The protocol was reviewed and approved by the Independent Institutional Ethics Committee of INCLEN, and the exercise was undertaken between 2012 and 2016. The context, in which the research priorities were identified in this exercise, are provided in Box 1.

The exercise was woven around four key structures, namely, the National Steering Group (NSG), the Thematic Research Subcommittees (RSCs) constituted for each of the four MNCHN themes (112 experts in India were identified based on active contribution to contemporary research), the Nation-wide Network for Crowdsourcing (experts of various disciplines related to MNCHN with due attention to regional representation

Box 1. Context of the Indian Council of Medical Research-International Clinical Epidemiology Network (ICMR-INCLEN) National Research Priority Setting Exercise for maternal, newborn, child health and nutrition

Purpose: Priority setting in maternal, newborn, and child health and nutrition for efficient and rewarding investment in research using a systematic, transparent, inclusive and consultative method.

Geography: India (National) and three regional levels *viz*., Empowered Action Group (EAG) & North-Eastern States, Southern & Western States, and Northern States & West Bengal.

Target population: Women of reproductive age (15-49 yr); pregnant women, newborns (0-28 days), under-five children (0-59 months) and children (up to the age of 18 yr).

Major areas of concern for research: Conditions that together contributed to at least 75% of the mortality and morbidity burden in Maternal, Newborn, Child Health and Nutrition in India during 2012-2013 as per the available evidence and expert opinion.

Time frame: 2016-2025.

Stakeholder constituencies (public and private sectors, health and non-health sectors): Researchers, professionals, public health functionaries, policy makers, communities and their leadership, civil society and donor agencies.

Translation and implementation context: Public and private health systems of India and their existing as well as future policies and programmes.

Source: Ref. 11, reproduced with permission with minor modifications

from 256 institutions) and the Larger Reference Group (LRG) (84 members group) constituted with Central and State policy decision makers, politicians and bureaucrats from key ministries, MNCHN programme managers, eminent researchers and representatives from research funding organizations. The list of participants in the Nationwide Network is provided in Supplementary Table I (available at *http://www.ijmr.org.in/articles/2017/145/5/images/IndianJMedRes_2017_145_5_611_215547_sm6.pdf*). [The list of all participants in the exercise with respective institutional affiliation is available on *www.inclentrust.org*].

The NSG for the exercise, co-chaired by the Secretary, Department of Health Research (DHR) and Director General (DG)-ICMR and the Executive Director of The INCLEN Trust International, was formed with key officials from concerned Ministries, namely, Ministry of Health & Family Welfare (MoHFW) (National Health Mission, Child Health, Maternal Health and Nutrition Divisions, Directorate General of Health Services and DHR-ICMR), Ministry of Women and Child Development [Integrated Child Development Services (ICDS), Food and Nutrition Board] and Ministry of Science and Technology (Department of Biotechnology, Department of Science & Technology). There was a wide range of invited subject experts, Central and State programme managers, national and international donors and multilateral agencies, who were members. Two NSG meetings were organized, one at the initiation of the exercise to ratify the context and protocol (April 18, 2013) and second, at the conclusion for reviewing and endorsing the findings (February 4, 2016).

The Thematic RSCs contributed to research ideas in the first round of crowdsourcing, helped in refining and consolidating the ideas into research options, finalizing the scoring criteria, participated in second round of crowdsourcing for scoring the research options and presented the results to the NSG for ratification.

The Nationwide Network of experts participated in the first and second round of crowdsourcing for pooling of research ideas and scoring the research options, respectively.

The LRG assigned relative weights to the five scoring criteria, namely answerability, relevance, equity, innovation and out-of-the-box thinking and investment on research.

The exercise was centrally coordinated by the RPS Management Team at the Executive Office of The INCLEN Trust International, New Delhi.

The RPS Management Team established a national network of 1066 experts from institutions across India during 2012-2013. During the same period, it completed an extensive review of literature (research, academic and policy documents) on burden of diseases of MNCHN in India and presented the summary to the NSG at its first meeting. The NSG decided that topmost causes collectively accounting for at least 75 per cent of mortality and morbidity burden (Areas of Concern) for each of the RPS themes so identified shall guide pooling of research ideas and subsequent framing of research options for priority setting. Between September and December 2013, 3498 research ideas were pooled from the nationwide network using custom-designed online software (1st round of crowdsourcing). The participation rate was 42.3 per cent [of the 1178 experts contacted (1066-national members and 112-RSC members), 498 experts contributed research ideas]. Several of these research ideas were narrations comprising more than one research idea spanning across themes, areas of concern and domains. With the help of RSC members (January 2014-February 2015), these were split and refined into 4003 research ideas that were further consolidated into 373 research options (Maternal: 122, Newborn: 56, Child: 101 and Nutrition: 94) (*http://inclentrust.org/inclen/?page_id=8666*). Five criteria (answerability, relevance, equity, innovation and out-of-the-box thinking and investment on research) were identified and defined for scoring the research options (March-June 2015) (Box 2). This was done through a comprehensive review of criteria that had been used in previous exercises at national and global levels and iterative discussion with RSC members and national and international CHNRI experts (University of Edinburgh, Johns Hopkins Bloomberg School of Public Health and the WHO).

Scoring of the research options was done independently by 893 experts (of the 1536 experts approached; Participation rate: 58.1%) using a customized online (*SurveyMonkey.com*) platform (July-October, 2015) (2nd round of crowdsourcing). The scores obtained by the research options were adjusted with criteria weights as assigned by the LRG (November, 2015-January, 2016) as per standard CHNRI data analysis practices[10]. The Average Expert Agreement (AEA) was also calculated for each research option score. The detailed methodology and process adopted for this priority setting has been published

Box 2. Criteria used for scoring the research options

Answerability: Can the research be done through ethical, transparent, well-designed, 'do-able' studies with the existing local and national capacities and or by strengthening the existing capacities through regional or global collaboration?

Relevance: Is it likely that the research would address a high burden condition and critical gap in knowledge?

Innovation and out-of-box thinking to resolve complex and refractory challenges: Does the new research have the potential for transformative change in the health system/ health care?

Equity: Is it likely that the research product will address the differences in health and nutrition that are systematically associated with social, cultural and economic hierarchies, ethnicity, gender, environment and geographic disadvantages, thereby reducing inequities?

Investment on research: Is it likely that the potential impact and benefits of the new knowledge on health/ nutrition will outweigh the considerations of investments on research?

Source: Ref. 11, reproduced with permission

elsewhere[11]. The research options were categorized into four domains; description, discovery, delivery and development.

In addition to national priorities, the States and Union Territories in the country were grouped into three subnational regions to obtain regional priorities [Empowered Action Group (EAG) and North-Eastern States, States in Western and Southern India and States in Northern India (including West Bengal)] (Fig. 1).

The number of scorers ranged between 60 and 96 scorers across each region and theme. Therefore, four priority lists were obtained for each theme: one national and three regional priority lists. The NSG reviewed and discussed the ranked list of priorities and made focused observations on the patterns of research that had evolved as priorities and the possible interlinks between the priorities identified. It also discussed other potential priority research options that might not have made it to the topmost priority list. This helped enrich the structuring of the national research agenda and identify the way forward.

Outcome of the research priority setting (RPS) exercise in the four themes

About 43 per cent of all the research options scored pertained to the delivery domain and required implementation research methodology (Fig. 2). It was observed that in each of the four themes, a large

Fig. 1. Geographical context of the ICMR-INCLEN National Research Priority Setting Exercise for Maternal, Newborn, and Child Health and Nutrition (2016-2025) (Map courtesy: *www.mapsofindia.com* modified with permission).

proportion (70%) of the top ten prioritized issues were dealing with delivery domain of research and implementation of programmes. Amongst the top ten priorities identified at national level, delivery domain research options accounted for 80 per cent in maternal health, 70 per cent in newborn health, 60 per cent in child health and 70 per cent in nutrition themes. Significant differences were also observed between national and regional research priorities for all the four themes. The AEA was very high for the top ten priorities of research in the four themes both nationally and regionally. There were research options in the top ten regional priorities under various themes that did not figure in the national priority list. The Table enlists the top ten priorities identified under each theme by the exercise at the national level. Top ten priorities and their scores along with the national and region-specific ranks are provided in Supplementary Table II (available at *http://www.ijmr.org.in/articles/2017/145/5/images/IndianJMedRes_2017_145_5_611_215547_sm7.pdf*). Key priority research options under each MNCHN theme are summarized below.

Maternal health

The network indicated the need for developing and evaluating screening checklists and management algorithms for severe acute maternal morbidities (SAMMs), near-miss events, high-risk pregnancies,

Table. Top ten priority research options in maternal, newborn, and child health and nutrition themes at national level

Theme	Rank	Research option
Maternal Health	1	Development and validation of algorithms for prevention, early detection and management of severe acute maternal morbidities and near-miss events in resource-constrained settings
	2	Strategies to improve quality of care during childbirth in the public health system, for example, medical practices, LSCS, active management of third stage of labour, EmOC, biophysical profiling for foetal assessment, application of epidural anaesthesia during delivery; beneficiary counselling and communication inside the labour room
	3	Early identification, referral and management of high-risk pregnancies (having maternofoetal morbidities including IUGR, stillbirths and preterms) at all levels of health care
	4	Introduction of a validated and cost-effective cancer screening programme of reproductive system for women in the community and health facilities
	5	Improving EmOC services [*e.g*., risk prediction, identification and communication; prompt referral; service availability (safe transportation, skilled personnel, capacity, logistic, blood storage); accountability; innovations]
	6	Assess blood transfusion needs, current availability and delivery mechanisms of blood for pregnant women based on PHC and CHC catchment areas in the context of prevailing burden of severe anaemia and post-partum haemorrhage
	7	Implementation research for effective delivery of evidence-based care protocols/algorithms for prevention and management of post-partum haemorrhage at different levels of care
	8	Improving maternal death audits, protocols and practices in the public health care system (body handling, support to family, communication, autopsy, death audit and causality ascertainment)
	9	Process and impact evaluation of public health programmes targeted for adolescents (ARSH, AFHS, RMNCH+A, RTI/STI screening services) in urban and rural areas
	10	Develop and validate a self-assessment check list for pregnant women to identify warning signs and need for care seeking
Newborn Health	1	Designing and evaluating curriculums for skill building and their retention for health personnel involved in newborn care in the community and at various levels of health care system (*e.g*., training in identification of warning signs, safe injection practices, administration of oxygen therapy, *etc*.)
	2	Engaging and empowering family members and community in the care of newborn (including family centred care): barriers, strategies to overcome, impact, cost-effectiveness
	3	Identifying appropriate and effective strategies (messages and channels of communication) to promote community awareness on newborn care practices and social mobilization for early healthcare seeking (including utilization of existing nutrition and health services) to prevent adverse outcomes
	4	Low cost, feasible, portable technological innovations in equipment to improve capacity (diagnosis, identification and management) and outreach for foetal & neonatal care (especially, LBW, preterm: CPAP, surfactant therapy, *etc*.,) at various levels of the health system and their impact evaluation
	5	Improving the implementation (service availability, quality, programme management and referral chain robustness) of neonate centric programmes and services (RMNCH+A, JSSK, NSSK, IMNCI & F-IMNCI, SNCUs, *etc*.)
	6	Implementation of an integrated and comprehensive maternal and newborn healthcare package for delivering continuum of care: barriers, strategies to overcome, need for governance modification, maternal and newborn outcomes
	7	Strategies to scale up home-based newborn care: Role assignment and rationalization for frontline workers, barrier identification and mitigation, cost-effectiveness, impact

Contd...

