On admission		On discharge		On follow up	
		SSS	FIM	SSS	FIM	SSS	FIM
1	Cortical level	57%	60%	85%	85%	93%	93%
2	Internal capsular level	53%	40%	85%	78%	85%	86%
3	Brainstem level	63%	72%	82%	92%	100%	99%

From the above table it is learnt that the neurological and functional recovery on discharge and follow-up are fair if the stroke is at the level of the internal capsule. The neurological and functional recovery on discharge and follow up are better if the stroke is at the levels of cortex or brainstem.

DISCUSSION

The above results indicate that the condition of stroke has significantly improved at the time of discharge and follow up when compared to the condition at the time of admission. It is possible to say that the different forms of "intense sensory motor stimulation" would have contributed much for the recovery of the stroke patients. Similarly even after the discharge, the improved condition was maintained significantly. This has proven the efficiency of the intense sensory motor stimulation in stroke rehabilitation. In the follow up it was found that most patients were able to maintain their functions and to make further improvements. Also their psychological well-being was also quite good.

The benefits of this recovery were maintained for a longtime, perhaps because all patients continued to do exercise. Some patients continued with their assigned exercise programme at the hospital and others continued exercise programme at home.

The above findings prove that the functional independence of stroke patients have improved very much at the time of discharge and follow up. The possible reason could be due to the attack of stroke, the movements of the extremities were lost. That could be the possible reason for their low level of functional independency. Since the stroke level is highly related with the motor function, it would have retarded the physical function. [22] Once the severity of the stroke level is decreased, the functional independency will also improve significantly. Another possibility could be the beneficial effects of exercise therapy for the upper limbs and motor training for the lower limbs, which could have improved the functional independency of the stroke patients during discharge and follow up. These results are in accordance with the intensive task specific training to improve lower limb function and gait in acute stroke individuals. [23, 24]

The management of stroke, so long a "Cinderella condition", is changing rapidly as new developments appear for acute treatment, rehabilitation and secondary prevention. Stroke is no longer an untreatable or unpredictable condition and it is vital that hospitals design appropriate systems to manage patients in an interdisciplinary environment. [25]

Though this study size was relatively small, a large treatment effect was demonstrated. In our study, the maximum improvement in the motor recovery was observed at 3 months. These results improved again slightly and remained constant up to the follow up period. Significant improvement in motor recovery in the stroke patients indicates that "intense

sensory motor stimulation" is an effective method of stroke rehabilitation to augment motor recovery. Electrical stimulation is a relatively low cost intervention. Concerns that subjects would find the treatment uncomfortable or inconvenient were unfounded. All subjects reported that the sensation of the muscle contraction following electrical stimulation and the resultant movement of the limb were encouraging. No stimulation induced complications requiring medical attention such as burns, falls or fractures occurred for any patient. A few subjects showed minor skin irritation transiently. Thus intense sensory motor stimulation programme could achieve a better functional outcome in stroke patients and could shorten the hospital stay for rehabilitation.

CONCLUSION

The following conclusions are drawn from the above study:

1. There was a significant level of neurological and functional recovery in the study group during the time of discharge and in the follow up period, when compared to their neurological and functional status at the time of admission. This shows the effectiveness of intense sensory motor stimulation in augmenting motor recovery in stroke patients.
2. The improvements in the neurological and functional status observed at the time of discharge were maintained during the follow-up period. Stroke cases with severe neurological damage and severe functional impairment as evidenced by low scores in the Scandinavian Stroke Scale score and FIM score on admission, required longer duration of treatment.
3. In the hemorrhagic stroke cases, the neurological and functional recovery at the time of discharge and follow up are less, when compared to thrombotic and embolic stroke cases. The neurological and functional recovery on discharge and follow up are better if the lesion is at the level of the cortical than at the capsular level.

Summary

Electrocardiogram (ECG) signal transmission and monitoring plays a paramount role in long-term cardiac monitoring and analysis to provide remote health care in time, especially for the postoperative people and people in remote areas. The accuracy of ECG signals is of fundamental importance in cardiac diagnosis like R-peak detection. So we need to incorporate analytical methods in existing healthcare systems, to capture more meaningful ECG components and to represent physical cardiac sources more clearly. With this aim, hardware optimized FCAICA (fast confluence adaptive independent component analysis) algorithm is proposed to extract pure ECG components from the ECG mixtures. The extracted signals are then subjected to R-peak detection for further analysis. The proposed improved fast confluence adaptive independent component analysis (IFCAICA) method occupies less hardware resources, consumes low power, improves accuracy, and sensitivity in R-peaks detection. In 0.18 nm technology, the IFCAICA consumes 10.13 mW of power and operates with 3.4 MHz operating frequency.

1 | INTRODUCTION

Electrocardiogram (ECG) is a conventional means of a biomedical signal for the finding heart abnormality. It is well known that ECG signals acquired noninvasively are widely used in clinical area for patient health monitoring including pacemaker follow-up and long-term monitoring.[1] In this industrialized world, millions of people die annually due to various coronary heart diseases and lack of timely detection of abnormal heart rhythms. To detect the heart abnormalities in time, the ECG measures should provide the cardiac signals without any mixtures or other disturbances. Real-time ECG monitoring system is a medical telemetry instrument used by medical personnel to monitor patients' ECG signal while allowing the patients to remain fully mobile and comfortable. It uses wearable ECG sensors to measure electrical signals generated from the patients' heart in hospitals. Figure 1 shows the architecture of Cloud-based remote cardiac monitoring system with the proposed IFCAICA (improved fast confluence adaptive independent component analysis) technique for future implementation in hospitals.

ECG signals are collected using wearable ECG electrodes from postoperative patients or remote patients and their data are sent to a preprocessing unit. This subsystem performs an important task of removing high-frequency noise. This filtered signal is then fed to the proposed independent component analyzer which extracts the original ECG components from its mixtures. The extracted signals are then sent to the Cloud after processing and the cardiac activity of the patient

 © 2020 John Wiley & Sons, Ltd.

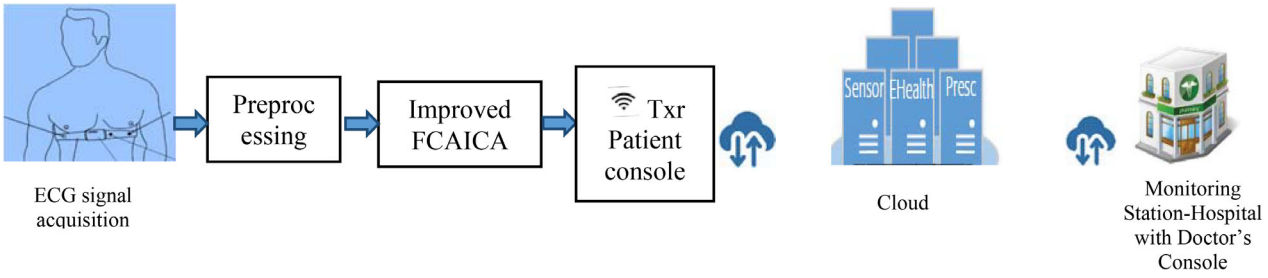

FIGURE 1 Cloud-based architecture for remote cardiac monitoring system [Colour figure can be viewed at wileyonlinelibrary.com]

can be monitored from the Cloud. So the entire system encompasses the subsystems for ECG acquisition, ECG extraction/enhancement using ICA, processing of ECG, and sending it to Cloud for transmission and storage. This entire system will developed in tie-up with PSG hospitals. In this article, an optimal IFCAICA technique is proposed for ECG extraction and R-peaks are estimated using QRS detection algorithm. Independent component analysis (ICA) is a blind source separation (BSS) technique, used to find the original sources from the mixtures when there is no knowledge about the sources.[2] It extracts the essential structure of the data from the acquired signal.[3,4] Here N electrodes are considered with sources represented by $S_1, S_2 \ \ldots \ S_N$. When ECG data are recorded from these electrodes, recorded signals are not pure source signals but they are mixture of each other. These generated signals are represented by $X = (x_1, x_2 \ \ldots \ x_n)$ which are linear combination of statistically independent sources. With an unknown nonsingular mixing matrix A of size $N \times N$, the observed mixture is mathematically represented as $X = \mathrm{AS}$ and is given by (1)

$$\begin{pmatrix} x_1(t) \\ x_2(t) \\ . \\ . \\ . \\ x_N(t) \end{pmatrix} = \mathrm{A} \begin{pmatrix} s_1(t) \\ s2(t) \\ . \\ . \\ . \\ s_N(t) \end{pmatrix} + n \tag{1}$$

Neglecting the noise n, the sources are estimated by multiplying the mixtures X with a demixing matrix B. This demixing data model B is estimated using ICA algorithms by formulating an objective function or contrast function and then minimizing or maximizing it. In order to realize the real-time, long-term ECG monitoring, and to optimize device size and power, the proposed algorithm has been implemented in very large scale integration (VLSI) technology and accuracy is improved using floating-point arithmetic operations. Recent works done on ECG signal using ICA techniques are described in Chapter II. Chapter III explains the improved FCAICA (fast confluence adaptive independent component analysis) with its internal hardware architecture. ECG waveforms, extracted results using the proposed method, R-peak detection and comparison results are provided in the chapter IV. Chapter V concludes the article explaining the applications and future work.

Main objectives of this article are:

- To develop improved FCAICA unit to extract the sources from the ECG mixtures.
- To perform R-peak detection on extracted ECG.
- To provide accurate ECG signal to the physicians for continuous remote monitoring with lesser hardware resources and power.

2 | RELATED WORK

According to the report from World Health Organization (WHO), the overall death rate due to cardiovascular diseases (CVD) is significant. Increase in death rates due to CVD is attributed to the collective amount of patients with obesity, smoking habit, diabetes mellitus, and other lifestyle changes. Some of the CVD among many others is atrial and ventricular arrhythmias, that happen due to cardiac rhythm disturbances. Ventricular fibrillation and flutter arrhythmias

are life threatening and they result in hemodynamic collapse, cardiac arrest, and sudden cardiac death.[5] Many methods that are used to filter out the noise and artifacts from ECG were only partially successful. The filters often lead to a reduction in the amplitudes of the component waves and the QRS complex. As some noise and artifacts are random in nature and have a wide range of frequency content, the filters fail to remove the interference when they are within the same frequency range as the cardiac signal. Principal component analysis (PCA) and ICA methods occupy a specific place in higher order statistical methods for superior feature extraction and ECG interpretation. It has been already proved that ICA is a valuable tool for enhancing EEG/ECG signals, suppressing artifacts, and irrelevant noises produced by eye blinks and muscle activity. Artifact and noise removal is the first step in ECG signal processing. ICA was used for removing breathing artifact from ECG and promising results were provided which led authors to apply ICA technique for more noise separation.[6] ICA-based architecture for BSS separation of linearly mixed signals was developed by using well established MIT-BIH database.[7] Some motion artifacts are ectopic and hence they cannot be detected easily by conventional methods. PCA-ICA–based algorithm was developed for motion artifact removal.[8] Carrying the idea forward, the author, Sarfraz used ICA methods for motion artifact removal along with ECG feature extraction with two-lead design.[9] In 2010, Romero extended the use of PCA and ICA for noise reduction and motion artifacts removal in ambulatory conditions where noise level rises and signal quality greatly reduces relative to activity. BSS for post-nonlinear mixtures and general nonlinear mixtures was discussed by Reference 10. It is then found that, when the mixtures as well as separation structure are structurally constrained, nonlinear BSS problem can be solved appropriately. The prior information on sources helps in simplification of the algorithms or reduction in indeterminacies in the solutions.