Theme	Rank	Research option
	8	Strategies for social, economic, skill and knowledge empowerment of women and its impact on newborn, child and women's health
	9	Establishing an innovative framework of monitoring and supervision with in-built mechanism of accountability to improve performance of frontline workers and health personnel involved in neonatal care (*e.g*., physical supervision; engaging PRIs and clients; use of ICT, telemedicine, maternal health)
	10	Development and validation of protocols for the management of pregnant women at risk of pre-term delivery, in the healthcare system [*e.g*., nutritional, pharmaceutical (steroids, betamimetics, progesterone, nitroglycerine patches, prophylactic antibiotics, *etc*.), surgical, exercise and lifestyle counselling]
Child Health	1	Develop locally relevant cost-effective strategies to expand the coverage of UIP by reaching segments of populations that are traditionally left out (address system 1 and community-Level 2 challenges) (*i*) VPD epidemiology, system capacity, cold chain, safety surveillance; (*ii*) Hesitancy, dropout, outreach strategies, KAP of care provider, community and clients
	2	Improving administrative data quality and strengthening data-driven child health programme monitoring, action and accountability at PHC and district levels (*e.g*., line listing of households with children with NDD, use of ICT, develop novel indicators)
	3	Development and validation of low-cost technologies for screening, referral and management of childhood pneumonia and ARI in the community and at various levels of health care (*e.g*., maternal health, point-of-care diagnostics & therapeutics, management protocols, *etc*.)
	4	Strategies to promote WASH practices in the community to improve child health and nutrition
	5	Development of cost-effective, feasible, validated point-of-care diagnostics for malaria in children for use at community and different levels of healthcare
	6	Development of evidence-based guidelines for rational use of antibiotics for childhood morbidities in India: choice of antibiotic; route and delivery systems (*e.g*., nebulizers); duration of therapy; monitoring criteria; adjunct therapies
	7	Development of an integrated child health programme for improving quality of life of children: challenges and barriers; strategies to overcome; feasibility across the country; effectiveness, cost-effectiveness
	8	Establishing an effective and sustainable vaccine preventable disease surveillance programme (especially, measles and rubella, pneumonia and diarrhoea) in India [*e.g*., defining syndromes (fever and rash) and programme thresholds, forging PPPs, building upon polio infrastructure, using technology (maternal health, GIS, *etc*.)]
	9	Identifying cost-effective strategies for supplementation of micronutrients and probiotics to prevent and control childhood diarrhoea, pneumonia and other infections
	10	To establish nationwide multicentric antimicrobial surveillance and antibiotic stewardship programme for infectious morbidities during childhood
Nutrition (Maternal and Child)	1	Identify and evaluate strategies to promote healthful lifestyle (physical activity and diet behaviour) in children through school and home-based interventions
	2	Determine characteristics of mother friendly work place policies and governance framework that enable optimal care and nutrition of pregnant and lactating women and their children: identify barriers and challenges to implement (*e.g*., financial security and compensation for loss of pay; crèches at workplaces; provision for breast milk expression and storage for working mothers)
	3	Process, impact and economic evaluation of NRCs for management of severely malnourished children (*e.g*., quality of care and client satisfaction; implementation gaps and challenges, reasons for underutilization and relapse; IEC to mothers during stay and at discharge; impact assessment, effectiveness of the RUTF used in NRCs and plausibility of indigenous preparation with the help of SHGs)

Contd...

Theme	Rank	Research option
	4	Identifying strategies for engaging the male partners, families and communities to improve the nutrition of women of reproductive age group and under-five children
	5	Process, impact, and economic evaluation of community-based management of childhood malnutrition (including SAM): role, effectiveness and accountability of various stakeholders (including frontline workers)
	6	Impact and economic evaluation of WASH practices in the community on the nutrition of women and children
	7	Cost-effective strategies to improve the quality, quantity and coverage of food supplements provided under the Mid-Day Meal Programme to improve the nutritional status of school-going children
	8	Determining optimal growth trajectory of LBW (preterm, SGA) babies: nutrient and calorie requirements; strategies to minimize, mitigate development of chronic diseases
	9	Development and popularisation of improved varieties of traditional food items rich in micronutrients (*e.g.*, iron rich millets): adoption of viable business models and modifying value and supply chains
	10	Strategies to overcome barriers and improve implementation of WASH practices in the community with particular focus on poor, socially disadvantaged groups

AFHS, Adolescent Friendly Health Services; ARI, Acute respiratory infections; ARSH, Adolescent reproductive and sexual health; CHC, Community Health Centre; CPAP, Continuous positive airway pressure; EmOC, Emergency obstetric care; F-IMNCI, Facility-based Integrated Management of Newborn and Childhood Illnesses; GIS, Geographic information system; ICT, Information and communication technology; IEC, Information, education, communication; IMNCI, Integrated Management of Newborn and Childhood Illnesses; IUGR, Intra uterine growth restriction; JSSK, *Janani Shishu Suraksha Karyakram*; KAP, Knowledge, attitude and practice; LBW, Low birth weight; LSCS, Lower segment cesarean section; NDD, Neuro-developmental disorders; NRC, Nutrition rehabilitation centres; NSSK, *Navjaat Shishu Suraksha Karyakram*; PHC, Primary Health Centre; PPP, Public private partnership; PRI, *Panchayati Raj* Institutions; RMNCH+A, Reproductive maternal newborn child and adolescent health; RTI, Reproductive tract infections; RUTF, Ready-to-use therapeutic food; SAM, Severe acute malnutrition; SGA, Small-for-gestational age; SHG, Self help group; SNCU, Special Newborn Care Units; STI, Sexually transmitted infections; UIP, Universal Immunization Programme; VPD, Vaccine preventable diseases; WASH, Water, sanitation and hygiene

post-partum haemorrhage, stillbirth, eclampsia and cancers. Development of point of care diagnostics and technological solutions for SAMMs, perinatal hypoxia and foetal distress were ranked as high priorities. Research on strategies to empower families and women for better self-care and timely care seeking, and skill enhancement (including role rationalization, task shifting and sharing) along with accountability of health providers at different levels were scored as important priorities. Process and impact evaluation of existing maternal health programmes to improve outcomes, developing implementation strategies to improve the quality of different aspects of maternal care in health system and expanding their coverage were considered important research areas. Development of pharmaceutical protocols for prevention and clinical management and novel technological solutions for identifying SAMMs, epidemiology of stillbirths and expanding coverage of reproductive tract infection (RTI)/sexually transmitted infection programmes and specific studies on symptomatic and asymptomatic RTI and its impact on stillbirth, low birth weight (LBW), intrauterine growth restriction (IUGR) and abortions were scored as important regional priorities.

Newborn health

Newborn health priorities included strategies to improve delivery and quality of care of newborn health-oriented programmes; skill and capacity enhancement of service providers including pre-service changes in the curriculum with in-built mechanisms of accountability; empowering mothers, families and communities to improve care seeking and quality of care in home environments; multicentric antimicrobial surveillance and antibiotic stewardship programme; development of point-of-care diagnostics/biomarkers for improving neonatal outcome, particularly for LBW neonates (preterm and IUGR) and neonatal sepsis; use of information and communication technology and utilization of m-Health to improve access to newborn care.

Child health

Six areas emerged prominently within child health: (*i*) issues related to coverage of Universal

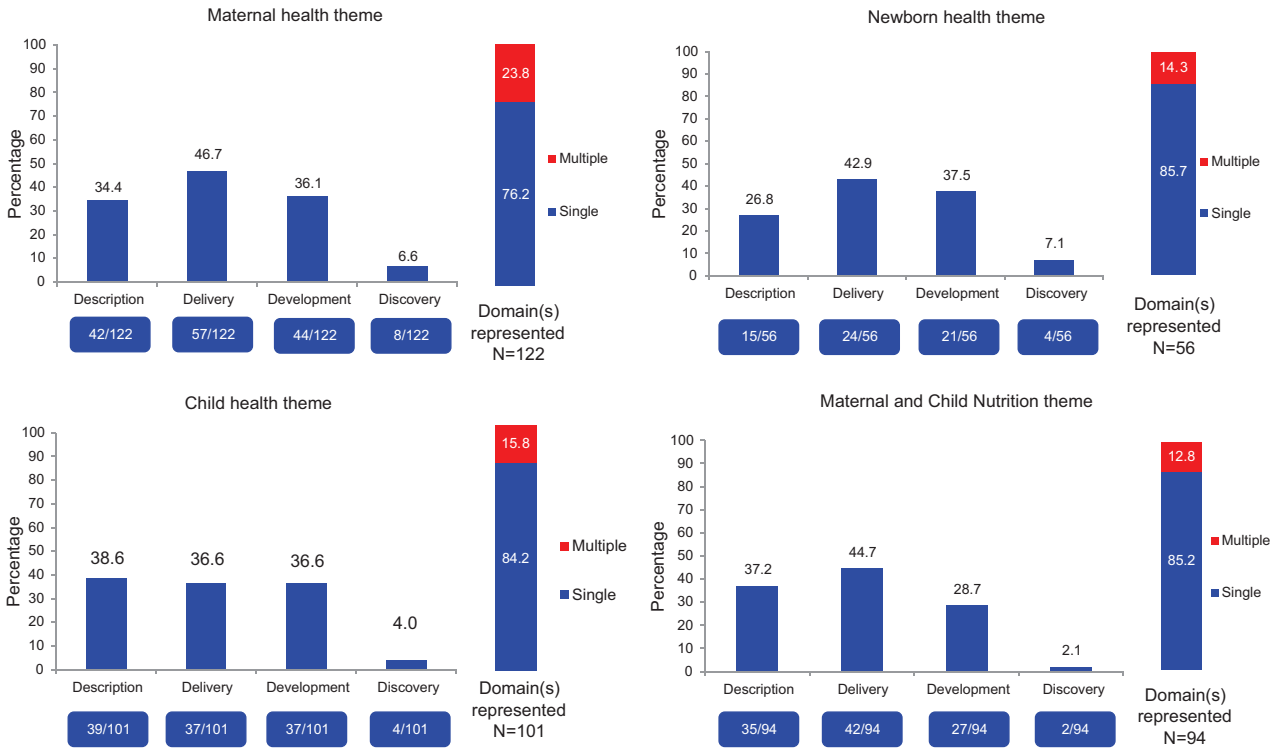

Fig. 2. Distribution of the research options in maternal, newborn, and child health and nutrition themes across the four domains of research.

Immunisation Programme (UIP) and surveillance for vaccine preventable diseases; (*ii*) point-of-care diagnostics; (*iii*) use of technology and development of biomarkers for the screening, referral and management of common childhood illnesses, namely, diarrhoea and acute respiratory infections (ARIs) along with improved control and management of malaria; (*iv*) rational use of antibiotics; (*v*) early childhood risk factors of adverse metabolic outcomes in later life, namely, obesity and metabolic syndrome; and (*vi*) water and sanitation hygiene (WASH). Operational and implementation research to effectively deliver different child health interventions in an integrated manner, including improving administrative data quality for decision-making, achieving Indian Public Health Standards at facilities, engaging community and its resources for better care seeking and care at home, strengthening curriculums for skill building and retention of personnel, was another area that scored high at both national and regional levels.

Maternal & child nutrition

Creation of mother friendly environments was an interesting and important priority to address issues of maternal and child nutrition. Research options that addressed the issues related to chronic diseases (*i.e.,* lifestyle behaviour modification interventions, point-of-care diagnostics and biomarkers for metabolic syndrome and nutrition of women around conception to prevent foetal programming and consequent risk for foetal origin of adult diseases) also scored high. Research options for enhancing skill of care providers and empowerment of families and communities including behavioural change communication were prioritized as was observed for other thematic areas. Research options around WASH (environmental and water hygiene) were scored high by experts across the country. Importantly, these research options were seen across all four themes. Research options to explore the performance and impact of various nutrition and food supplementation programmes (including community-based management of childhood malnutrition, midday meal, ICDS and food items provided under National Food Security Programme), improvement of administrative data quality for decision-making and the multisectoral governance of agriculture-nutrition-health nexus were prioritized at both national and regional levels. Anaemia (including issues related to absorption of nutrients), growth trajectory of LBW and breastfeeding were important cross-cutting areas for both mother and child perspective and were scored high.

The LRG had assigned the highest weight to the scoring criterion of 'relevance' and the lowest weight to 'investment in research'. The relative weights assigned to the five scoring criteria by different categories of members within the LRG did not vary significantly.

Discussion

The NSG strongly endorsed the research priorities identified by the exercise as appropriate for investment by different science and research departments of the Government of India and other national and international donor agencies and academic institutions over the next decade. It felt that the research agenda established with this exercise was in alignment with the national programme for achieving the recently enunciated health-related Sustainable Development Goals (SDGs) and will facilitate in accomplishing the unfinished agenda of the MDGs.

The exercise engaged experts who were well dispersed across the country. Thus, for the first time, regional MNCHN research priorities could be identified. In all the four thematic areas, there were differences between the top ten national and regional priorities. This observation made it imperative to take cognizance of the unique research needs of the regions. Although not part of the current project, the NSG suggested that a systematic effort must be made to determine factors that could explain differences in national and subnational (regional) priorities. The States falling under the three regions vary in terms of their health infrastructure, programme implementation and governance, development indicators and availability of baseline information on various health indicators. This may to some extent, explain the differences in the emerging research priorities. Better understanding of these factors will be important to design need-based research programmes and policies for different parts of the country. There are significant rural and urban differences for the health challenges and these have assumed greater significance in the light of rapid urbanization in certain parts of the country. The rural-urban divide will also have to be kept in mind when decisions on research investments are made.

In addition to the top priorities identified by the exercise, the NSG highlighted some more areas of research in MNCHN themes that deserve investment. These included role of environmental exposures in the occurrence of neurodevelopmental disorders such as autism; early childhood care and stimulation for improving cognitive outcomes; better description of childhood cancers and their risk factors; unsafe abortions; innovations to solve the 'nutrition enigma'; factors interfering with iron absorption in both women and children; impact of fluoride on health and nutrition of women and children; micronutrient deficiencies and occurrence of congenital birth defects (*e.g*., neural tube defects with folic acid deficiency); research into processes and strategies to make multisectoral governance for human nutrition workable and effective and technology innovation for developing better tools of nutrition assessment.

As part of Infant and Young Child Feeding and Complementary Feeding research agenda, NSG has also suggested that it is important to innovate strategies to promote breastfeeding; innovation is also needed in the development of low cost nutritious and healthy processed foods that require minimal cooking, are prepared from indigenous raw material and are appropriately fortified. This is important in the context of giving relief to severely time-constrained mothers who have now entered the workforce in a considerable way. Legislations affecting women and child health and nutrition are an important aspect to consider when research programmes and investment decisions are made. NSG suggested that researchers and funding agencies should work with Food Safety and Standards Authority of India in MoHFW to better understand regulatory issues related to food processing and related nutritional impacts.

Adolescents constitute almost 25 per cent of the Indian population. They suffer from several health problems that have been hitherto neglected. The foundation of several chronic diseases in the form of exposure to risk factors is laid during the adolescent years. NSG advised that adolescent-related research options were culled from the four themes and put forward separately with a caveat that scorers did not have an opportunity to see all the options in this section together. These have been put together in Supplementary Table III (available at *http://www.ijmr.org.in/articles/2017/145/5/images/IndianJMedRes_2017_145_5_611_215547_sm8.pdf*). However, as adolescent health was not stated as a theme on its own for prioritization, the research options that were chosen from within the other sections may not reflect the true priorities in adolescent health. An independent exercise may be undertaken where adolescent health is given a focus (One example where a gap can easily be seen is interventions to target adolescent boys or interventions looking at accidental

injury or drowning which carry a huge burden in this age group).

The NSG acknowledged implementation research as an important area for consideration. This necessitates bridging the 'disconnect' between the research community, the policy and programme makers, implementers and the communities to achieve the desirable impact. Implementation research involves behavioural changes of health providers, and this cannot be overlooked. Some of the prioritized implementation research options can also help the national and State administrators to either commission research studies or decide to reset the way, in which the health system is working. This will also provide an opportunity for re-engineering health systems and programmes to improve their efficiencies: by dropping redundant programmes and/or making way for newer, refined and 'need of the hour' programmes. As a cross-cutting research priority, the NSG strongly pitched the imperatives of improving the quality of administrative data for better use in decision-making at ground level.

The NSG members observed that several of the priority research issues were cross-cutting and common across the four themes; these should be brought together as common research agenda for MNCHN. This will make the research investment efficient and effective by addressing more than one theme at a time and also align the research projects with the national goal to achieve universal healthcare in India. As a follow up on this suggestion, the investigator team has prepared a separate list of cross-cutting research options [Supplementary Table IV (available at *http://www.ijmr.org.in/articles/2017/145/5/images/IndianJMedRes_2017_145_5_611_215547_sm9.pdf*)]. Similarly, as technology has cross-cutting usage, another list of research options related to research on the use of technology for health has been prepared for consideration by agencies with mandate to exclusively fund such research [Supplementary Table V (available at *http://www.ijmr.org.in/articles/2017/145/5/images/IndianJMedRes_2017_145_5_611_215547_sm10.pdf*)].

The NSG strongly advised that the DHR and other science ministries along with MoHFW should make efforts to pool resources for addressing priority research issues and also encourage national and international agencies to come together to invest strategically for greater and faster impact. The NSG has suggested that a number of research issues have the ability to be 'game changers' for the health systems, and for the health and nutrition of mothers and children, in general. These can be systematically identified and taken up in a mission mode by science ministries and donor agencies as per their own prioritization and investment policies. Recognizing the challenges of programme delivery in the context of weak infrastructure, national policymakers and programme planners have already identified north-eastern States and EAG States for the focus of several developmental schemes including health and nutrition (*http://nhm.gov.in/nhm/nrhm.html*). To further accelerate the developmental process, region-specific research agenda should become natural corollary. Health is a State subject in India and implementation of research issues can be integrated with the programme monitoring and evaluation frameworks existing therein. The research agenda could be accomplished in an accelerated manner and effectively with multistakeholder and multi-agency engagement through a broader convergent innovation coalition that will add to existing sectoral and cross-sectoral capacity for science, social sciences, economics, technology, innovation, strategy and policy to achieve better health and nutrition for mothers and their children in India.

Conclusion

It was concluded that the logical way forward for this exercise would be to take up these research priorities with different governmental and non-governmental agencies for investment. Various government and non-governmental funding agencies were requested to now re-align their investment with these priorities to achieve better health and nutrition for women and children of India effectively and efficiently. Further, bridging the gap between researchers and programme implementers at the grass root level would be essential along with decentralization of strategies to have State and possibly, district centric solutions for the betterment of health and nutrition scenario in India. In view of the predominance of delivery and implementation research identified as priority in all thematic areas, it was suggested to explore the possibility of supporting such research projects from the programme funds.

Acknowledgment

This exercise was co-funded by the ICMR, the CHNRI Secretariat and the INCLEN Trust International, New Delhi. The team is grateful to the experts from different parts of India for their enthusiastic participation in this exercise and kind support. The teams thank Drs Geeta Chibber, Meenu Maheshwari, Manish Singh Chundawat, Kriti Agarwal, Sarvshri Amit K Sagar, Gaurav Banyal

and Chandan Singh from INCLEN Executive Office, for their assistance during various phases of the exercise. Public-Private Partnership For Tuberculosis Control In India: Are The Private Practitioners Anywhere Near To Thisrntcp Sponsored Mission?

Prashanth Ashok Kumar[1], Ramaraju Karthikeyan[2] and Anupama Murthy Kaza[3]
[1](Medical Intern, PSG Institute of Medical Sciences and Research, India.)
[2,3](Department of Respiratory Medicine, PSG Institute of Medical Sciences and Research, India.)

Abstract:
Background: Revised National Tuberculosis Control Program (RNTCP) sponsored Public Private Partnership (PPP) is undermined by poor participation by private practitioners (PPs).There is an urgent need to realizefactors influencing private practitioners' preference of directly observed treatment short course (DOTS) for their patients. We attempted to study the knowledge and current practice characteristics of PPs while managing TB patients and to identify factors influencing their referral preferences for sputum microscopy and treatment under DOTS.
Methods: This was a cross-sectional survey involving 100 allopathic medical practitioners in private sector from an urban area. A self - designed and pretested questionnaire was administered to obtain data.
Results: The participants on an average managed 6.13 ± 14.87 patients with tuberculosis (TB). Most of them relied on sputum microscopy for diagnosis however only 49% referred their patients to Designated microscopy centres. A significant number participants still used serological and mantoux testing for diagnosing TB. Very few participants knew correct regimens, dosage and duration of anti TB therapy but only 46% referred their patients for DOTS based treatment. Frequent use of fluoroquinolones in anti TB therapy was noted. Factors predicting referrals to DOTS were younger age of participants,recent years in clinical practice with lesser outpatient turnover and better awareness about DOTS services. TB notification rate was low (41%) possibly due to lack of awareness about procedure involved .A lack of communication was noted between RNTCP staffs and participants indicating a significant drift in the "partnership"
Conclusion: This study has highlighted fallacies in TB management in private sector and identified correctable factors leading to sluggish involvement of PPs in DOTS based management. We recommend large scale interventional studies to evolve strategies for further strengthen the Public Private Partnership

Keywords: Public Private Partnership, Tuberculosis referral, Notification

I. Introduction

Global burden of tuberculosis is enormous and is increasing despite availability of good quality chemotherapy in organized regimens.Standardized diagnostic and therapeutic approach is the yardstick for unified struggle by mankind against Tuberculosis.World health organization declared TB as "Global Emergency" in 1993 and since then strongly advocates Directly Observed Treatment Short Course (DOTS) in standardized regimens delivered through national health programme across the world. Indiacontributes to about one third of global TB burden andhas gone a long way implementing DOTS through its Revised National Tuberculosis Control Program (RNTCP)[1]. Despite excellent coverage by RNTCP program, many patients with tuberculosis stillcontinue to seek other source of health care like practitioners modern and alternate medicine in private sector[2]. It is estimated that between 34% and 57% of tuberculosis cases are diagnosed and managed outside the public sector[3-5]. The same is also confirmed by studies on Anti TB drugs sales in India which show that the number of cases treated in the private sector alone exceeds estimated overall TB incidences[6].

While health sectors sponsored by government follow principles of DOTS, the status in private health sector is variable and often inappropriatevia improper use of diagnostic modalities, inadequate therapy and inadequate mechanisms to ensure compliance and adherence to therapy[7]. Realizing the importance of involving private health sector for effective control over tuberculosis in India, RNTCP implemented public-private partnership (PPP) during the last decade with only limited success. An attempt was made through mandatory notification since 2012, to bring into account all TB cases managed in private sector which also suffers with poor progress[8].There could be several reasons for sluggish participation of private practitioners in RNTCP which need tobe identified urgently in order to evolve strategies to improve this vital partnership. This study, using a self-designed questionnaire, attempted to study knowledge and practice characteristics of urban private medical practitioners in managing tuberculosis patients,their awareness about DOTS, aspects of notification and their level of interaction with RNTCP. The findings of this study will be useful in designing interventions to

Predicting Healthcare Utilization by Patients Admitted for COPD Exacerbation

KAVITHEYAN RAMARAJU, ANURADHA MURTHY KAZA, NITHILAVALLI BALASUBRAMANIAN, SIDDHURAJ CHANDRASEKARAN

ABSTRACT

Introduction: Chronic obstructive pulmonary disease (COPD) is a major cause of morbidity and mortality worldwide. Acute exacerbation of COPD (AECOPD) is a frequent cause for hospitalization. Predictors of healthcare utilization by patients admitted for AECOPD in resource limited settings are not well studied.

Aim: To characterize the pattern of healthcare utilization by patients hospitalized for AECOPD and to identify clinical factors and laboratory predictors of prolonged hospital stay (PHS) and prolonged intensive care (PIC).

Materials and Methods: This study involved retrospective data analysis, to identify risk factors and evolve prediction models for increased healthcare utilization namely PHS and PIC for AECOPD. The data were extracted from 255 eligible admissions for AECOPD in 166 patients from Aug 2012 to July 2013. A logistic regression analysis was used for identification of predictors and models were tested using receiver operating characteristic curve.

Results: Independent predictors of prolonged hospital stay (> 6 days) were chronic respiratory failure at baseline, low saturation (<90%), high HbA1c level and positive isolates in sputum. Independent predictors of prolonged intensive care (for 24 hours) were past history of pulmonary tuberculosis, chronic respiratory failure at baseline, low saturation at admission, high leukocyte count and positive culture isolates in sputum. Prediction models evolved from variables available at admission had AUC of 0.805 (95% CI 0.729 – 0.881) and 0.825 (95% CI 0.752 – 0.899) for PHS and ICU admissions respectively.