Authors in Reference 11 described the process of BSS technique for ICA. This article mainly aimed at separation of the source components from complex mixtures of signals based on statistical assumptions. Authors in Reference 12 extended a conventional constrained ICA framework for communication and signal processing. In Reference 13, the ICA with cyclo-stationary constraints (ICA-CC) and ICA with spatial constraints (ICA-SC) were described. Authors in Reference 14 designed an expectation maximization algorithm for noisy ICA. The authors of this article have proved that the proposed model was able to perform the BSS with the noisy ICA model. They also recommended ICA method for harmonic separation in which, the least square method was used to determine the amplitudes and phases of harmonic components. The authors suggested that the ICA was one of the most widely used techniques for BSS problems and demonstrated fast ICA algorithm to solve the BSS problems.

The authors in Reference 15 presented a comparative study of a fixed-point algorithm on a fixed-point platform with respect to another floating-point processor. ICA algorithm has been tested on a 32-bit fixed point and a 32-bit floating-point digital signal processors (DSPs). DSP processors have been increasingly important in the biomedical signal processing and research. Most of the research publications in this area are focused on offline processing of the biomedical signals. These algorithms cannot be applied to real-time essential features extraction and artifact removal processes.[16] They also impose constraints on area, power, speed, and cost of the processors. VLSI technological advancement has created a significant impact on biomedical signal processing.[17]

Joint approximation diagonalization of Eigen-matrices (JADE) ICA algorithm for determination of order of ICA components was described in Reference 18. This method was successfully applied to the ECG data and it provides potential solution for online ECG processing. This technique alleviates the limitation of ICA that one has to depend on visual review of the ICA components for advanced processing.

The ICA method with PCA variance estimator proposed in Reference 19 cleans the noisy, corrupted ECG signals and finds the true, false, and actual R-peaks. In this method, JADE algorithm was applied to the three-channel ECG data and it is observed that the approach is quite effective in extracting the original components and the method provides improved signal to noise ratio. In Reference 20, authors combined parameterization and multidimensional ICA approach and showed higher accuracy and automation. ECG analysis may be done with morphological basis or statistical model or neural model. Among these methods, ICA neural model has been successful in ECG analysis that separates ECG data recorded with multiple electrodes into independent components. Though the JADE algorithm performs better compared to Infomax algorithm, TDSEP (temporal de-correlation source separation) algorithm and MRMI-SIG (maximization of Reny's mutual information) algorithms, JADE is very fast for low dimensionality data. TDSEP is rapid but does not always reach the critical SIR (signal to interference ratio) when thermal noise is added, whereas Fast ICA have the best computation time for all data sets and is faster.[21] So FCAICA was developed based on Fast ICA algorithm and has been taken as a reference for the proposed work. The Fast confluence adaptive ICA algorithm has been shown to offer better performance in finding demixing matrix B, compared to other ICA algorithms in term of convergence speed and signal to noise ratio.[22,23] This method optimizes the contrast function by adaptively changing the weight vectors based on the fitness value. It has been successfully applied to separate signals from mixtures of super Gaussian and sub-Gaussian signals. This article proposes improved FCAICA algorithm to produce the best score function with lesser hardware resources for

separating the mixtures before QRS extraction. Among different ECG feature extraction techniques, QRS detection plays a significant role in ECG analysis. QRS detection should consider not only the physiological variability of the QRS complexes of the waves, but also the causes of various types of noise that can be present in the ECG signal. Noise sources include muscle noise, powerline interference and artifacts due to electrode motion, baseline wander, and T waves with high-frequency characteristics related to QRS complexes. This improved FCAICA algorithm is applied to remove such noises from the ECG signal.

3 | ECG SIGNAL SEPARATION USING IMPROVED FCAICA AND R-PEAK DETECTION

This section presents the detailed description of the improved FCAICA algorithm and R-peak detection technique. We consider that, there exist n unknown ECG signals, S_i, $i = 1, 2, \ldots n$ which are mutually independent. It is supposed that the original signal is linearly mixed together with a mixing matrix $A_{n\times n}$ and provides mixture X.

$$X = AS \tag{2}$$

where $S = [S_1, \ldots S_n]$ and $X = [x_1, \ldots x_n]$ are n dimensional source and mixed signals, A represents the interference matrix. The estimates of signals $Y = [y_1, \ldots y_n]$ are found by,

$$Y = X.B \tag{3}$$

where B is the $n \times n$ separating or demixing matrix whose columns are found using the proposed algorithm. In this research work, the acquired ECG signals are applied to a conversion unit which performs the real number to IEEE-754 floating point number conversion. The converted data are then stored in a memory. After that, these signals are passed into a preprocessing block, where the redundant data are eliminated by data centering and whitening techniques. Preprocessing reduces the correlation between the signal and so algorithm estimates the components faster. Then, the iterative improved FCAICA algorithm is implemented to extract the original signal from the ECG mixtures and the R-peak detection algorithm is applied.

3.1 | Signal preprocessing

In signal separation, data centering and whitening are essential preprocessing steps. Centering is a simple operation that refers to subtracting the mean of the mixtures from each observed sample $m = \epsilon\{X\}$ to produce zero mean outputs. After centering the signals, new white vectors are obtained by whitening the signals. Whitening transformation mainly uses Eigen value decomposition of the covariance matrix. The whitening step includes the normalization of the variances to one. It is performed by using covariance, Eigen value, and Eigen vector calculators. The observed signal X is linearly transformed and thus a new whitened signal Z is obtained. The whitening process reduces the correlation between the signals to be estimated. The whitening matrix is found by using,

$$W = [D^{-1/2}E^T]\,X \tag{4}$$

where W represents the whitening matrix, E is the orthogonal matrix of eigenvector found from the covariance matrix, D is the diagonal matrix of Eigen values associated with each Eigen vector S.

$$Z = WX \tag{5}$$

The whitening process is completed by finding whitened vector Z.

3.2 | Improved fast confluence adaptive ICA

The next process is to perform iteration to meet convergence and signal extraction. The algorithm presented below finds the 2×2 separation matrix for extracting the two ECG signals from their mixtures.

Algorithm 1. Fast confluence adaptive ICA

Step 1: Form a weight matrix W_M by assuming N sub matrices or column vectors as,

$$W_M = \{w_1, w_2, w_3, w_4, \ \dots \ w_N\}$$

where $w_i = (w_{i1}, w_{i2}, \ \dots w_{in})^T$

w_{ij} represents the jth weight of ith column vector and n is the number of sources. N defines the size of the search space to obtain globally best solution.

Step 2: Find norm of each vector and divide it by corresponding norms

Step 3: Find the updated weight vector W_{new} for all the weights in W_M.

$$w_{\text{new}i}(k+1) \leftarrow E\{Z(w(k)\overline{Z}^T)^3\} - 3w_i(k) \tag{6}$$

where Z represents the whitened speech vector.

Step 4: Calculate the fitness value

$$\boldsymbol{\Phi} i = w_i(k+1) - w_i(k) \tag{7}$$

Step 5: If convergence is achieved, the corresponding vector is one of the columns of demixing matrix. If it is not converged go to the next step.

Step 6: Divide the N weight vectors into M groups ($N = 2 \times M$) with 2 ($n = 2$) weights in each group.

Step 7: In each group,

If $\boldsymbol{\Phi} i(k) < \boldsymbol{\Phi} i\ (k+1)$ **then**

$$\text{ref}_i(k) = \boldsymbol{\Phi} i(k)$$

else

$$\text{ref}_i(k) = \boldsymbol{\Phi} i(k+1)$$

end

Step 8: **If** $\text{ref}_i(k)$is positive

$$w_i(k) = w_i(k) - C;$$

where C represents a random non-negative floating point number between "0" and "1."

else

$$w_i(k) = w_i(k) + C$$

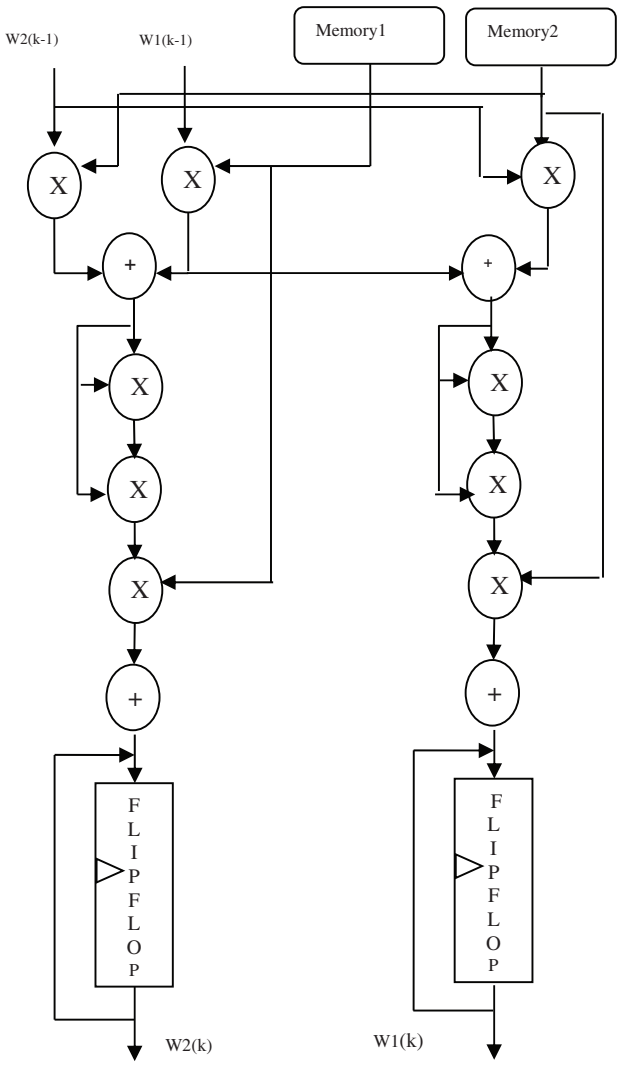
end

Step 9: Repeat from step 3 to find $w_i(k+1)$ until $\boldsymbol{\Phi} i \approx 0$.