Conclusion: Our prediction models derived from simple and easily available variables show good discriminative properties in predicting PHS and PIC for AECOPD. When prospectively validated, these models are useful for rational allocation of services especially in resource limited settings.

Keywords: Length of hospital stay, Intensive care

INTRODUCTION

Chronic obstructive pulmonary disease (COPD) is a major cause of mortality and morbidity worldwide whose burden is projected to increase in near future [1,2]. Prevalence of COPD ranges from 0.8% to 6.0% globally [3-5]. Acute Exacerbation of Chronic Obstructive Pulmonary Disease (AECOPD) is an event in the natural course of disease which has significant negative impact on the lung function, quality of life and survival [6-8]. All-cause mortality of these patients is as high as 49% within 3 years after hospitalization for AECOPD [9,10]. Exacerbations also involve enormous cost burden, especially in hospitalized patients [11]. These implications of AECOPD have attracted many researchers to explore ways to predict and prevent this event of paramount clinical importance. Several studies have attempted to predict and thereby prevent the occurrence of AECOPD especially severe forms leading to hospitalization [9,12]. However, when these patients get hospitalized for AECOPD, only limited data are available on how they utilize healthcare facility.

Healthcare utilization by patients admitted for AECOPD is characterized by varying periods of hospital stay, pharmacy consumption, need for various diagnostic modalities and at times ICU admissions with ventilatory or other life support measures. These characteristics, in particular length of hospital stay and ICU admissions, determine the overall outcome of AECOPD in terms of morbidity and mortality [13]. An increased healthcare utilization also means enormous burden to resource limited peripheral centres where these patients may get admitted for AECOPD. In this context, prediction of increased healthcare utilization for AECOPD at the time of admission may be useful for individualizing therapeutic approach and for rational allocation of limited resources to needy patients. This study attempted to characterize the pattern of healthcare utilization by COPD patients hospitalized for acute exacerbation, and to identify clinical and laboratory predictors of 'prolonged hospital stay'(PHS) and 'prolonged intensive care'(PIC) which is, in turn, aimed at increased health care utilization by these patients.

MATERIALS AND METHODS

The study involved retrospective analysis of data from patients admitted with a primary diagnosis of AECOPD in a tertiary care teaching hospital in southern India, during a period from August 2012 to July 2013. After obtaining approval from the institutional ethics committee, the data were extracted from electronic medical database of the hospital using ICD-10 codes. Our review of past medical records revealed that the diagnosis of COPD in all patients was made based on spirometry along with characteristic clinical and radiological findings. Admissions for AECOPD were made when the patients had worsening breathlessness along with either increased prevalence or quantity of sputum, severe enough to warrant hospitalization. This a sample of eligible admissions for AECOPD was identified for data extraction. The extracted data included demographic details, co-morbidities, clinico-laboratory and treatment related variables during admission for AECOPD. Data from hospitalizations which culminated with either of death or transfer against medical advice were excluded for evaluating predictors of PHS but included for PIC. Burden of comorbidities was quantified by Charlson's comorbidity index. Exacerbations were categorized into three types based on the presenting symptoms of worsened breathlessness, sputum purulence and increased quantity of sputum as proposed by Anthonisen NR et al., [14]. Accordingly, type 1 exacerbation was defined when all three symptoms were present at the time of admission. Type 2

Effect of inhaled corticosteroids on systemic inflammation in asthma

Abstract

Background: Recent research using serum high sensitivity C-reactive protein (hs-CRP) has evidenced existence of low grade systemic inflammation in asthmatics whose correlation with various clinical indices is not fully studied. **Objective:** To investigate the relationship between systemic inflammation and various clinical and treatment characteristics of asthma. **Materials and Methods:** Forty asthmatics (22 steroid inhaling and 18 steroid naïve) and 40 healthy subjects matched for age and sex were examined cross-sectionally. Along with clinical assessment, serum hs-CRP levels were measured for all subjects using latex enhanced immunoturbidimetry method. **Results:** Serum hs CRP levels were significantly higher in steroid naïve asthmatics when compared to normal subjects (0.93 ± 1.18 vs 0.24 ± 0.31 mg/dl, respectively; Mann-Whitney U test, $P < 0.001$). This association persisted after adjusting for age, gender, body mass index (BMI), and socioeconomic status (adjusted odds ratio 10.47; 95% CI 1.88-58.3; $P < 0.01$). Steroid inhaling asthmatics had serum hs-CRP levels comparable with control group (0.17 ± 0.18 vs 0.24 ± 0.31 mg/dl respectively, $P > 0.05$). Among the clinical and treatment related variables, duration of inhaled steroids usage alone correlated significantly with serum hs-CRP levels (Pearson correlation coefficient r = 0.449, $P < 0.05$), which was independent of age, BMI, duration of illness, and frequency of emergency visits. **Conclusion:** This study confirms the existence of low grade systemic inflammation in asthma which is effectively controlled by inhaled steroids. Such an effect of inhaled steroids appears to be more pronounced in recent users than that of long-term users, possibly due to lower adherence rate among the latter.

Key words: Asthma, high sensitivity C-reactive protein, inhaled steroids, systemic inflammation

INTRODUCTION

Asthma is characterized by airway inflammation and hyperresponsiveness. Besides local inflammation, asthma is also

[illegible] systemic inflammation was evidenced by increased levels of plasma fibrinogen and serum amyloid A.[1] Serum C-reactive protein (CRP) levels have been used extensively as a surrogate marker of systemic inflammation in several diseases as well as to predict adverse cardiovascular events.[2] Estimation of high sensitivity CRP (hs-CRP) with its enhanced sensitivity is useful in conditions with low grade systemic inflammation like asthma. Defining the role of hs-CRP in asthma has been a topic of interest in recent research.

Is serum cholesterol a risk factor for asthma?

Karthikeyan Ramaraju, Srikanth Krishnamurthy, Sowthi Maamidi, Anupama Murthy Koza, Nithilavalli Balasubramanian

Department of Respiratory Medicine, PSG Institute of Medical Sciences and Research, Coimbatore, Tamil Nadu, India

ABSTRACT

Background: Proinflammatory role of serum cholesterol in asthma has been recently explored with contradicting results. Clarity on the link between serum cholesterol and asthma may lead to new evolutions in planning management strategies. The objective of our study was to examine the relationship between the serum cholesterol, asthma and its characteristics. Materials and Methods: A total of 40 asthmatics and 40 normal subjects were examined cross-sectionally and their serum fasting cholesterol and serum high sensitivity C reactive protein (hsCRP) levels were measured along with other baseline investigations. All subjects were non-smokers. Results: Serum total cholesterol (mean ± SD) among asthmatics was 176.45 ± 30.77 mgs/dL as compared to 163.33 ± 26.38 mgs/dL among normal subjects ($P < 0.05$). This higher serum cholesterol level was found to be associated with asthma independent of age, gender, body mass index (BMI), socio-economic status and serum hsCRP levels. However, the association was only modest (adjusted odds ratio 1.033; 95% confidence interval [CI] 1.008-1.059). There was no association between the serum cholesterol and asthma characteristics such as duration of illness, intake of inhaled steroids and frequency of emergency department visits. Other risk factors identified were poor ventilation (adjusted odds ratio 9.27; 95%CI 1.83-46.99) and overcrowding (adjusted odds ratio 41.9; 95% CI 3.15-557.46) at home. Conclusion: Our study found a modest but significant association between higher levels of serum cholesterol and asthma, which is independent of age, gender, BMI, socio-economic status and serum hsCRP. Future research is required in a larger population to substantiate above association and its clinical implications. Poor ventilation and overcrowding at home are risk factors for asthma possibly facilitating increased exposure to indoor allergens.

INTRODUCTION

Asthma currently affects about 300 million people worldwide;[1] and with this, number of patients seeking specialized asthma care has also increased.[2] Global Initiative for Asthma (GINA) 2011, has defined asthma as a chronic inflammatory disorder of the airways in which many cells and cellular elements play a role.[3] The chronic airway inflammation is associated with airway hyperresponsiveness that leads to recurrent episodes of wheezing, breathlessness, chest tightness, and coughing, particularly at night or in the early morning. Such a chronic inflammatory state in asthma is triggered and maintained at various levels by environmental factors. There are many host related factors that add upto inflammation and consequently increase the occurrence of asthma. One such proinflammatory host factor that has gained interest among researchers in recent years is serum cholesterol level. It is well established that hypercholesterolemia is associated with enhanced expression of proinflammatory mechanisms leading to increased levels of proinflammatory cytokines,[4] cellular adhesion molecules[5] and inflammation sensitive plasma proteins.[6]

Going by these proinflammatory properties, it has been hypothesized that serum cholesterol may also potentiate eosinophilic inflammation in those with genetic susceptibility for asthma thereby leading to its increased phenotypic expression [Figure 1]. Studies at cellular level[7] have indicated an undeniable role of

ABSTRACT

Context: It is well-documented that high-fidelity simulated training can be used to improve very important aspects of clinical interventions which include clinical decision-making, technical skills, soft skills like communication and leadership qualities. Many of the procedural skills can also be learnt effectively through simulations, using manikins of lower fidelity. **Aim:** Present report is an attempt to substantially enhance the 'must possess' attributes of a good clinician, which are quite often difficult to achieve by conventional teaching methods. **Methods:** This programme was aimed at providing training to the medical interns in cardiopulmonary resuscitation, as well as basic and advanced cardiac life support in medical emergencies, in an attempt to help them to efficiently manage commonly encountered cardiorespiratory emergencies. The programme was evaluated by comparing their performance before and after the intervention. **Results:** Their performance scores reflected the positive effects of the simulation-based teaching. In general, in addition to improving their skills in handling certain selected medical emergencies, the programme has also proved to enhance 'entrustable professional activities' of the young medical graduates. **Conclusion:** Our study, while highlighting the desirability of utilising simulation-based clinical training (SBCT), has also sought ways and means of incorporating SBCT as a mandated programme during the medical internship at an institutional level.

INTRODUCTION

The realm of medical education is undergoing significant changes globally. Some of these changes are warranted because of the great technological advances made in this field and others are due to an increasing awareness of patient safety measures warranted during the clinical procedures. The latter set of changes affects the general approach to patient care and calls for curricular changes to be brought in while training the medical undergraduate students, to effectively bring in the required attributes in the qualifying doctors. As it has been established that human error is a very significant factor as a cause for fatalities in a hospital, it is important to be able to avoid this single deterring factor while training the undergraduate medical students. There is increasing evidence to suggest that this can be achieved by effectively adopting simulation-based clinical training (SBCT), as an adjunct to conventional clinical teaching[1].

Competency-based medical education was advocated as an effective remedy for bringing in effective clinical training with consistency between different medical schools in terms of skills taught and competencies achieved[2]. In an effort to achieve this, many schools of medicine quite correctly thought of resorting to simulation-based medical education (SBME). Thus, in

Multimodal imaging of choroidal tubercles

T Lekha, Ramaraju Karthikeyan

Dr. T.M. Subba Rao, M.D.,
PRINCIPAL
PSG Institute of Medical Sciences
& Research / PSG Hospitals
Coimbatore - 641 004.

Key words: Choroidal tubercles, enhanced depth imaging spectral-domain optical coherence tomography, fundus autofluorescence imaging, near-infrared reflectance imaging

Case Report

A 39-year-old woman with disseminated tuberculosis and bilateral solitary choroidal tubercles [Fig. 1a and b] was subjected to multimodal imaging including enhanced depth imaging spectral-domain optical coherence tomography (EDI-OCT), near-infrared reflectance (NIR), and fundus autofluorescence (FAF) imaging. FAF imaging revealed hyperautofluorescent lesion with central hypoautofluorescence [Fig. 1c and d]. NIR imaging revealed hyperreflective lesion with a hyporeflective halo [Fig. 2a and c]. EDI-OCT [Fig. 2b and d] showed lobulated hyporeflective choroidal lesion with loss of vascular pattern and dome-shaped elevation of the overlying retina. Characteristic "increased transmission effect" was seen beneath the lesion. A small cap of subretinal fluid at the apex of lesion was noted in the right eye. Antituberculous therapy resulted in systemic improvement and regression of choroidal tubercles [Figs. 3 and 4 a–d].

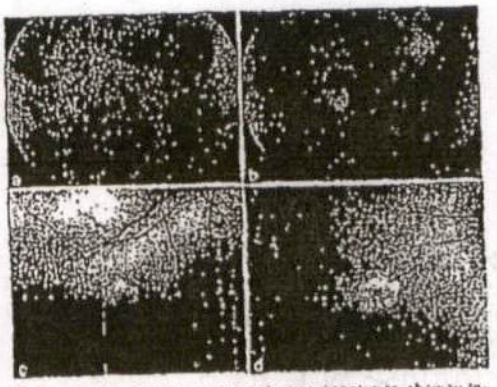

Figure 1: Color fundus photograph at presentation showing multiple yellowish nodular choroidal tubercles, temporal, in the right eye (a) nasally in the left eye (b). Corresponding fundus autofluorescence imaging showed the lesions as hyperautofluorescent with central hypoautofluorescent core (c and d)

Discussion

Characterization of choroidal lesions has evolved with the advent of modalities that enable imaging of the choroid and sclera (EDI-OCT); melanin, collagen, or fibrin (NIR imaging), and fluorophores (FAF).[1,2] EDI-OCT enables morphological evaluation of lesions, precise localization and measurement, and monitoring during treatment. NIR imaging which provides high-resolution in vivo images of subretinal pathologies demonstrated choroidal tubercles as hyperreflective due to unmasking of scleral collagen caused by defective choroidal pigmentation. There is only a single report of FAF imaging of choroidal tubercles.[3] Active lesion was hyperautofluorescent due to increased lipofuscin in the diseased retinal pigment epithelium (RPE), and the central hypoautofluorescence could be due to absent RPE, sparse lipofuscin, or secondary retinal infiltration. Posttreatment lesion may become isohypoautofluorescent. This FAF pattern is distinct from the heterogeneous appearance of choroidal metastasis, amelanotic melanomas, or nevus which results from lipofuscin, fluid, or RPE atrophy.[4,5] Thus, combined imaging helped to evaluate and monitor the chorioretinal pathology noninvasively in our patient with choroidal tubercles. Immunohistochemical studies of excised tuberculous pulmonary granulomas have shown that increased accumulation of lipid-rich caseum in the granulomas due to dysregulation in the host lipid metabolism signifies the progression of latent disease to active infection.[6] Further studies with FAF might help to detect similar changes in choroidal granulomas in vivo and thus obtain valuable insights into our understanding of ocular tuberculosis.

Allergic Bronchopulmonary Aspergillosis Complicating Childhood Asthma

Sunil K. Chhabra, Sandeep Sahay and Karthikeyan Ramaraju

Department of Cardiorespiratory Physiology, Clinical Research Centre, Vallabhbhai Patel Chest Institute, University of Delhi, Delhi, India

ABSTRACT

While Allergic bronchopulmonary aspergillosis (ABPA) is known to complicate asthma in adults, its association with childhood asthma is very rare. We present two patients, a four-and half year old boy who presented with severe asthma and a 12 year-old girl whose previous chest radiographs revealed fleeting opacities. Both were diagnosed to be suffering from ABPA. [Indian J Pediatr 2009; 76 (3) : 331-332] *E-mail: skchhabra@mailcity.com*

Key words: Allergic bronchopulmonary aspergillosis; Asthma; Aspergillus

Allergic bronchopulmonary aspergillosis (ABPA), one of the spectrum of lung diseases caused by *Aspergillus* species, is a result of colonization of the fungus in the airways and the development of hypersensitivity to its antigens. It has been well documented as a complication of severe asthma in adults.[1] However, it is very rare in children except in association with cystic fibrosis[2]. Untreated or diagnosed late, ABPA may lead to parenchymal and airway damage terminating in respiratory failure and cor-pulmonale. A high degree of suspicion and application of well-defined major and minor diagnostic criteria should usually provide the diagnosis.[3] In view its rarity, we present two cases of ABPA complicating child hood asthma.

CASE REPORTS

Case 1

A four and a half year old boy presented with complaints of recurrent episodes of wheezing and cough with occasional passage of bronchial plugs of sputum since infancy. He had had frequent exacerbations sometimes with low-grade pyrexia and required hospitalizations. He also had nasal blockage and a family history of atopy. There was no history of gastrointestinal disturbances. The child was observed to be in respiratory distress with an arterial oxygen saturation of 84%. Auscultation of chest revealed bilateral diffuse polyphonic rhonchi. Treatment with oxygen and oral and nebulized corticosteroids/bronchodilators was instituted.

Total white blood count was 18,300/cmm with 7% eosinophils. PA Chest radiograph was not remarkable. In view of recurrent exacerbations of symptoms and mucoid sputum plugs, a diagnosis of bronchial asthma complicated by ABPA was considered. A contrast enhanced computed tomography (CECT) of the thorax revealed central bronchiectasis with normal tapering distally. A diagnosis of ABPA was suspected. Serum precipitins were detected against *Aspergillus Fumigatus*. Skin prick tests (1:10 dilutions) revealed positive type I reactions with *Aspergillus Niger* and *Aspergillus Fumigatus*. Serum total IgE level was 1947 IU/ml. (normal: 0-90 IU/ml). Specific IgG against *Aspergillus Fumigatus* was positive while specific IgE against the same was 4.5 (normal: 0.35 kU/L). Thus, the diagnosis of ABPA was confirmed by these criteria. Absence of eosinophilia may have been the result of treatment taken outside before presentation, possibly corticosteroids. This can produce substantial declines in eosinophil counts.

The child was started on oral prednisolone 1mg/kg/day for two weeks followed by an alternate day schedule along with a combination of inhaled formoterol and budesonide. He responded favourably to the treatment.

Case 2

A thin-built 12-year-old girl presented with recurrent wheezing with productive cough for the last two years. Family history of atopy was present. A review of serial chest radiographs done over last one year showed 'fleeting shadows'. Sputum examination for

UNUSUAL PRESENTATION OF AN UNCOMMON LUNG MALIGNANCY

Ramaraju K[1], Aggarwal B[1], Kularathe R[1], Chhabra SK[1]

ABSTRACT

Combined type of small cell lung carcinoma (SCLC) is a rare malignancy and the lung that is usually peripheral and diagnosed after resection. We report an unusual case of centrally located combined SCLC with squamous cell component that was diagnosed on endobronchial lung biopsy.

Lung India 2008; 25 : 132-134

Key words : Lung cancer, Combined carcinoma

INTRODUCTION

Small cell lung carcinoma (SCLC) accounting for 20-25% of all lung cancers, remains one of the most frequently diagnosed cancers and the most common cause of cancer deaths worldwide[1,2]. Combined type has been reported to occur in 1-3% of all cases of SCLC. These tumours contain of SCLC with a component of squamous cell carcinoma and/ or adenocarcinoma[3]. The rarity and heterogeneity of the tumour make the identification of combined SCLC difficult. Most are peripheral and diagnosed after resection. We report an unusual case of centrally located combined SCLC with squamous cell component that was diagnosed on endobronchial lung biopsy.

CASE REPORT

A 65 year-old male patient, current smoker (50 pack years) presented with complaints of dry cough and breathlessness for the past two months. He was also on treatment for hypertension for the last 3 years. Physical examination revealed no pallor, clubbing or lymphadenopathy. Examination of the respiratory system was not remarkable. The complete blood counts, electrocardiograph, and liver and kidney function tests (biochemistry) were within normal limits. The chest radiograph postero-anterior (PA) view taken one month apart showed a progressing mass lesion in the left paratracheal and parahilar region. Contrast enhanced computed tomography scan of the chest revealed a mass lesion with peripheral enhancement in the left hilum compressing the left main bronchus and encroaching on the wall of the descending aorta (Fig 1). Subcarinal lymph nodes were enlarged. Spirometry showed moderately

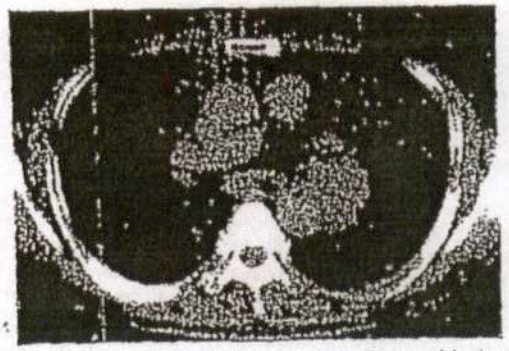

Fig.1 : Contrast enhanced computed tomography scan of the chest showing the left hilar mass compressing the left main bronchus and enlarged subcarinal lymph nodes.

severe airflow limitation with FEV_1/FVC of 68%, forced expiratory volume in one second (FEV_1) of 56% predicted and forced vital capacity (FVC) of 67% predicted. Change after bronchodilator was not significant. Fibreoptic bronchoscopy under local anesthesia revealed extramural compression superomedially in the left main bronchus. A smooth surfaced growth was seen just beyond the compression. The overlying mucosa was hyperemic and the growth bled on touch. Biopsy was taken.

Bronchial aspirate did not show any atypical cells on microscopic examination. However, post-bronchoscopy sputum showed a cluster of small atypical cells with dark blue hyperchromatic nuclei, nuclear overlapping and scant cytoplasm. Occasional singly arranged atypical keratinized squamous cells having irregular, angulated cytoplasmic

Abstract
Background: Frequent coexistence of Chronic Obstructive Pulmonary Disease (COPD) and Ischemic Heart Disease (IHD) is often speculated to be related to lipid abnormalities. However studies reveal contradicting results, thus raising serious doubts about higher prevalence of dyslipidemia as reason for this coexistence. The objectives of this study were to examine the characteristics of lipid metabolism in COPD and to evaluate causal association between dyslipidemia and IHD among COPD subjects
Methods: This was a retrospective analysis of data from 98 COPD subjects randomly selected from the hospital medical records database. All eligible subjects were males with current or past history of smoking, with no evidence of active infections, chronic inflammatory disease or malignancy. Must had history of statin intake prior to index measurement of lipid profile. Data extracted were analyzed using SPSS 19 version. A recently published data from reference population were used for comparison.
Results: Most prevalent comorbidities were systemic hypertension (SHT), IHD and diabetes mellitus (DM). Prevalence of IHD was significantly higher than the reference population. Prevalence of hypertriglyceridemia was significantly lower in COPD subjects who also had low mean total cholesterol level than the reference population. On logistic regression analysis, elderly age and low HDL cholesterol predicted coexistence of IHD among COPD subjects independent of DM, SHT and duration of COPD. Other lipid parameters were not associated with increased prevalence of IHD among the study subjects.
Conclusion: This study has highlighted that atherogenic pattern of lipid profile among COPD subjects was comparable with that of reference population. Increased risk of IHD among COPD patients appears to be related to factors other than quantitative aspects of lipid metabolism/dyslipidemia which warrants investigations.

Keywords: Chronic obstructive pulmonary disease, ischemic heart disease, dyslipidemia.

I. Introduction

Chronic obstructive pulmonary disease (COPD) is a preventable and treatable disease characterized by chronic airway inflammation in response to noxious stimuli resulting in airflow obstruction that is not fully reversible (1). World health organization predicts that by 2020, COPD will become third leading cause of death (currently fourth) and fifth leading cause of disability (currently twelfth) worldwide (2, 3). COPD has many extra-pulmonary manifestations of which ischemic heart disease (IHD) coexist frequently with COPD determining its morbidity and mortality rates. Large population based studies have also shown that COPD patients are two or three times more at risk for cardiovascular mortality which accounts for about 50% of the total number of deaths (4, 5, 6). The pathogenetic mechanism of this coexistence, though is unclear, is frequently speculated to be related to lipid metabolism in COPD patients. A deranged lipid profile is expected in COPD, for various reasons like smoking, age factor, steroid intake etc. However several studies have raised serious doubts about whether dyslipidemic state is characteristic for COPD and whether it can explain the increased risk of ischemic heart disease in these patients. This study is intended to clear these doubts with specific focus on quantitative lipid profile of COPD patients and its association with prevalence of ischemic heart disease in this subset of general population. COPD and IHD being two of top five major killer diseases, the rationale behind this study is to identify pathogenetic mechanisms linking these diseases that might open up therapeutic potential to contain the mortality and morbidity in above settings.