The first step in this algorithm initializes the weight vectors. The assumed weights are normalized, updated, and then the fitness value is calculated. Then, the convergence-checking unit is used to check the fitness value. On convergence, the iteration process is terminated and the data are sent for separation matrix estimation. Otherwise, the fitness parameter is checked for having a positive or negative value. If the fitness value is negative, the addition operation is performed on the weight vectors with a non-negative floating-point number. Otherwise, the subtraction is performed on the weight vectors. Then this process is repeated from step 3 until convergence is achieved. Once the convergence is achieved, the vector

with best fitness value is used as one of the columns of demixing matrix. As the matrix is considered to be orthogonal, second column of demixing matrix is easily found. Since there can only be one vector possible, which is orthonormal to first column of B, without any loss of generality, demixing matrix can be found. Then, the two signals are estimated by combining the separation matrix and original mixture. This method provides much simpler computation, lower chip area, and lower power consumption during VLSI implementation. In traditional methods, random weight vectors generated from random number generator unit are directly given to input of weight vector update system, when the convergence is not met. In previous FCAICA method, the weight vectors are updated in adaptive manner by an adaptive optimization unit according to the fitness value by performing the sampling formation of weight update. The optimization unit consists of subtraction module and comparator units, which are mainly used to update the weight values based on a kurtosis function given in (6). Comparator unit is used to decide the traversal direction of weight vectors. In proposed IFCAICA, the number of arithmetic units used in iterative process has been reduced. Figures 2 and 3 show the architecture of weight update units of FCAICA and proposed IFCAICA algorithms, respectively. FCAICA contains four adders and nine multipliers. In improved FCAICA, the number of adders and multipliers are reduced to three and six, respectively. This IFCAICA unit efficiently separates the source signals with lesser resources. Here, $W1(k-1)$ and $W2(k-2)$ represent the input weight vectors, k indicates the iteration number, and $W1(k)$ and $W2(k)$ are the output weight vectors.

Here, memory1 and memory2 act as internal registers used to store the whitened data. As area, power, and speed are the major design issues in VLSI circuits, this research work concentrates on them. Reconfigurable components (RCs) of improved FCAICA algorithm such as, weight vector updating unit, convergence checking unit, and separation matrix calculator units are individually developed, optimized, and are integrated together to form a complete module. The estimates found using proposed FCAICA algorithm are then applied for R-peak detection.



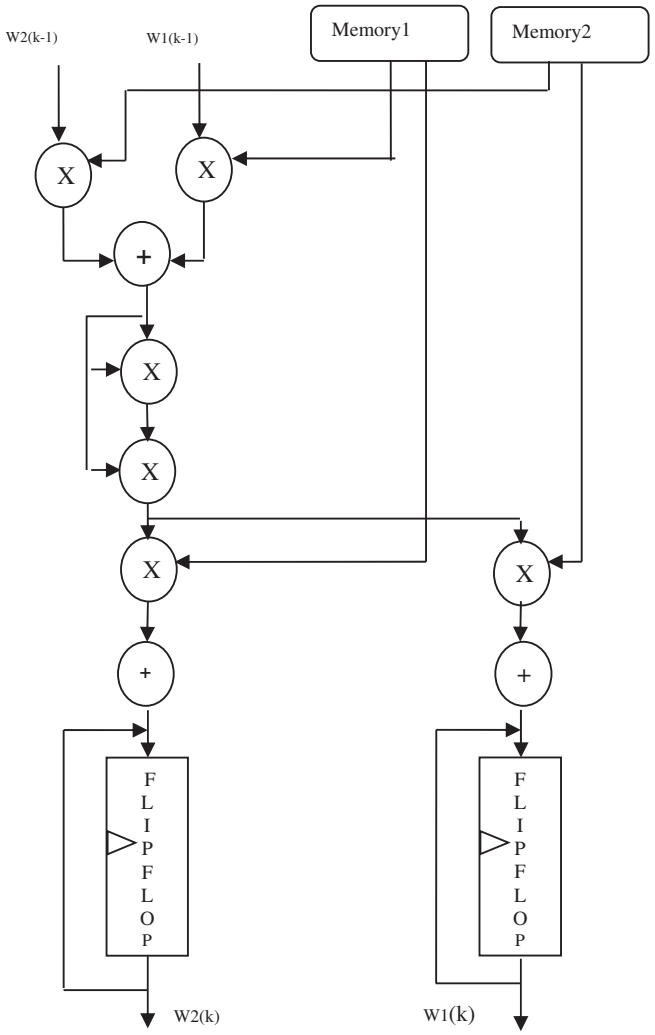


FIGURE 2 Weight update unit in FCAICA

FIGURE 3 Proposed weight update unit in IFCAICA

3.3 | R-peak detection algorithm

The widely used and often cited QRS detection algorithm proposed by Pan Tompkins[24] is used to calculate the R-peaks after sources are estimated using the proposed IFCAICA technique. This method recognizes the peaks with high detection sensitivity. The algorithm adjusts parameters periodically according to changes in ECG waves. The simulation, implementation results, and comparison results are provided in the next chapter.

4 | PERFORMANCE ANALYSIS

This section provides the experimental results of the proposed system. Extensive simulations were carried out on ECG dataset to validate the performance of IFCAICA. The ECG data provided in this result are of a 68 years old male with sampling rate of 1 KHz. The leads shown are V1 and V5.

4.1 | Results of ECG

The ECG signals acquired from the patient in two-channel case are shown in Figure 4, where the *x*-axis represents the number of samples and the *y*-axis represents the amplitude in microvolts. After reading the input signals and preprocessing, the proposed improved FCAICA algorithm is applied to separate the original signals from the mixtures. The centering and whitening processes are performed to eliminate the redundancy present in the input signals. This experiment is carried out with 11 600 samples. The reconstructed ECG signals are shown in Figure 5.

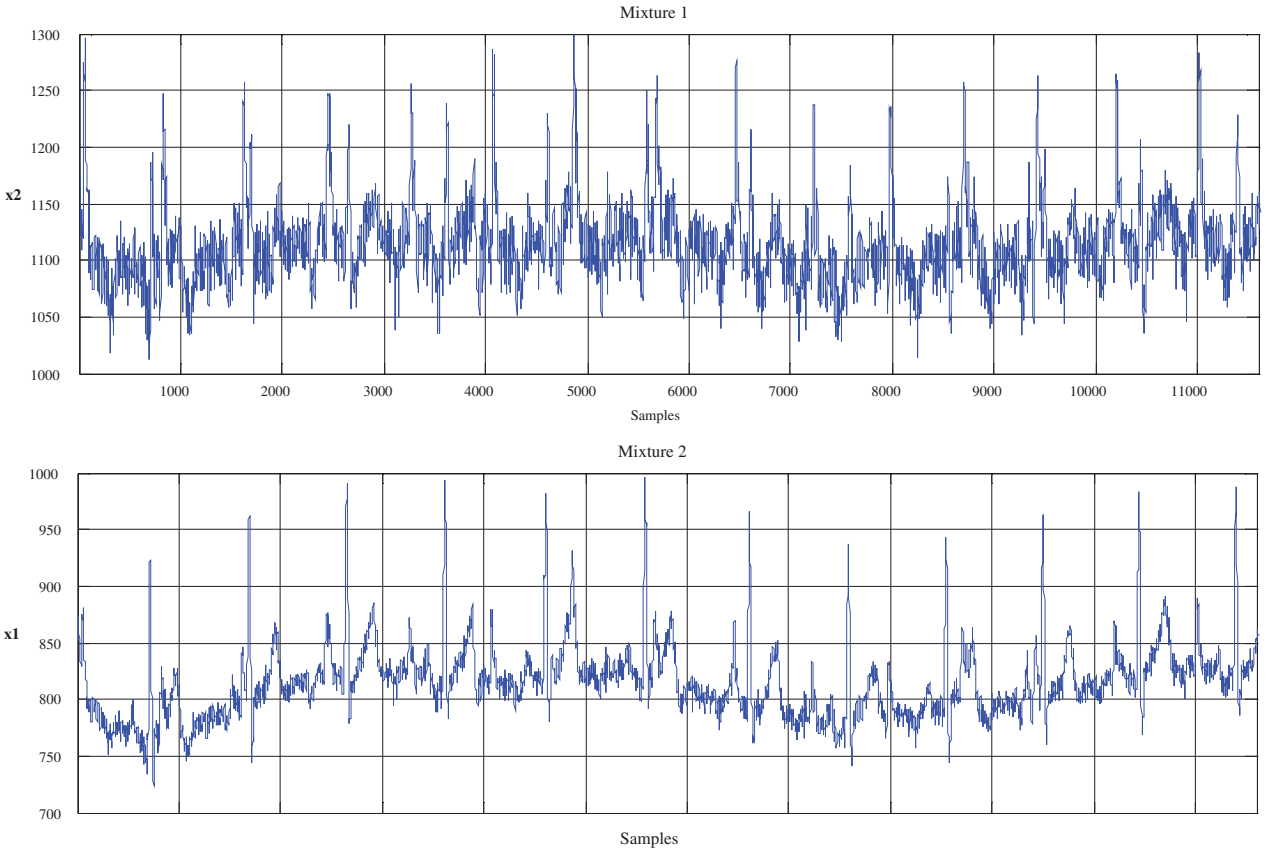

FIGURE 4 ECG mixtures [Colour figure can be viewed at wileyonlinelibrary.com]

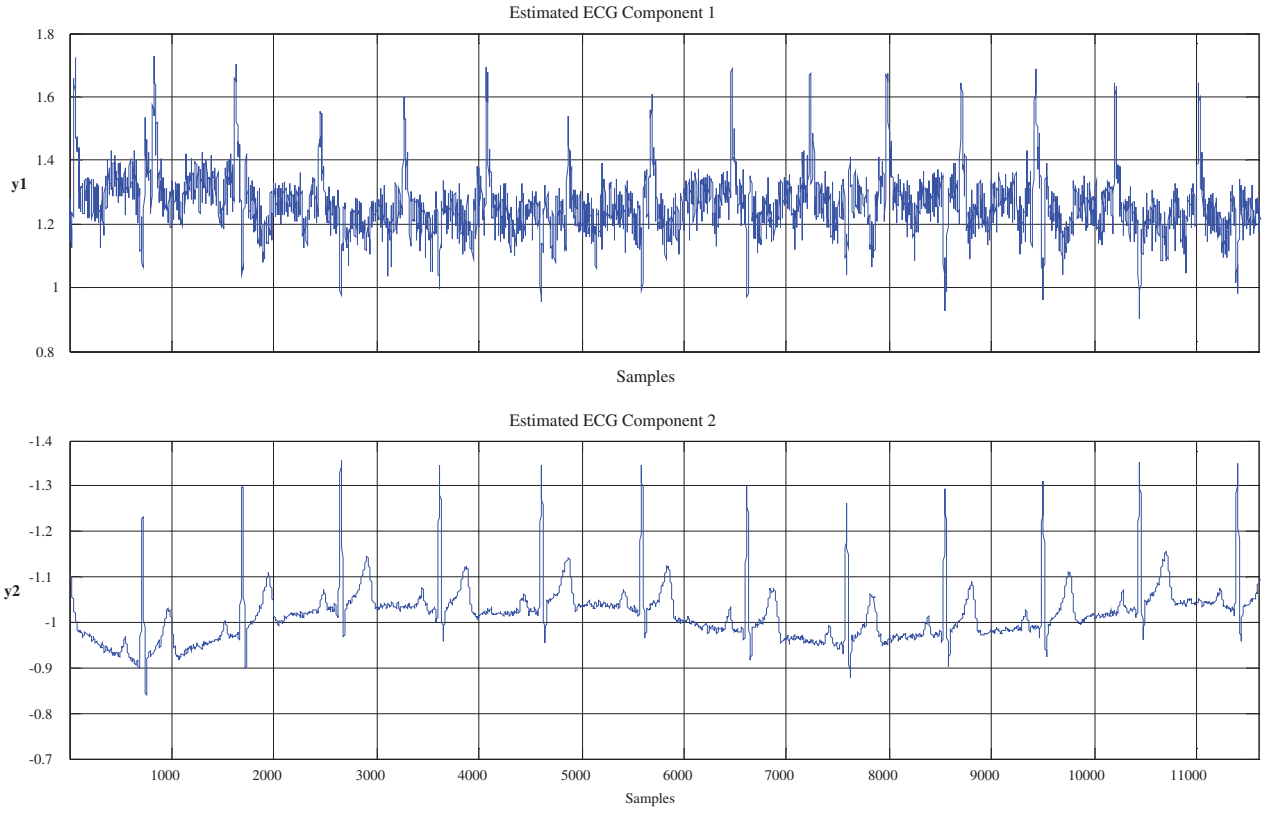

FIGURE 5 Reconstructed ECG [Colour figure can be viewed at wileyonlinelibrary.com]

4.2 | R-Peak detection

For a complete long-term cardiac monitoring and classification system, R-peak detection is required as the primary step. The performance of the classification may be affected if R-wave detection results with errors. A number of investigation works published in the literature realized high detection rates of more than 99.5% remarkably.[25,26] So, it is straightforward to incorporate the R-wave detection algorithms into the proposed scheme to develop a fully automatic heartbeat classification system. The results obtained with the R-peak detection algorithm after ICA processing are shown in Figure 6.

4.3 | Sensitivity analysis with R-Peak detection

The effectiveness of the proposed method is also validated with six-leads of ECG data (V1-V6), by evaluating the sensitivity using true and false peaks before and after applying proposed ICA method. Table 1 provides the details of true positive, false positive, and false negative peaks found in ECG components before applying ICA. After the application of ICA, true positive, false positive, and false negative values are found to be reduced and are shown in Table 2.

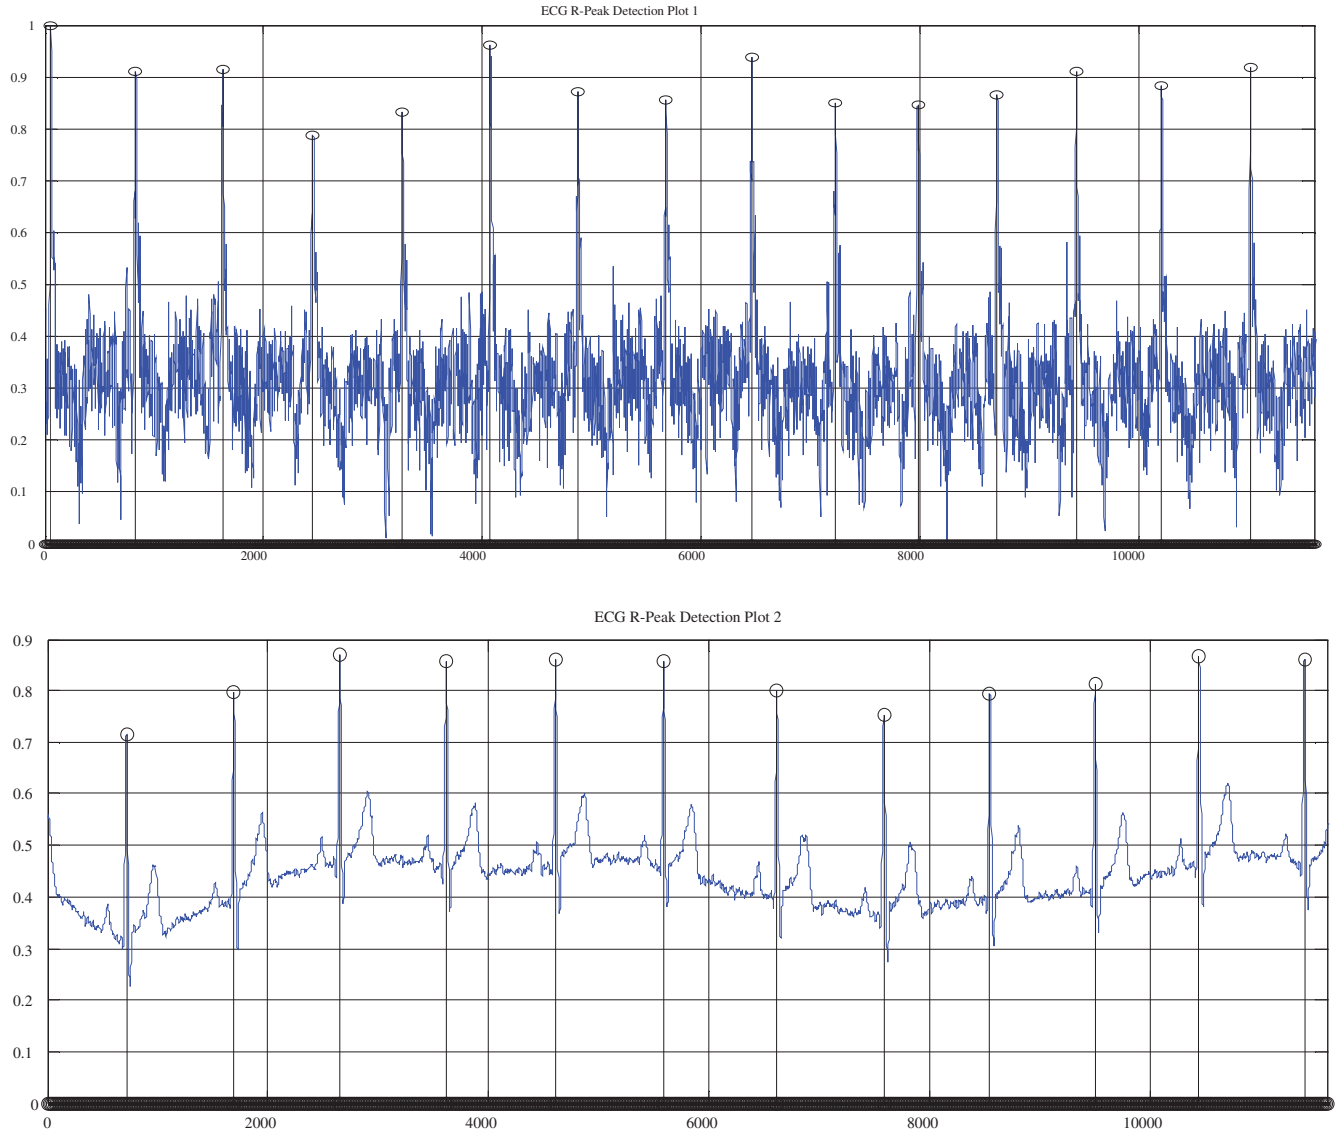

FIGURE 6 Results of R-peak detection [Colour figure can be viewed at wileyonlinelibrary.com]

TABLE 1 Sensitivity before applying ICA

Lead	Actual R-peaks	True positive (TP)	False positive (FP)	False negative (FN)
V1	150	150	8	1
V2	150	150	9	1
V3	150	149	6	3
V4	150	149	7	2
V5	150	150	7	1
V6	150	148	3	2
Total		896	40	10

Note: Sensitivity $= \frac{TP}{(TP+FN)} = 97.5\%$.

TABLE 2 Sensitivity after applying ICA

Lead	Actual R-peaks	True positive (TP)	False positive (FP)	False negative (FN)
V1	150	150	71	5
V2	150	147	32	4
V3	150	149	14	3
V4	150	148	25	3
V5	150	149	20	2
V6	150	146	14	5
Total		889	176	22

Note: Sensitivity $= \frac{TP}{(TP+FN)} = 98.89\%$.

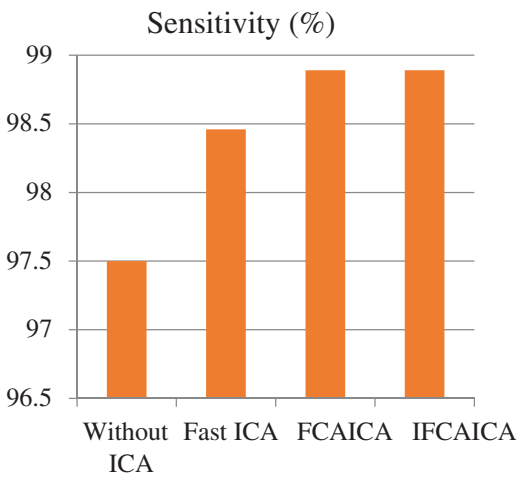

FIGURE 7 Sensitivity analysis [Colour figure can be viewed at wileyonlinelibrary.com]

The R-peak estimator with the proposed ICA algorithm gives a sensitivity of 98.89%, whereas before applying ICA the sensitivity is 97.5% and it is illustrated in Figure 7. The results are derived by taking 100 000 samples for all the algorithms. The leads used in this analysis are V1 to V6. Comparing the results of Jade algorithm in the literature that has a sensitivity of 98.07[19] with the Fast ICA algorithm, FCAICA algorithm, and proposed IFCAICA technique, it is proved that the proposed method performs better in terms of sensitivity and hence provides better accuracy in separation. The performance metrics of R-peak detection algorithm with performance metrics true positive (TP), false positive (FP), and false negative(FN) values are plotted in total and shown in Figure 8. As the proposed ICA method implicitly incorporates higher order statistics through a nonlinear function to achieve independence, it provides better results compared to other algorithms.