II. Materials And Methods

It was a retrospective analysis of data from 98 consecutive COPD subjects visiting a tertiary care chest clinic, aged 40 years and above, whose index measurement of lipid profile was documented prior to any history of statins / steroids intake. The eligible subjects registered during a period from January 2014 to December 2014, were recruited by random sampling method, whose files were then used for data extraction. All recruited subjects were free from active infections and did not have other chronic inflammatory diseases during the index

PSG Institute of Medical Sciences and Research, Coimbatore, Tamil Nadu, India

Abstract:

Background

Medical education is rapidly evolving field with paradigm shift from information to competency based skills. Simulation has been accepted as an ethical tool, but not been incorporated into medical curriculum. We assessed the ability of residents during internship to manage respiratory emergencies and evaluated simulation as education and assessment tool

Method:

A prospective study was done with forty three residents during the internship period, which had completed emergency medicine postings. They were assessed in clinical knowledge by questionnaire and clinical skills were assessed by checklist scores in three common respiratory emergencies. The knowledge gained after the workshop was reassessed with post tests questionnaire. We evaluated student feedback with questionnaire responses

Results

43 interns were included in the study. All of them had completed respiratory medicine postings, during internship. Checklist scoring was done for five core competencies sub competencies were scored and validated with subject experts[cut off > 75%]There was remarkable difference in pre and post test scores with a mean which was statistically significant. Only 55.6% demonstrated skills in clinical knowledge with lowest scores (23%) at problem based learning. Core competencies which needed to be strengthened by practice and reinforcement were identified. Students felt that such training need to be extended for other medical emergencies and they wanted such training to be integrated in their curriculum.

Conclusion

Simulation based workshop is effective tool to teach respiratory emergencies and should be incorporated in medical curriculum as an education and assessment tool.

Keywords: Simulation based clinical training, Respiratory emergencies, Assessment tool

1. Introduction

Medical education is rapidly evolving field with paradigm shift from information to competency based skills. An important outcome of medical undergraduate training is that at the end of training, they should be able to manage range of clinical emergencies. Much evidence exists in previous studies that clinical skills may be taught poorly and students may not be able to handle demands of training during internship (1). Clinical knowledge is gained through reading, lectures, tutorials, seminars and bedside clinics. Even though clinical simulation has been accepted as an ethical tool, it has not been incorporated into medical curriculum (2-4). Simulation based workshops are effective and should be incorporated into medical curriculum which will help for

Public-Private Partnership For Tuberculosis Control In India: Are The Private Practitioners Anywhere Near To Thisrntcp Sponsored Mission?

Prashanth Ashok Kumar[1], Ramaraju Karthikeyan[2] and Anupama Murthy Kaza[3]
[1](Medical Intern, PSG Institute of Medical sciences and Research, India.)
[2](Department of Respiratory Medicine, PSG Institute of Medical Sciences and Research, India.)

Abstract:
Background: Revised National Tuberculosis Control Program (RNTCP) sponsored Public Private Partnership (PPP) is undermined by poor participation by private practitioners (PPs).There is an urgent need to realizefactors influencing private practitioners' preference of directly observed treatment short course (DOTS) for their patients. We attempted to study the knowledge and current practice characteristics of PPs while managing TB patients and to identify factors influencing their referral preferences for sputum microscopy and treatment under DOTS.
Methods: This was a cross-sectional survey involving 100 allopathic medical practitioners in private sector from an urban area. A self - designed and pretested questionnaire was administered to obtain data.
Results: The participants on an average managed 6.15 ± 14.87 patients with tuberculosis (TB). Most of them relied on sputum microscopy for diagnosis however only 49% referred their patients to Designated microscopy centres. A significant number participants still used serological and mantoux testing for diagnosing TB. Very few participants knew correct regimens, dosage and duration of anti TB therapy but only 46% referred their patients for DOTS based treatment. Frequent use of fluoroquinolones in anti TB therapy was noted. Factors predicting referrals to DOTS were younger age of participants,recent years in clinical practice with lesser outpatient turnover and better awareness about DOTS services. TB notification rate was low (41%) possibly due to lack of awareness about procedure involved. A lack of communication was noted between RNTCP staffs and participants indicating a significant drift in the "partnership".
Conclusion: This study has highlighted fallacies in TB management in private sector and identified correctable factors leading to sluggish involvement of PPs in DOTS based management. We recommend large scale interventional studies to evolve strategies for further strengthen the Public Private Partnership.
Keywords: Public Private Partnership, Tuberculosis referral, Notification

I. Introduction

Global burden of tuberculosis is enormous and is increasing despite availability of good quality chemotherapy in organized regimens.Standardized diagnostic and therapeutic approach is the yardstick for unified struggle by mankind against Tuberculosis.World health organization declared TB as "Global Emergency' in 1993 and since then strongly advocates Directly Observed Treatment Short Course (DOTS) in standardized regimens delivered through national health programme across the world. Indiacontributes to about one third of global TB burden andhas gone a long way implementing DOTS through its Revised National Tuberculosis Control Program (RNTCP)[1]. Despite excellent coverage by RNTCP program, many patients with tuberculosis stillcontinue to seek other source of health care like practitioners modern and alternate medicine in private sector[2]. It is estimated that between 34% and 57% of tuberculosis cases are diagnosed and managed outside the public sector[5-8]. The same is also confirmed by studies on Anti TB drugs sales in India which show that the number of cases treated in the private sector alone exceeds estimated overall TB incidences[9].

While health sectors sponsored by government follow principles of DOTS, the status at private health sector is variable and often inappropriatevia improper use of diagnostic modalities, inadequate therapy and inadequate mechanisms to ensure compliance and adherence to therapy[2]. Realizing the importance of involving private health sector for effective control over tuberculosis in India, RNTCP implemented public-private partnership (PPP) during the last decade with only limited success. An attempt was made through mandatory notification since 2012, to bring into account all TB cases managed in private sector which also suffers with poor progress[4].There could be several reasons for sluggish participation of private practitioners in RNTCP which need tobe identified urgently in order to evolve strategies to improve this vital partnership. This study,

Predicting Healthcare Utilization by Patients Admitted for COPD Exacerbation

KARTHIKEYAN RAMARAJU[1], ANUPAMA MURTHY KAZA[2], NITHILAVALLI BALASUBRAMANIAN[3], SIDDHURAJ CHANDRASEKARAN[4]

ABSTRACT

Background: Healthcare utilization, especially length of hospital stay and ICU admission, for acute exacerbation of chronic obstructive pulmonary disease (AECOPD) determine overall outcomes in terms of morbidity, mortality and cost burden. Predicting prolonged hospital stay (PHS) and prolonged intensive care (PIC) for AECOPD is useful for rational allocation of resources in healthcare centres.

Aim: To characterize the pattern of healthcare utilization by COPD patients hospitalized for acute exacerbation, and to identify clinical and laboratory predictors of 'prolonged hospital stay' (PHS) and 'prolonged intensive care' (PIC).

Materials and Methods: This study attempted through retrospective data analysis, to identify risk factors and evolve prediction models for increased healthcare utilization namely PHS and PIC for AECOPD. The data were extracted from 255 eligible admissions for AECOPD by 166 patients from Aug 2012 to July 2013. Logistic regression analysis was used for identifying predictors and models were tested with area under receiver operating characteristic curve.

Results: Independent predictors of prolonged hospital stay (≥ 6 days) were chronic respiratory failure at baseline, low saturation at admission, high HbA1c level and positive isolates in sputum culture. Independent predictors of prolonged intensive care (for ≥ 48 hours) were past history of pulmonary tuberculosis, chronic respiratory failure at baseline, low saturation at admission, high leukocyte count and positive culture isolates in sputum. Prediction models evolved from variables available at admission showed AUC 0.805 (95% CI 0.729 – 0.881) and 0.825 (95% CI 0.75 – 0.90) for PHS and ICU admissions respectively.

Conclusion: Our prediction models derived from simple and easily available variables show good discriminative properties in predicting PHS and PIC for AECOPD. When prospectively validated, these models are useful for rational allocation of services especially in resource limited settings.

Keywords: Length of hospital stay, Intensive care

INTRODUCTION

Chronic obstructive pulmonary disease (COPD) is a major cause of mortality and morbidity worldwide whose burden is projected to increase in near future [1,2]. Prevalence of COPD ranges from 0.8% to 6.0% globally [3-5]. Acute Exacerbation of Chronic Obstructive Pulmonary Disease (AECOPD) is an event in the natural course of disease which has significant negative impact on the lung function, quality of life and survival [6-8]. All-cause mortality of these patients is as high as 49% within 3 years after hospitalization for AECOPD [9,10]. Exacerbations also involve enormous cost burden, especially in hospitalized patients [11]. These implications of AECOPD have attracted many researchers to explore ways to predict and prevent this event of paramount clinical importance. Several studies have attempted to predict and thereby prevent the occurrence of AECOPD especially severe forms leading to hospitalization [9,12]. However, when these patients get hospitalized for AECOPD, only limited data are available on how they utilize healthcare facility.

Healthcare utilization by patients admitted for AECOPD is characterized by varying periods of hospital stay, pharmacy consumption, need for various diagnostic modalities and at times ICU admissions with ventilatory or other life support measures. These characteristics, in particular length of hospital stay and ICU admissions, determine the overall outcome of AECOPD in terms of morbidity and mortality [13]. An increased healthcare utilization also means enormous burden to resource limited peripheral centres where these patients may get admitted for AECOPD. of healthcare utilization by COPD patients hospitalized for acute exacerbation, and to identify clinical and laboratory predictors of 'prolonged hospital stay' (PHS) and 'prolonged intensive care' (PIC) which in this study, defined increased health care utilization by these patients.

MATERIALS AND METHODS

This study involved retrospective analysis of data from patients admitted with a primary diagnosis of AECOPD in a tertiary care teaching hospital in southern India, during a period from August 2012 to July 2013. After obtaining approval from the institutional ethics committee, the data were extracted from electronic medical database of the hospital using ICD-10 codes. Our review of past medical records revealed that the diagnosis of COPD in all patients was made based on spirometry along with characteristic clinical and radiological findings. All admissions for AECOPD were made when the patients had worsening breathlessness along with either increased purulence or quantity of sputum, severe enough to warrant hospitalization. Thus a sample of eligible admissions for AECOPD was identified for data extraction. The extracted data included demographic details, co-morbidities, clinico-laboratory and treatment related variables during admission for AECOPD. Data from hospitalizations which culminated with either of death or discharge against medical advice were excluded for evaluating predictors of PHS but included for PIC. Burden of co-morbidities was quantified by Charlson's co-morbidity index. Exacerbations were categorized into three types based on the presenting

Abstract

Background: Recent research using serum high sensitivity C-reactive protein (hs-CRP) has evidenced existence of low grade systemic inflammation in asthmatics whose correlation with various clinical indices is not fully studied. **Objective:** To investigate the relationship between systemic inflammation and various clinical and treatment characteristics of asthma. **Materials and Methods:** Forty asthmatics (22 steroid inhaling and 18 steroid naïve) and 40 healthy subjects matched for age and sex were examined cross-sectionally. Along with clinical assessment, serum hs-CRP levels were measured for all subjects using latex enhanced immunoturbidometry method. **Results:** Serum hs CRP levels were significantly higher in steroid naïve asthmatics when compared to normal subjects (0.93 ± 1.18 vs 0.24 ± 0.31 mg/dL, respectively; Mann-Whitney U test, $P < 0.001$). This association persisted after adjusting for age, gender, body mass index (BMI), and socioeconomic status (adjusted odds ratio 10.47; 95% CI 1.88-58.3; $P < 0.01$). Steroid inhaling asthmatics had serum hs-CRP levels comparable with control group (0.17 ± 0.18 vs 0.24 ± 0.31 mg/dL respectively, $P > 0.05$). Among the clinical and treatment related variables, duration of inhaled steroids usage alone correlated significantly with serum hs-CRP levels (Pearson correlation coefficient r = 0.449, $P < 0.05$), which was independent of age, BMI, duration of illness, and frequency of emergency visits. **Conclusion:** This study confirms the existence of low grade systemic inflammation in asthma which is effectively controlled by inhaled steroids. Such an effect of inhaled steroids appears to be more pronounced in recent users than that of long-term users, possibly due to lower adherence rate among the latter.