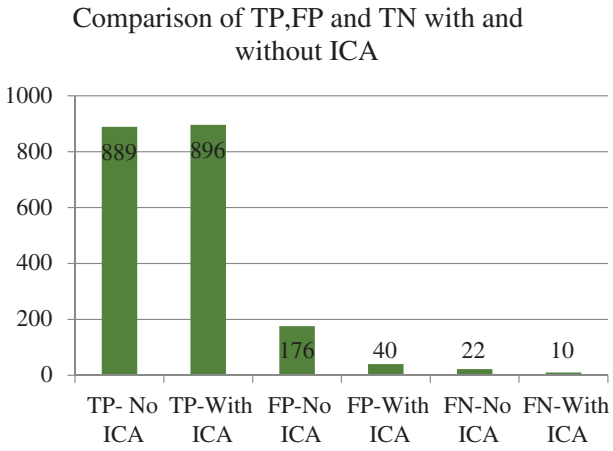

FIGURE 8 Performance metrics [Colour figure can be viewed at wileyonlinelibrary.com]

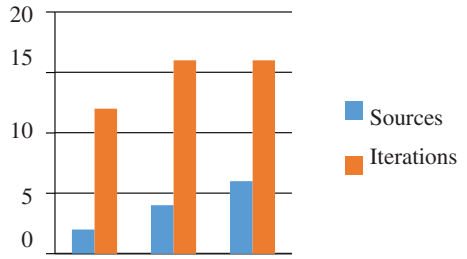

FIGURE 9 Number of sources vs iterations [Colour figure can be viewed at wileyonlinelibrary.com]

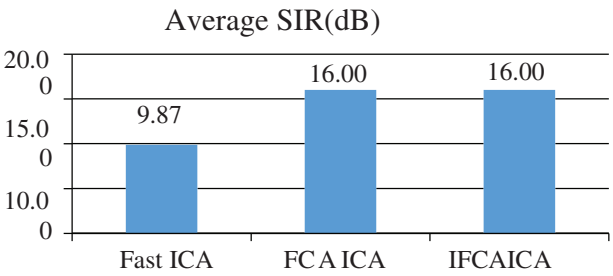

FIGURE 10 SIR analysis of ICA algorithms [Colour figure can be viewed at wileyonlinelibrary.com]

4.4 | Iterations and SIR

The simulation was carried out to find the number of iterations needed for convergence of the algorithm. At first two leads were used and then it was extended to six leads (V1-V6).The average number of iterations are 12, 16, 16 with the sources 2, 4, and 6, respectively. The number of iterations taken to extract the independent components using proposed IFCICA technique is shown in Figure 9. The average SIR value obtained using this algorithm for two-lead case is 16 dB which is fine enough to extract the required ECG information. The usage of floating point arithmetic operations significantly improves the SIR of separation system. The SIR obtained for IFCAICA is compared with Fast ICA and FCAICA which is shown in Figure 10.

4.5 | Comparative analysis-VLSI implementation

Once all the performance metrics are calculated for evaluation of the algorithm, hardware implementation is done. Experimental results are analyzed, evaluated, and hardware results are obtained using the Cadence tools NCsim, rc, and encounter. GDSII (graphical data stream information interchange) file is created in 180 nm technology for VLSI implementation. Comparative analysis among the existing and proposed methods is done. Figure 11 depicts the cell instances, area, total power consumption, and maximum operating frequency of Fast ICA, FCAICA, and improved FCAICA algorithms. IFCAICA provides better results compared to FCAICA in terms of area, power, and maximum frequency. Since the operating frequency of FCAICA is high compared to other algorithms, it separates the mixture with a maximum

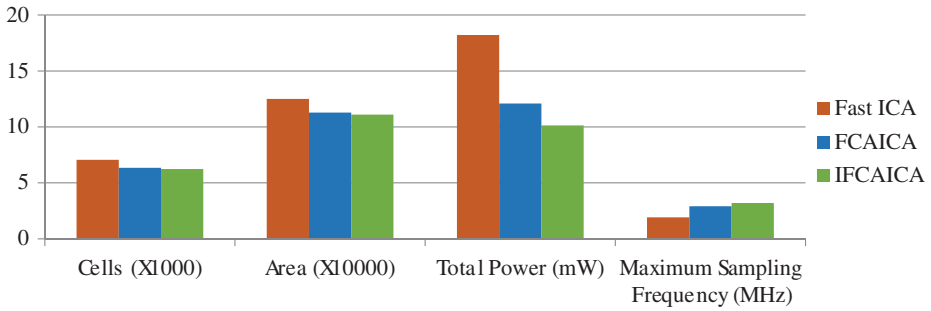

FIGURE 11 Comparative analysis between existing and proposed methods [Colour figure can be viewed at wileyonlinelibrary.com]

possible speed. Due to the reduced complexity of adaptive optimization unit of algorithm, the resource utilization and power consumption are reduced, and the operating speed is increased.

It is observed from these results that, there is an improvement of 16% optimization in power and 14.7% improvement in speed (operating frequency) achieved when compared to FCAICA algorithm. Fast ICA results are also shown for reference.

5 | CONCLUSION AND FUTURE WORK

The main aim of development of this algorithm is to extract pure ECG component from the mixture signals with lesser hardware resources and improved speed. This technique can be used in the development of a healthcare system for continuous monitoring of clean ECG signal when the patient is away from the hospital. Wireless connectivity enables us to transmit the acquired ECG signals directly to the Cloud server. The physicians could use these data from cloud for further analysis and clinical review. The experimental results show that the proposed improved FCAICA algorithm occupies lesser hardware compared to existing techniques. The sensitivity of the algorithm for R-peak detection is also good. So it can be well applied for ECG signal separation. The proposed IFCAICA algorithm may also be enhanced for other signals such as EEG and spread spectrum signals.

Abstract

Background: TENS by neuro-physiological means seems to help in relieving labour pain. Most of the pregnant women are not aware of the coping strategies for labour pain. As a result they tend to be restless and stress themselves by shouting or screaming due to pain. By using TENS, women in labour can save their energy without stressing themselves and make use of the saved energy for pushing the fetus during the second stage of labour. The objective was to analyze the effect of TENS on relieving labour pain among the postnatal mothers who had used TENS to cope up with the labour pain.

Methods: Data collected from 1041 women [Primipara (n=702) and Multipara (n=339)] who used TENS to cope up pain throughout the labour was used for this retrospective study.

Results: 88% of women had vaginal delivery and only 12% of women had cesarean section. More than 50% of both primiparous and multiparous women who had normal and vacuum assisted vaginal delivery experienced excellent pain relief using TENS. Almost 40 % of both primiparous and multiparous women who had forceps delivery and lower segment cesarean section experienced excellent pain relief using TENS. Except 2% of women with normal vaginal delivery, none of them stated that there was no relief of pain using TENS.

Conclusions: TENS had a very good effect in coping up the labour pain and could be used during the first and second stages of labour.

Keywords: Labour pain, Pain gate theory, TENS

Introduction

The pain experienced in labour is affected by the processing of multiple physiological and psychosocial factors. Transcutaneous electrical nerve stimulation (TENS) is widely used for chronic or postoperative pain control, either replacing or complementing analgesic drugs, and is based on the gate theory of pain proposed by Melzack and Wall in 1965. According to this theory, the modulation of pain perception induced by TENS is attributed to the recruitment of A-beta (Aβ) afferent fibers in the posterior horn of the spinal cord, which would prevent or hamper the activation of the pain-conducting small A-delta (Aδ) fibers. It is further thought that by reducing anxiety, increasing a sense of control and by providing distraction, TENS increases a woman's sense of well-being and thereby reduces pain in labour (Brucker 1984; Findley 1999; Gentz 2001; Simkin 2004). The first report on the use of TENS in obstetrics came from Scandinavia in the 1970's, where it was introduced as a non-pharmacological resource for pain relief during labor.[1] TENS by neuro-physiological means seems to help in relieving pain during the first stage of labour. It

fulfils the criteria of an efficacious, simple to administer method of pain relief with no side effects on the mother and the baby. It would be a useful addition to the present methods of pain relief in labour.[2]

Most of the pregnant women are not aware of the coping strategies for labour pain. As a result, they tend to be restless and stress themselves by shouting or screaming due to pain. It would be better to make them understand about the labour pain beforehand, usually at their final review at obstetrics and gynecology (OG) outpatient department (OPD) and also teach them the method of operating the obstetric TENS equipment to cope up with the labour pain. This would help the women in labour to save their energy without stressing themselves and make use of the saved energy for pushing the fetus during the second stage of labour.

There was no evidence from previous studies with larger sample size and usage of TENS throughout the first and second stage of labour. Hence, this study was conducted with an objective to analyse the effect of TENS on relieving labour pain among the postnatal mothers who had used TENS to cope up with the labour pain during their first and second stages of labour.

M□□□□□□

Design and sample size

This is a retrospective study and the data collected from both the primipara and multipara mothers who had used TENS for coping up labour pain throughout labour was used for this study. Ethical clearance was obtained from Institutional Human Ethical Committee, PSG Institute of Medical Sciences and Research, Coimbatore, Tamil Nadu, India. Out of 2595 women who delivered between February 2015 and February 2016, the data of 1041 women [Primipara (n=702) and Multipara (n=39)] were taken for this study.

The data of 1554 women could not be included, 3 women had assisted breech delivery, 2 women underwent vaginal birth after cesarean (VBAC), 403 underwent elective cesarean, 10 women had twin gestation, 142 women had already had an experience of using TENS for previous delivery, 95 women had immediate progression of labour and 309 women were not willing to use TENS to cope up labour pain.

The data of all the participants showed that they had undergone the awareness programme on the coping strategies of labour pain and about the method of application of TENS equipment when they had visited OG OPD during their final review. The data was then segregated into normal vaginal delivery (NVD), forceps delivery (FD), vacuum assisted vaginal delivery (VAVD) and lower segment cesarean section (LSCS). The feedback forms on relief of labour pain which were collected from the mothers on the first post natal day were used for data analysis.

Intervention

ELLE Obstetrics TENS equipment had been used for this study. The technique of TENS application involved placement of two pairs of flat electrodes on both side of the woman's thoracic and sacral spines (T10-L1 during the first stage of labour) and (S1-S4 during second stage of labour) as pain is felt at the dermatomal distribution T10 and Ll.

During full dilation and stretching of the birth canal, pudendal nerve is stimulated at S2-S4 level. These electrodes provided continuous, low-intensity electrical impulses or stimuli from ELLE TENS (battery- operated) device. The pulse frequency used was between 16 Hz and 100 Hz with pulse duration of 150 µs. Two modes are available on the ELLE TENS, each with a burst and boost function (Table 1).

Mode 1 is primarily used for the earlier stages of labour. Mode 2 is used when the labour advanced and when the contractions became more frequent. The burst function button is used in between contractions which promotes secretion of endorphins and encephalins. The boost function button was used during contractions. This gives an extra surge of power required to combat the pain during contractions. The labour ward therapist fixed the electrodes and the women operated the device themselves. The labour ward therapist ensured the proper use of the device and the position of the electrodes frequently.

□

Outcome measures and statistical analysis

The pain index and degree of pain relief were used as outcome measures. The percentage of pain relief was assessed both by the postnatal women and by the therapist (Table 2 and 3). Pain index was calculated by multiplying the pain relief scores assessed both by the postnatal women and therapist. The degree of pain relief was graded accordingly by the therapist in-charge of the obstetrics and gynecological physiotherapy (Table 4).

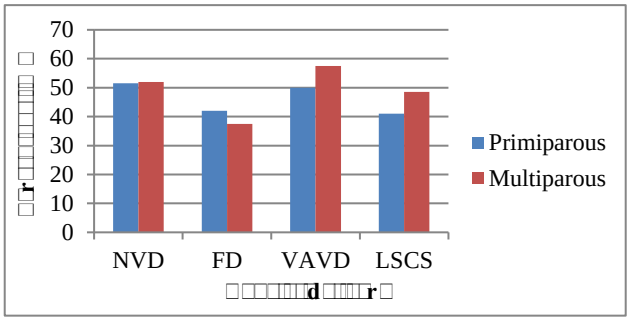
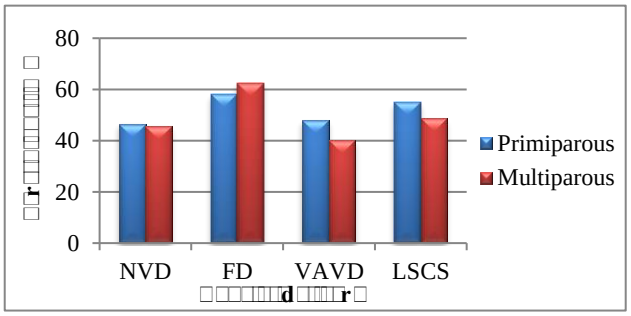
Subjective assessment of labour pain (by the postnatal women)



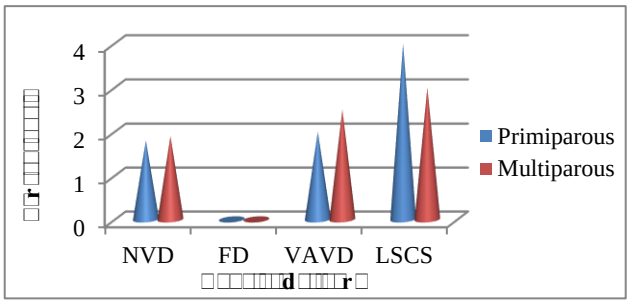
This variable was standardized by visual analog scale. The distance marked were calculated as a percentage of line length (from 0-100%). Scores were given according to the percentage of pain relief.

Observer assessment of labour pain (by the therapist)



This grading of percentage of pain relief and scoring was done by the labour ward therapist who attended the pregnant women during labour.

□□□□ □□□



Among the 1041 pregnant women who had used TENS for coping up labour pain, it was found that only 12% of women underwent cesarean section and 88% of women had vaginal delivery (NVD, FD and VAVD), out of which 58% were primigravida women. The average duration of application of TENS for the primiparous women was 6.19±0.46 hours (Mean and SD) and for that of the multiparous women was 6.09±1.26 hours (Mean and SD).

NVD: Normal vaginal delivery; FD: Forceps delivery; VAVD: Vacuum assisted vaginal delivery; LSCS: Lower segment cesarean section.

Normal vaginal delivery

It was analyzed from the data that, 740 mothers had normal vaginal delivery. Among them, 482 were primiparous (24.76±3.32 years) and 258 (26.88±3.89 years) were mulitparous. More than 50% of both primiparous and multiparous women (51.5% and 52% respectively) experienced excellent pain relief using TENS (Figure 1) and more than 45% of both primiparous and multiparous women (46.5% and 45.7% respectively) had good pain relief (Figure 2). Fair relief and no relief of pain by using TENS have been stated by less than 2 % of the NVD mothers (Figure 3 and 4).

Forceps delivery

Only twenty seven mothers had forceps delivery. Among the 19 primiparous (24.15±2.26 years) and 8 multiparous (27.62±2.66 years) women who had FD, 42% of the primiparous women and 37.5% of multiparous women experienced excellent pain relief using TENS (Figure 1). More than 55% of both primiparous and multiparous women experienced good pain relief by using TENS (Figure 2). None of them have stated that they had fair relief or no relief after using TENS (Figure 3 and 4).

Vacuum assisted vaginal delivery

One hundred and forty four mothers [primiparous (n=104; 25.10±3.37 years) and multiparous (n=40; 27.1±3.78 years)] had VAVD. 52% of primiparous and 55% of multiparous women had excellent pain relief (Figure 1). 48% of primiparous and 40 % of multiparous women experienced good relief (Figure 2). Less than 3 % of them had stated fair relief and none of the VAVD mothers had stated that they had no relief of pain by using TENS to cope up labour pain (Figure 3 and 4).

Lower segment caesarean section

One hundred and thirty mothers had lower segment cesarean section. Among them 97 mothers were primiparous (25.82±3.94 years) and 33 were multiparous (27.42±4.86 years). 41% of primiparous and 48.5% of multiparous mothers experienced excellent relief (Figure 1). 55% of primiparous and 48.5% of multiparous women experienced good relief of pain (Figure 2). Less than 4% of them experienced fair relief of pain by using TENS. None of the LSCS participants had stated that there was no pain relief using TENS for coping up labour pain (Figure 3 and 4). These results are summarised in Table 5.

□□□□ □ □□□□ □ □

The present study evaluated the relief of pain by the mothers who had used TENS for labour. It was observed in this study that 50.3 % of the mothers had experienced excellent pain relief and 47.4% of the mothers had experienced good pain relief by using TENS. The knowledge about effectiveness of TENS for labour pain given to the antenatal women during their last review had provided confidence among the women to use the TENS equipment during labour. This correlated with a study which had stated that by reducing anxiety, increasing a sense of control and by providing distraction, TENS increases a woman's sense of well-being and thereby reduces pain in labour.[3] A study included 14 randomized controlled trials comparing women receiving TENS during labour versus routine care or placebo devices. The authors demonstrated little difference in satisfaction with pain relief or in pain ratings between the TENS and control groups. However, approximately two-thirds of women who had received TENS reported that they would prefer to use it again for future labour and one another study states that 74% of the parturient in their experimental group reported being satisfied with TENS, and 100% of them would prefer to use this method again for future childbirths.[4,5]

The findings of the present study are similar to the previous studies with respect to the mode of delivery for the women who had used TENS during labour. In present study about 88% had vaginal delivery (including NVD, FD and VAVD) and 12 % had emergency caesarean. Thomas et al reported that in their intervention group, 80.3% vaginal births, 8.3% forceps/vacuum and 11.4% caesarean sections. Normal delivery occurred in all women in TENS groups in comparison to 98% in tramadol group and 99% in control group.[6] Use of TENS

was associated with the shortest first and second stages of labour, and highest rate of spontaneous delivery.[7]

The pulse frequency of the ELLE TENS device which was used in this study ranged between 16 Hz and 100 Hz with pulse duration of 150 μs. The parameters used in present study were similar to the few other related studies, Fayis F El-shamy and Anees G Saleh have applied TENS (Medsana, China) on acupuncture points for 30 minutes, at a frequency of 100 Hz with a burst frequency of 2 Hz, pulse width 150 μs, and intensity according to patients tolerance.[5,8] They have stated that different opioid peptides have been released in central nervous system by TENS application. Encephalins and β-endorphins are released with TENS application of 2Hz, while dynorphin is released in the spinal cord with 100-Hz, a combination of both frequencies allows synergistic interaction among the three endogenous opioid peptides and provides a powerful analgesic effect. Santana et al, had applied TENS continuously for 30 minutes starting at the beginning of the active phase of labour (4 cm of cervical dilation).[5] The TENS unit produced a modified biphasic asymmetric pulse and was set to a pulse width of 100 ms and a frequency of 100 Hz.

Elle TENS machine has been used in our study. Lai Fong HO et al have used the same machine and have stated that we can encourage the labouring women to mobilise even when they are using the TENS machine, which will help in shortening the latent or first stage of labour.[7] Moreover, it also reduces the incidence of neonatal respiratory suppression caused by pethidine.

In present study, the mean duration of application of TENS for the NVD was 6.09±4.86 hours [(Mean and SD); primiparous] and 5.29±4.40 hours [(Mean and SD); multiparous]. Most of the studies have used TENS for the early stage of labour for 30 minutes.[5,8] Experienced practitioners state that TENS may be more effective if initiated in early labour, presumably to allow for a build-up in endorphin production before the pain becomes severe.[9] TENS provides continuous, low-intensity electrical impulses or stimuli and during the contractions the woman increases the stimulation from low to high intensity by turning the control knobs on the device. High intensity should be maintained for at least 1 minute to facilitate release of endorphins.[10] Similarly one another study has stated that during labour, low-intensity electrical stimulation is given continuously or is applied by the woman herself as the contraction begins. This stimulation blocks the afferent fibers, preventing pain from traveling to the spinal cord synapses from the uterus. As labour and descent progresses, the electrodes are moved to stimulate the S2 and S4 level. High intensity stimulation is generally needed to control the pain at this stage.[11] In present study, the TENS was given continuously during labour with the women operating the machine, switching to boost and burst modes during contractions and in between contractions respectively. The electrodes were applied at the level of T10-L1 during first stage of labour and S2-S4 during second stage of labour. Duration of application of TENS for the primipara women was comparatively more than that of the multipara women who had ND and FD with a mean difference of 0.8 and 1.27 hours respectively. The current study evaluated the perception of labour pain of 1041 pregnant women and analyzed the effect of TENS to cope up labour pain. This study has strong evidence to state that usage of TENS had good effect in reducing the labour pain for both primigravida and multigravida women.

Limitation

The intensity of pain depends upon several factors. The most important being the emotional stability of the women.[8] It also depends upon the pain threshold of women. As it is a retrospective study, the pain threshold of the individual woman could not be identified. Correlation of pain threshold and pain index could be included in future studies. Lack of control group is another limitation of this study. Comparing the women using TENS for labour pain with the women who had sedation could yield good evidence for the effect of TENS for labour pain. Further high quality randomized controlled trials could be done to support the evidence of usage of TENS for labour pain.

□□□□□□□□□□

It is concluded that TENS had a very good effect in coping up the labour pain and could be used during the first and second stage of labour by both the primigravida and multigravida women. The awareness of labour pain and usage of TENS for labour pain forms the important concept in the childbirth education programme.