Key words: Asthma, high sensitivity C-reactive protein, inhaled steroids, systemic inflammation

INTRODUCTION

Asthma is characterized by airway inflammation and hyperresponsiveness. Besides local inflammation, asthma is also found to have systemic inflammation as evidenced by increased levels of plasma fibrinogen and serum amyloid A.[1] Serum C reactive protein (CRP) levels have been used extensively as a surrogate marker of systemic inflammation in several chronic diseases as well to predict adverse cardiovascular events.[2-4] Estimation of high sensitivity CRP (hs-CRP) with its enhanced sensitivity is useful in conditions with low grade systemic inflammation like asthma. Defining the role of hs-CRP in asthma has been a topic of interest in recent research.

Is serum cholesterol a risk factor for asthma?

Karthikeyan Ramaraju, Srikanth Krishnamurthy, Smrithi Maamidi, Anupama Murthy Kaza, Nithilavalli Balasubramaniam

Department of Respiratory Medicine, PSG Institute of Medical Sciences and Research, Coimbatore, Tamil Nadu, India

ABSTRACT

Background: Proinflammatory role of serum cholesterol in asthma has been recently explored with contradicting results. Clarity on the link between serum cholesterol and asthma may lead to new evolutions in planning management strategies. The objective of our study was to examine the relationship between the serum cholesterol, asthma and its characteristics. **Materials and Methods:** A total of 40 asthmatics and 40 normal subjects were examined cross-sectionally and their serum fasting cholesterol and serum high sensitivity C reactive protein (hsCRP) levels were measured along with other baseline investigations. All subjects were non-smokers. **Results:** Serum total cholesterol (mean ± SD) among asthmatics was 176.45 ± 30.77 mgs/dL as compared to 163.33 ± 26.38 mgs/dL among normal subjects ($P < 0.05$). This higher serum cholesterol level was found to be associated with asthma independent of age, gender, body mass index (BMI), socio-economic status and serum hsCRP levels. However, the association was only modest (adjusted odds ratio 1.033; 95% confidence interval [CI] 1.008-1.059). There was no association between the serum cholesterol and asthma characteristics such as duration of illness, intake of inhaled steroids and frequency of emergency department visits. Other risk factors identified were poor ventilation (adjusted odds ratio 9.27; 95% CI 1.83-46.99) and overcrowding (adjusted odds ratio 41.9; 95% CI 3.15-557.46) at home. **Conclusion:** Our study found a modest but significant association between higher levels of serum cholesterol and asthma, which is independent of age, gender, BMI, socio-economic status and serum hsCRP. Future research is required in a larger population to substantiate above association and its clinical implications. Poor ventilation and overcrowding at home are risk factors for asthma possibly facilitating increased exposure to indoor allergens.

KEY WORDS: Asthma, cholesterol, high sensitivity C reactive protein, indoor hygiene, inflammation

Address for correspondence: Dr. Srikanth Krishnamurthy, Department of Respiratory Medicine, PSG Institute of Medical Sciences and Research, Coimbatore, Tamil Nadu, India. E-mail: drsrikanthcbe@gmail.com

INTRODUCTION

Asthma currently affects about 300 million people worldwide,[1] and with this, number of patients seeking specialized asthma care has also increased.[2] Global Initiative for Asthma (GINA) 2011, has defined asthma as a chronic inflammatory disorder of the airways in which many cells and cellular elements play a role.[3] The chronic airway inflammation is associated with airway hyperresponsiveness that leads to recurrent episodes of wheezing, breathlessness, chest tightness, and coughing, particularly at night or in the early morning. Such a chronic inflammatory state in asthma is triggered and maintained at various levels by environmental factors. There are many host related factors that add upto inflammation and consequently increasing the occurrence of asthma. One such proinflammatory host factor that has gained interest among researchers in recent years is serum cholesterol level. It is well established that hypercholesterolemia is associated with enhanced expression of proinflammatory mechanisms leading to increased levels

ABSTRACT

Context: It is well-documented that high-fidelity simulated training can be used to improve very important aspects of clinical interventions which include clinical decision-making, technical skills, soft skills like communication and leadership qualities. Many of the procedural skills can also be learnt effectively through simulations, using manikins of lower fidelity. **Aim:** Present report is an attempt to substantially enhance the 'must possess' attributes of a good clinician, which are quite often difficult to achieve by conventional teaching methods. **Methods:** This programme was aimed at providing training to the medical interns in cardiopulmonary resuscitation, as well as basic and advanced cardiac life support in medical emergencies, in an attempt to help them to efficiently manage commonly encountered cardiorespiratory emergencies. The programme was evaluated by comparing their performance before and after the intervention. **Results:** Their performance scores reflected the positive effects of the simulation-based teaching. In general, in addition to improving their skills in handling certain selected medical emergencies, the programme has also proved to enhance 'entrustable professional activities' of the young medical graduates. **Conclusion:** Our study, while highlighting the desirability of utilising simulation-based clinical training (SBCT), has also sought ways and means of incorporating SBCT as a mandated programme during the medical internship at an institutional level.

INTRODUCTION

The realm of medical education is undergoing significant changes globally. Some of these changes are warranted because of the great technological advances made in this field and others are due to an increasing awareness of patient safety measures warranted during the clinical procedures. The latter set of changes affects the general approach to patient care and calls for curricular changes to be brought in while training the medical undergraduate students, to effectively bring in the required attributes in the qualifying doctors. As it has been established that human error is a very significant factor as a cause for fatalities in a hospital, it is important to be able to avoid this single deterring factor while training the undergraduate medical students. There is increasing evidence to suggest that this can be achieved by effectively adopting simulation-based clinical training (SBCT), as an adjunct to conventional clinical teaching[1].

Competency-based medical education was advocated as an effective remedy for bringing in effective clinical training with consistency between different medical schools in terms of skills taught and competencies achieved[2]. In an effort to achieve this, many schools of medicine quite correctly thought of resorting to simulation-based medical education (SBME). Clinical

Abstract

Background

India is the second most populous country in the world, but India has more new TB cases than any other country, with high mortality. Under Revised National Tuberculosis Control Programme, much emphasis has been laid on health education and counselling of tuberculosis patients to ensure adherence to treatment and achieve 95% cure rate. Not many studies have been done among paramedical students to assess adequacy of knowledge on tuberculosis.

Aim

The aim of this study is to evaluate knowledge, attitude and practice skills in tuberculosis care amongst final year students of undergraduate paramedical courses (pharmacy, physiotherapy and nursing) and also to evaluate differences of awareness between them.

Methodology

This study was a cross-sectional survey conducted for final year students of nursing, physiotherapy and pharmacy using a self-administered questionnaire designed and validated by a panel of subject experts. In all, 152 students were surveyed and data collected were analysed with SPSS software.

Results

The present study showed that adequacy of knowledge about tuberculosis amongst final year paramedical students was generally low. Adequacy of knowledge on tuberculosis was better amongst physiotherapy and nursing students as compared with pharmacy students. On the contrary, knowledge on how to diagnose case of tuberculosis was better amongst pharmacy students (53.3%) compared with physiotherapy and nursing students. Knowledge on special topics like multidrug-resistant tuberculosis and public health was lacking amongst all these categories.

Conclusion

Overall and domain-specific knowledge is found to be poor among final year paramedical students. Improvement in knowledge is expected to aid in primary and secondary prevention against tuberculosis.

Tuberculosis-Associated Chylothorax: Case Report and Systematic Review of the Literature

Srinivas Rajagopala Roopa Kancherla Ramanathan Palaniappan Ramanathan

Department of Pulmonary Medicine, PSG Institute of Medical Sciences and Research, Peelamedu, Coimbatore, India

Established Facts

- Trauma is the most common cause of chylothorax.
- Tuberculosis (TB) is described as a cause of nontraumatic chylothorax, but several large series do not include any patients with TB-chylothorax.

Novel Insights

- TB is a very rare cause of chylothorax with only 37 cases reported in the literature.
- TB-chylothorax developed subsequent to the diagnosis of TB in 27.8% (10/36) of the patients after a median of 6.75 weeks (IQR 4–9) while on anti-TB treatment.
- TB-chylothorax developed during an immune reconstitution syndrome in 16.7% (6/36) of the patients, even in immunocompetent ones.
- TB-chylothorax developed in the absence of any mediastinal lymphadenopathy in 45.9% (17/37) of the patients; 13.5% (5/37) had isolated tubercular empyema alone.
- TB-chylothorax developed along with chylous ascites in 10.8% (4/37) of the patients.
- Most patients with TB-chylothorax responded to anti-TB treatment and dietary manipulation alone, and only 17.1% (6/35) needed thoracic duct ligation.

Keywords
Tuberculosis · Chylothorax · Pleural effusion · Chylomicron

Abstract
Tuberculosis (TB) is a rare cause of chylothorax. We describe a case and the results of a systematic review of all reported cases of TB-chylothorax. We identified 37 cases of TB-chylothorax. The symptoms at presentation were constitutional (85.7%; 30/35), dyspnea (60.6%; 20/33), and cough (54.5%; 18/33). Chylothorax developed subsequent to the diagnosis of TB in 27.8% (10/36) of the patients, after a median of 6.75 weeks (IQR 4–9). Chylothorax developed during an immune reconstitution syndrome (IRS) in 16.7% (10/36) of the patients, including immunocompetent ones. TB was disseminated in 45.9% (17/37) of the patients at the diagnosis of chylothorax. Chylothorax developed in the absence of any mediastinal lymphadenopathy in 45.9% (17/37) of the patients; 13.5% (5/37) had isolated tubercular empyema alone. The diagnosis of TB was established microbiologically in

72.2% (26/36) and by biopsy alone in 27.8% (9/36) of the patients. Anti-TB treatment (ATT) was administered for a median of 7.57 months (IQR 6–9). Steroids were administered to 22.9% (8/35) of the patients, often for suspected IRS. Thoracic duct ligation and octreotide were required for only 17.1% (6/35) and 8.6% (3/35) of the patients, respectively. In all, 94.4% (34/36) of the patients had resolution of chylothorax and completed treatment successfully; only 5.6% (2/36) died. In conclusion, TB-chylothorax may develop without obvious mediastinal lymphadenopathy and be associated with tubercular empyema alone. TB-chylothorax can develop during treatment of TB due to IRS, even in immunocompetent patients. ATT and dietary manipulation are associated with good resolution and low mortality, and duct ligation is needed for only a small minority of patients.

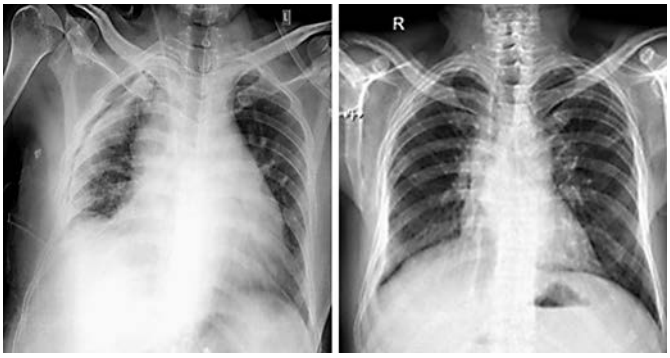

Fig. 1. Left: chest radiograph at diagnosis showing a right pyopneumothorax with pleural thickening and intercostal drain in situ. Right: chest radiograph at completion of anti-tuberculosis treatment showing significant interval resolution with minimal pleural thickening.