ABSTRACT

Background: *Workers in the transport industry are at greater risk for cardio vascular diseases (CVD) due to their increased diet and sedentary behavior.* ***Aims:*** *The aim of the present study is to estimate the prevalence of hypertension among truck drivers and its associated factors.* ***Methods and materials:*** *This study was conducted at Walayar check post which is located on a National highway of South India in August 2016. A detailed physical examination was conducted by a team of medical doctors. Socio demographic information were also elicited.* ***Results:*** *The prevalence of overweight was 50% and the prevalence of hypertension was 40%. In multivariate data analysis, only history of chronic disease was significantly associated with hypertension. Overweight was not significantly associated with hypertension when controlled for age, duration of driving, smoking, marital status, and history of chronic disease (odds ratio=1.987, P=0.054). On further stratified analysis, it was found that higher age (odds ratio=3.160 P<0.001) and longer duration of driving (odds ratio=1.076 P<0.001) were significantly associated with overweight. Overweight (odds ratio=2.210 P<0.05) and history of chronic disease (odds ratio=10.178 P<0.001) were significantly associated with high blood pressure after removing both age and duration of driving from this model. Receiver operating characteristic curve analysis relating age with overweight identified 38 years as the optimum cut off value.* ***Conclusions:*** *The truck drivers must be educated at their younger age preferably early thirties to prevent overweight and thereby to reduce hypertension.*

Keywords: Truck drivers, hypertension, overweight, obesity

INTRODUCTION

The social and economic effect of increased morbidity and mortality associated with cardiovascular diseases (CVD) is a great challenge in both developed and developing countries [1-3]. Many studies have demonstrated that there is a strong correlation between risk factors of cardiovascular diseases and occupational factors [4-7]. Workers in the transport industry are at greater risk of an increased diet and sedentary behavior [8,9]. Truck drivers in India have to travel long distances in their life time on an extensive spread of national and state high ways that range from well-engineered roads to complete absence of concrete roads. Their occupation pre-disposes them to multitude of risk factors such as prolonged sitting and driving, tight running schedules, reduced rest breaks, traffic congestion, the sedentary nature of job and resultant physical, psychological, and behavioral problems [8-10]. Thus, professional drivers in particular have higher mortality, morbidity and absenteeism rates due to obesity. Hypertension is one of the main outcomes of the disease and is common among professional drivers. Considering the inherent risks associated with the profession of truck drivers, the importance of truck drivers to the country's economy and scarcity of studies aimed at evaluating the cardiovascular risk profile among these professionals, the present study is aimed to assess the prevalence of hypertension and the factors associated with hypertension among long distance truck drivers.

METHODS

Study design

This was a cross sectional study conducted at Walayar check post which is located on a National highway of South India on August 2016.

Ethics

Ethical clearance for the study was obtained from Institutional Ethical Committee, PSGIMS&R, Coimbatore.

Sample size: With an expected prevalence of hypertension as 45% [9] and with 20% allowable error, the sample size required for this study was estimated as 122. With a non-response of 20%, the total sample was 153. We totally studied 175 truck drivers.

Inclusion and exclusion criteria

Drivers who came with valid driving license for submission of documents at the check post on the day of survey and those who gave informed consent were included. Drivers with known congenital heart disease and genetic disorders were excluded.

Methodology

A detailed physical examination was conducted by a team of medical doctors. Blood pressure was measured on right arm in sitting position using digital sphygmomanometer. Two readings were taken at 3 minutes interval and the mean of the two was recorded. The following variables were also evaluated: socio demographic characteristics (age, education, family history of CVD, prior diagnosis of chronic disease), physically active, eating patterns, consumption of alcohol or other stimulants and smoking habits.

The following criteria and definitions were used [9]:

- Family history of CVD: when the individual mentions the occurrence of heart disease in a first degree relative.
- History of chronic diseases: truck drivers were asked whether they had been previously being diagnosed with any chronic diseases and what medicines they were taking.
- Subjects were considered physically active if they are performing aerobic (walking, biking, dancing, and racing) or anaerobic activities (body building) at least 150 minutes in a week and moderately active if they do 10 to 150 minutes in a week and insufficient if they do less than 10 minutes in a week.
- Subjects were considered active smokers if they use tobacco daily in any quantity or at quit smoking in the previous 12 months. Subjects were considered non-smokers if they had not used tobacco for the past 12 months.
- For determining the body mass index (BMI) the truck drivers were weighed (in kg) without shoes on a 150 kg mechanical anthropometric scale and height in meter. The BMI levels were classified according to the WHO guidelines [11]; subjects were normal if their BMI was 18.5 kg/m^2 to 24.5 kg/m^2, overweight if their BMI was 25.0 kg/m^2 to 29.9 kg/m^2, grade 1 obese if the BMI was 30.0 kg/m^2 to 34.9 kg/m^2, grade 2 obese if the BMI was 35.0 kg/m^2 to39.9 kg/m^2 and grade 3 obese if the BMI $\geq$ 40.0 kg/m^2.

Statistics

Data were analysed using SPSS (19). Mean (SD) were calculated for continuous variables and percentages were calculated for categorical variables. Logistic regression analysis was done to estimate the odds ratio and its statistical significance. Hypertension was defined as present in those with systolic blood pressure greater than or equal to 140 mm Hg or those with diastolic blood pressure greater than or equal to 90 mm Hg. For statistical analysis, BMI>25 kg/m^2 were considered as overweight. Variables significantly associated ($P<0.2$) with hypertension were subjected to multivariate regression analysis. However, due to multicollinearity, stratified analysis was further done to observe the association. Receiver operating characteristic curve analysis was then done to find the optimum cut off value.

RESULTS

The mean age of the study participants were 39.38 years with the minimum age of 22 years and the maximum of 67

years. The prevalence of overweight was 50% and the prevalence of hypertension was 40% (Table 1). In univariate analysis, positive family history, overweight, history of chronic disease, smoking, longer duration of driving, marital status and older age were significantly associated with hypertension (P<0.2) (Table 2). However, in the multivariate analysis, only history of chronic disease was found to be significant. Overweight was not significantly associated with hypertension when controlled for age, duration of driving, smoking, marital status and history of chronic disease (odds ratio=1.987; P=0.054). On further analysis, it was found that higher age (odds ratio=3.160; P<0.001) and longer duration of driving (odds ratio=1.076; P<0.001) were significantly associated with overweight. Overweight (odds ratio=2.210; P<0.05) and history of chronic disease (odds ratio=10.178; P<0.001) were significantly associated with high blood pressure after removing both age and duration of driving from this model. Receiver operating characteristic curve analysis relating age with overweight identified 38 years as the optimum cut off value. Hence it is concluded that the truck drivers must be educated at their younger age preferably early thirties to prevent overweight and thereby to reduce hypertension.

Table 1 Prevalence of hypertension and obesity among the study population

DISCUSSION

A number of studies have demonstrated that the high prevalence of obesity among workers in the transport industry. According to Moreno, et al. this category of workers has a higher incidence of obesity, physical inactivity, inadequate diet, smoking habits, higher levels of cholesterol and hypertension [12,13]. A study carried out in the United States involving more than six hundred thousand workers found the highest prevalence of obesity to be among male employees who work in the transport services [14]. The worldwide prevalence of hypertension was estimated at 1 billion individuals with approximately 7.1 million deaths occurring per year due to this condition [9]. According to the World Health Organization, systolic blood pressure greater than 115 mm Hg accounts for 62% of cases of cardiovascular disease and 49% of cases of ischemic heart disease. Moreover, arterial hypertension is one of the major risk factors of cerebrovascular accident. In our study, we observed a prevalence of 41%, with a prevalence of raised systolic blood pressure of 27.4% and a prevalence of raised diastolic blood pressure of 29.1% among truck drivers.

We observed that the truck drivers must be educated at their younger age particularly early thirties to prevent overweight and obesity and thereby to reduce hypertension. Young adulthood is a vulnerable period for weight gain and the health consequences of becoming obese during the life span are of serious concern. Unhealthy dieting habits include high sugar sweetened beverage consumption, lower vegetable intake and greater consumption of foods prepared outside

the home, which may place young adult long distance truck drivers at increased risk for overweight and obesity. To improve their nutrition and health, as they progress through the life cycle, it requires approaches specifically targeted to this group. Strategies and programs for obesity prevention of truck drivers should include both individual level and population level approaches. However, the evidence base for prevention of weight gain and halting overweight and obesity in young adulthood truck drivers is currently limited.

CONCLUSION

The data in the present study allow us to draw conclusion that long distance truck drivers are highly vulnerable to develop CVD because of the high prevalence of obesity and hypertension observed. The accumulation and association of risk factors and unique features of this profession indicate that traditional actions could not change the scenario. Appropriate health care actions based on comprehensive policies that focus on the truck drivers work environment and monitoring of these factors must be established. More research into programs tailored to the needs of young truck drivers is warranted.

ACKNOWLEDGEMENTS

The authors are extremely thankful to Dr. Arvind Pandey, Director, National Institute of Medical Statistics, New Delhi, Dr. Thomas V Chacko (Professor and Head), Dr. SL Ravi Shankar (Professor), Dr. M Sivamani (Professor), Dr. Sudha Ramalingam (Professor) and Dr. S Karthikeyan (Assistant Professor) of the Department of Community Medicine, PSG Institute of Medical Sciences and Research, Coimbatore for their valuable guidance at various stages of the study. The authors are also extremely thankful to Mr. Abdul Navas, Regional Transport Officer, Palghat for permitting us to do this study. We are also thankful to Mr. Vinod, Head of Marketing and Mr. Sirajudeen for helping us to conduct this study.

Abstract

Objective: Inclined surfaces or ramps are the common obstacles faced by elderly and cardiopulmonary disabled in accessing public amenities. Ramp walking is one of the most common functional demands to be met by a common man in the industrialized world. To assess the functional (uphill walking) capacity, we need a different functional stress test over the routinely used 6-min walk test (6MWT). Hence, a new 3-min steep ramp walk test (3MRWT) was constructed to meet the demands similar to an uphill walk and to provide more functional stress than routinely used 6MWT. **Methodology:** The observational, crossover study design was adopted for this study. Fifteen healthy participants (8 males, 7 females) performed both tests in a randomized order with a washout time of 6 h in between the tests. Walking distance to both ramp and ground, heart rate, blood pressure, saturation (S_pO_2), dyspnea, and fatigue with Borg exertion scale were compared prior and after the two walk tests. **Results:** The average distances covered in 6MWT were 510.5 ± 55.06 and 440.65 ± 25.08 meters and in 3MRWT were 270.18 ± 30.8, 230.05 ± 15.06 meters for male and female respectively. The difference between 3MRWT and 6MWT distances covered by the participants was statistically significant ($t = 0.893$). The mean difference between the heart rate, saturation and perceptions were highly significant ($P < 0.001$). **Conclusion:** The study results show that 3MRWT is valid over routinely administered 6MWT and may provide greater functional stress (uphill or ramp walk capacity) in a shorter duration in healthy individuals in assessing the maximal functional capacity in a ramp or uphill walking.

Keywords: 3-min ramp walk test, 6-min walk test, functional capacity, submaximal exercise test, valve replacement

Introduction

Inclined surface or ramps are the common obstacles faced by elderly and cardiopulmonary disabled in accessing public amenities. Ramp walking is one of the most common functional demands to be met by an ordinary man in the industrialized world. This component is usually neglected or overseen in human performance laboratories in the measurement of functional capacities.

Walk tests have been a fascinating attraction in the measurement of functional capacity in the modern clinical arena; 2-min walk test (2MWT), 6MWT, and 12MWT are the most common. Various exercise tests in clinical use represent increasing complexity – 6MWT, stair climbing, shuttle walk test (SWT), detection of exercise-induced asthma, and cardiac stress test – the latter being more complex than the former.[1] However, it may not check the ability of the individual to walk in slope or uphill. For the functional stress test, still step tests are utilized, but the validity is always questionable. Laboratory-based ramp walk protocols in a treadmill are not readily accessible, costly, needs expertise, and cumbersome for functional capacity testing in primary care centers.

Uphill or ramp walking demands balance in elderly. It also requires more energy and induces much hemodynamic stress than level-walking. Walk tests are convenient, cost little, and are easy to complete. In cardiac rehabilitation, symptom-limited exercise testing with bicycle or treadmill is used traditionally.[1] However, this might not be suitable for evaluating elderly patients who have problems with balance, neuromuscular coordination, vision, or gait.[2]

To assess the functional capacity, we need a short-term operational stress test over the gold standard 6MWT and to provide an operational stress test with better sensitivity. Hence, we developed a 3-min steep ramp walk test (3MRWT) which is fulfilling the criteria of the practical walk test. Although ramp walking can be trained using the treadmill, it is not feasible for the Indian patients as they are not familiar with the treadmill and their fear may also show variation in the functional assessment. When developing the new functional walk test, it should produce a similar cardiopulmonary response or higher response than with gold standard 6MWT, so we proposed this study to compare 3MRWT with 6MWT in normal healthy individuals.

We hypothesized that none of the available field tests (either walk test or step test) measures real hemodynamic parameters or the functional stress of the persons climbing slopes or ramps. The purpose of this study was to develop a self-paced ramp walk field test to assess the functional capacity in healthy individuals.

Methodology

Our study was initiated after getting approval from the institutional human ethics committee. The participants were assigned for two tests with washout time of 6 h between the tests [Figure 1] after getting informed consent in their language (Tamil and English). This study was conducted in the ward belonging to Department of Cardiothoracic and Vascular Surgery, Pulmonary Medicine department of PSG Hospitals, Coimbatore, Tamil Nadu, India.

Participants

Healthy volunteers were recruited through advertisement in hospital notice board and local institutional weekly newspaper, Ninety five people volunteered for the study. From them, 22 volunteers were selected by picking from a bowl having names of all volunteers. Participants aged 25-65 years, both male and female were included in the study. Participants with a known history of unstable cardiac disorders such as recent angina, cardiac surgeries <2 months, and uncompensated pulmonary ailments – current asthma, bronchitis exacerbations <3 weeks were excluded from the study. The participants with current orthopedic diseases such as osteoarthritis, neurogenic claudication, new vertebral disc, facet problems <3 weeks, and fractures <2 months were excluded from the study. Furthermore, participants with movement and balance disorders such as stroke, Parkinson's, recent surgeries on lower limbs and trunk <2 months, visually challenged, balance disturbances such as vertigo were excluded from the study. Height and weight were checked using calibrated measures for all the participants.

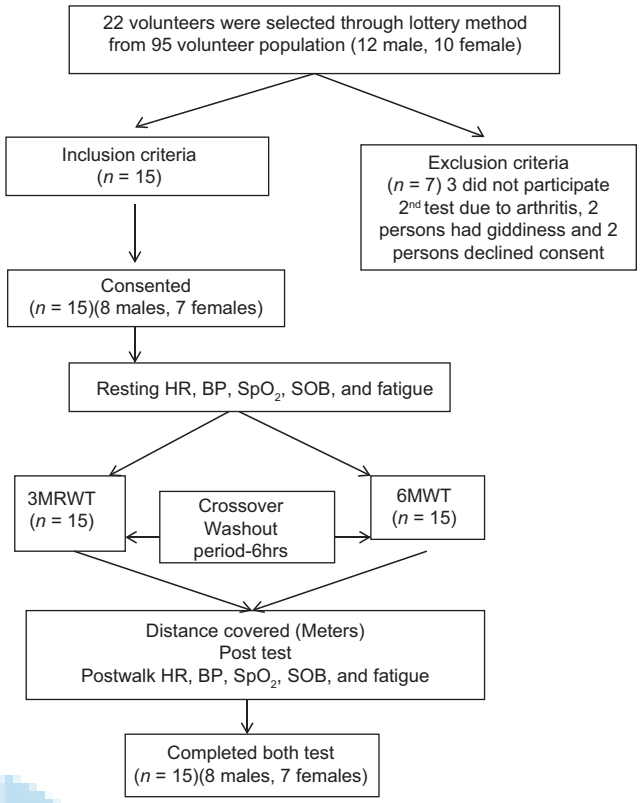

Figure 1: Flow of participants

6-min walk test

This is a self-paced walk test. It was conducted as per the American Thoracic Society (ATS) guidelines (2002). This test involves the participant to walk as far as possible in 6 min around two cones placed at 30 m. The encouragement words were delivered as per ATS guidelines at the end of every 1 min. During every lap, saturation, pulse rate, and exertion level were noted. Baseline and postwalk blood pressure was also noted.[3]

3-min Ramp walk test

This test was developed according to the standardization of 6MWT by ATS and American association of Respiratory Care, 2008. The standardization of the ramp parameters was done after auditing 15 hospitals and discussion with hospital-based Civil Engineers and contractors by the authors. The standardization of the ramp across hospitals are as follows: 20-m ramp with an elevation of 30°, 10-feet length for 1-foot steep raise, and 57 feet elevation [Figure 2]. The participant was instructed to walk in the ramp up and down for 3 min. 3MRWT is self-paced walk test such as 6-min level walk test in gauging the uphill walk capacity of the individual. Total time of test was set at 3 min because the investigators anticipated a similar exertion in walking uphill of 3 min rather than walking level ground 6 min. The encouragement similar to 6MWT was given during each minute of the test during ramp walk up and down.

Outcome measures

The data collected during the tests were pulse rate, SpO2, and after the tests distance walked, blood pressure changes. Symptoms of breathlessness and fatigue were evaluated through modified rate of perceived exertion scale.

Data analysis and interpretation

We summarize data as mean ± standard deviation (SD) and tested between group differences using unpaired *t*-test. We tested within-group change from baseline by paired *t*-test. $P < 0.05$ was considered statistically significant. Analysis was done using SPSS 17.0 software (SPSS Statistical Package, 2007, Chicago, IL, USA).

Results

Fifteen participants including 7 females and 8 males completed the study. All participants found it easy to pace themselves and no difficulties were encountered in administering both tests. The characteristics of the participants are described in Table 1. Both males and females performed well in the both walk tests [Figure 3]. Male participants walked better in both trials; it may be due to heterogeneity in anthropometry, physical activity, and motivation. Both genders showed a better performance in the 3MRWT rather than the 6MWT. The distance covered in both tests for male and female, respectively, in 6MWT was 510.5 ± 55.06, 440.65 ± 25.08 meters and in 3MRWT was 270.18 ± 30.8, 230.05 ± 15.06 m.

Table 2 summarizes the changes in cardiorespiratory parameters during the 3MRWT and 6MWT. It shows the mean ± SD values of SpO_2, heart rate, systolic and diastolic blood pressure, at the

beginning and the end of each exercise test. As compared to the 6MWT, the mean change in heart rate and arterial blood pressure were higher after the 3MRWT. These differences were statistically significant. However, the change in oxygen saturation was not significantly different. Moreover, no difference was observed in the symptoms of shortness of breath and fatigue after the two tests, since all of them were healthy participants.

This study results show that there is a significant difference between 3MRWT and 6MWT in assessing the maximal functional capacity of healthy individuals.

Discussion

We presented here preliminary results on normal healthy individuals to find a short-term functional stress test over the gold standard 6MWT and to provide an operational stress test with better sensitivity. Hence, we developed a 3MRWT which is fulfilling the criteria of the practical walk test. Our new functional walk test produced a higher cardiopulmonary response than routinely employed 6MWT.

Like the 6MWT, 3MRWT was also easy to administer, better tolerated, and reflects activities of daily living better than the other walk tests. It could be a useful measure of functional capacity to assess people with at least moderately severe impairment. The test could be used for preoperative and postoperative evaluations and for measuring the response to therapeutic interventions in patients with cardiac and pulmonary diseases.[3]

A recent review by De Feo *et al*., found that the assessment of the functional physical capacity by 6MWT early after cardiothoracic surgery may be useful to adopt the modalities of the training program to obtain the best result at the most appropriate training intensity.[4] Likewise, our 3MRWT also may be helpful in rehabilitation area to assess functional capacity and to guide operational activities.

In a randomized controlled trial involving patients with chronic obstructive pulmonary disease (COPD), cardiorespiratory performance during 6MWT and SWT were compared. Patients performed two 6MWTs and two SWTs in a randomized order on the same day. In this trial, SWT and 6MWT induced a similar cardiorespiratory performance in patients recovering from acute exacerbation of COPD. Both tests were reproducible and feasible even in hospitalized patients.[5] This trial formed the basis of our study.

In another randomized, double-crossover experimental study in patients with COPD showed that course length (10 m vs. 30 m) substantially influences the performance of patients in a 6MWT. The statistical and clinically meaningful difference in 6MWD in patients with COPD, singly depending on the length of the walk course, highlights a practical problem. Existing reference equations cannot be applied to predict the walking distance in the frequently used 6MWT on a 10 m course for people with COPD, due to a substantial overestimation. Unique reference equations for the 6MWT on a 10-m course seem necessary.[6]

The tests were performed only once to demonstrate the changes in cardiorespiratory parameters. For the results to be more significant, double cross-over method can be adopted. The participants of the study were not equally recruited according to the gender category (8 males, and 7 females). Each gender and age group may show some variation during the test. Further, the results may not be extrapolated to clinical populations. Due to lesser sample size, inherent variation in the baseline is inevitable and the washout period shall be prolonged.

This study can be conducted with composite sample across the country as a multicenter trial with healthy individuals, cardiorespiratory conditions such as COPD, coronary artery bypass grafting, and lung surgeries and presurgery screening, outcome measure in a cardiopulmonary rehabilitation and other functional capacity evaluation areas, exercise testing areas to prove the sensitivity of 3MRWT.

This study suggests that the staged incremental response may be similar in both tests that imply that 3MRWT may be an efficient possibly as equivalent to the gold standard 6MWT in clinical exercise testing arena. Thus, we propose that 3MRWT may provide a greater hemodynamic stress in the smaller time frame. As 3MWT takes smaller time frame, it may be reproducible that can be allowed for future studies to investigate.

Conclusion

In summary, 3MRWT might be an efficient alternative to the 6MWT in eliciting better cardiorespiratory stress responses to assess the maximal functional capacity. The 3MRWT is simple, easy to administer, requires no equipment, time and cost saving, safe, and is reproducible.