Introduction

Tuberculosis (TB) continues to be a global scourge. India has the highest TB burden and accounts for approximately more than one-fifth (21%) of the global disease burden, with recently revised higher estimates of disease burden [1, 2]. Chylothorax is characterized by the presence of chyle in the pleural space due to thoracic duct disruption [3, 4]. Accumulation of cholesterol or lecithin-globulin complexes in pleural fluid of long-standing effusions can occur and is described as a pseudochylothorax [3, 5]. TB is a well-described cause of pseudochylothorax [5]; the association of TB with chylothorax, however, is very rare but has been described. The mechanisms of development of chylothorax in TB (TB-chylothorax), clinical features, radiological findings, mode of diagnosis, and management aspects are unclear.

Case Report

A 50-year-old gentleman with diabetes mellitus of 5 years duration presented with productive cough for 15 days, intermittent fever, and right-sided pleuritic chest pain of 1-week duration. Chest radiography (Fig. 1, left) confirmed a right-sided pleural effusion, and diagnostic thoracocentesis showed pus-like material; an intercostal tube drain was inserted, and he was referred to this center for persisting purulent drainage from the drain. There was no history of trauma, anorexia, or weight loss. He did not report any significant illness in his family or contact with TB, did not smoke or drink alcohol, and did not raise pets. The examination showed pallor, pedal pitting edema, a regular heart rate of 72/min, and a blood pressure of 120/70 mm Hg. There was no evidence of alveolopleural fistulae, and the intercostal drain continued to drain 750 mL/day of whitish fluid.

Chest radiography showed a right pyopneumothorax (Fig. 1, left). Hemoglobin was at 6.9 g/dL, with normal leukocyte and platelet counts. Renal function testing showed renal failure with serum creatinine at 9.4 mg/dL (normal 0.8–1.0). Urine microscopy showed bland sediments without albuminuria. Ultrasound showed a normal kidney size with increased renal cortical echogenicity. Arterial blood gas showed metabolic acidosis (pH 7.25, HCO_3 14 mEq/L, pCO_2 30 mm Hg, anion gap 16 mEq/L). Fundus examination showed findings consistent with mild nonproliferative diabetic retinopathy. HbA_{1c} was at 9.2% (normal <6.5). Human immunodeficiency virus (HIV), hepatitis B, and hepatitis C tests by enzyme-linked immunosorbent assay were all negative. Two sputum smears were negative for acid-fast bacilli by Ziehl-Neelsen (ZN) staining. Liver function and thyroid function tests were normal. Pleural fluid analysis showed 99% neutrophils, with sugar <0.8 mg/dL. Pleural fluid cultures yielded *Candida albicans* twice; bacterial cultures were sterile, and the ZN smears of the pleural fluid were negative. Echocardiography showed normal left ventricular function with no valvular abnormalities, and fundoscopy was normal. A diagnosis of candidal empyema was made and fluconazole treatment was started according to sensitivity. Repeat pleural fluid cultures were sterile and showed an exudative (protein 4.1 g/dL, LDH 321 IU/mL), lymphocytic effusion (95%); however, the patient continued to have persistent drainage of purulent-looking fluid. A pleural fluid biochemical analysis was requested; it showed triglycerides at 135 mg/dL and cholesterol at 35 mg/dL. Because of diagnostic ambiguity, pleural fluid chylomicron testing was done (Christian Medical College, Vellore, India) and it was strongly positive for chylomicrons. Plain CT of the thorax (Fig. 2, 3) showed significant mediastinal adenopathy with calcification involving the pretracheal, aortopulmonary, bilateral hilar and subcarinal stations. He was planned for endobronchial ultrasound-guided needle aspiration, but, meanwhile, GeneXpert testing of the pleural fluid was positive for *Mycobacterium tuberculosis* (MTB), and *Mycobacterium* growth indicator tube cultures of the pleural fluid isolated MTB.

A final diagnosis of poorly controlled diabetes, disseminated TB with right-sided chylothorax complicated by candidal empy-

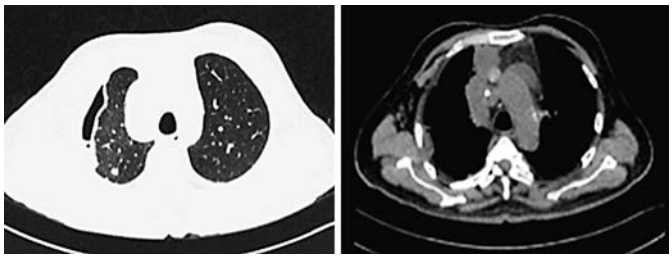

Fig. 2. Plain computed tomography images of the thorax (taken because of acute renal failure) showing moderate pericardial effusion and right mediastinal pleural collection and thickening; significant mediastinal adenopathy (largest: 2.5 × 2 cm) involving the pretracheal, aortopulmonary, bilateral hilar, and subcarinal stations was observed with calcifications.

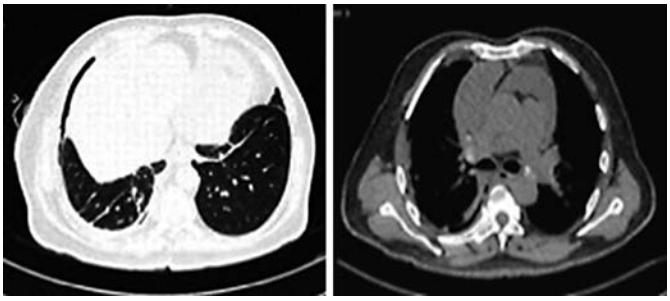

Fig. 3. Plain computed tomography images of the thorax at the level of the diaphragm indicating lack of pleural thickening and near-total lung expansion; mediastinal windows show calcified mediastinal nodes.

ema, and sepsis with acute renal failure was made. The patient underwent intermittent hemodialysis and was managed with oxygen, medium-chain fatty acid-based diet, intravenous fluids, weight-based anti-TB treatment (ATT) modified for renal failure, fluconazole, and deep venous thrombosis and stress ulcer prophylaxis. Surgery of the right trapped lung was postponed because of renal failure. His renal function gradually normalized, and the pleural drainage significantly reduced, with complete lung expansion by the second week. The intercostal drain was removed. His course was complicated by ATT-induced hepatotoxicity, necessitating initiation of levofloxacin, streptomycin, and continuation of ethambutol. He was subsequently rechallenged successfully with isoniazid and rifampicin and completed 9 months of TB treatment with clinical and radiological improvement (Fig. 1, right). He remains on follow-up and has had no further symptoms at 12 months.

Systematic Search of the Literature

Two of the authors (S.R. and R.K.) independently conducted a systematic search in PubMed (National Library of Medicine, Bethesda, MD, USA) using the terms "tuberculosis" AND "chylothorax" restricted by a publication date of 1980 onwards. These articles were screened, without blinding, by title and abstract review to identify relevant studies. Any discrepancy was resolved by consensus. This was further supplemented by a search in the Indian medical search engine IndMed, references from the retrieved articles, our personal records, and the Internet search engine Google. Full texts or abstracts were then retrieved to identify the spectrum of clinical features of chylothorax associated with TB. Articles identified in languages other than English were translated into English before data abstraction. If either the abstract or the full text was inaccessible, the corresponding author was contacted by mail requesting access to the published report. Only those articles that included patients who fulfilled the criteria (below) for chylothorax *and* TB as documented by the microbiologic or pathological criteria (below) were included for analysis.

Chylothorax was defined by (a) the presence of chylomicrons in the pleural fluid *or* (b), in the absence of an evaluation for chylomicrons, pleural fluid triglyceride >110 mg/dL *and* pleural fluid cholesterol <200 mg/dL (*or* a ratio of pleural fluid to serum cholesterol <1.0 if pleural fluid cholesterol ≥200 mg/dL). TB was defined by either (a) sputum, bronchoalveolar fluid, pleural, ascitic fluid, cerebrospinal fluid, or tissue biopsy positive for acid-fast bacilli by ZN staining *or* (b) growth of MTB by culture in the above, *or* (c) caseating granulomas *or* miliary nodules on radiology in the presence of a compatible clinical syndrome *and* a response to ATT alone.

Data Extraction

The data were abstracted in a predefined data extraction form (see online suppl. Table; for all online suppl. material, see www.karger.com/doi/10.1159/000484694). From the selected cases, the following data were gathered: (a) publication details (title, authors, year of publication, journal name, and other citation details); (b) the number of cases reported in each publication; (c) the demographic details of each case, including age and gender; (d) the duration of symptoms; (e) the symptoms at presentation, including constitutional symptoms in the form of fever, anorexia, or weight loss, dyspnea, cough, chest pain, or hemoptysis; (f) the side of the effusion; (g) details on concurrent organ system involvement; (h) the time to involvement of chylothorax, if sequential; (i) comorbidities and their details, including a diagnosis of HIV; (j) pleural fluid analysis results; (k) results of microbiologic testing of pleural and sputum samples; (l) tissue biopsy results when performed for the diagnosis of TB; (m) treatments administered, including details on steroids, ATTs, and their duration; and (n) outcome.

Informed consent was obtained from the index patient described in the paper. The institutional ethics committee approved the study.

Statistical Analysis

Continuous data are presented as mean (SD) or median (range or IQR), and categorical data as percentages and proportions. All statistical analyses were done using the statistical software SPSS IBM version 21 (PSG IMS&R).

Table 1. Clinical features of all patients with tuberculosis-associated chylothorax in the literature (n = 37 cases)[a]

Age (n = 35), years	39.27±4.13[b]
Gender (male:female) (n = 36)	20:16

Values are presented as mean ± SE, median (IQR), or n/total n (%). AFB, acid-fast bacilli by Ziehl-Neelsen staining; ATT, anti-tuberculosis therapy; BAL, bronchoalveolar lavage; FFD, fat-free diet; ICD, intercostal tube drainage; IRS, immune reconstitution syndrome; MFA, medium-chain fatty acids; MTB, *Mycobacterium tuberculosis*; NAAT, nucleic acid amplification test. [a] Includes the current case in the analysis. [b] 6/37 (17.1%) ≤16 years. [c] 6/36 (16.7%) with IRS. [d] 11.1% positive. [e] More than one reported in some.

Results

We identified 37 reports of chylothorax associated with TB in 36 case reports, including the present case (see online suppl. Table) [6–40]; we excluded 8 reports containing 12 cases [41–49] because neither the full texts nor abstracts were available, as well as another 5 reports with 5 cases because there was no microbiologic or pathologic evidence of TB [50–54]. The cases where full information was not available were treated as "missing data." There were 20 males and 16 females with a mean age of 39.27 ± 4.13 years; 13.9% (5/36) were children [15, 22, 23, 26]. The patients had had symptoms for a median of 1 month (range 0.1–24 months) prior to presentation to the hos-

Table 2. Causes of chylothorax and expected frequencies

Traumatic chylothorax	≈50%
Noniatrogenic (blunt trauma to chest or vertebrae; knife wound to chest/gunshot wound; childbirth; forceful emesis)	≈12–15%
Iatrogenic (thoracic surgery [esophagectomy, congenital heart disease, lung/mediastinal resections]; head and neck surgery; radiation; pacemaker; central line; embolization of arteriovenous malformations)	35–38%
Nontraumatic chylothorax	≈44%
Malignancy (lymphomas [non-Hodgkin or Hodgkin]; other solid tumors) and other miscellaneous diseases (lymphangioleiomyomatosis; filariasis; sarcoidosis; amyloidosis; tuberculosis; superior vena cava obstruction; constrictive pericarditis; hemangiomatosis [Gorham's disease]/lymphangiomatosis; cardiac failure; transdiaphragmatic movement in cirrhosis)	≈15–20%
Idiopathic	≈6%

pital (Table 1). Constitutional symptoms in the form of fever, anorexia, and weight loss (85.7%; 30/35), dyspnea (60.6%; 20/33), cough (54.5%; 18/33), and chest pain (30.3%; 10/33) were the most common symptoms at presentation. Close contact with a source of pulmonary TB [22, 23, 30] or a prior history of TB [6, 12, 31] was reported by 8.3% (3/36) of the patients each.

Forty-six percent (17/37) of all chylothoraces developed in patients with TB associated with comorbidities; 16.2% (6/37) were in association with HIV infection [12, 23, 25, 26, 33, 38]. A very high proportion also had disseminated TB at diagnosis (45.9%; 17/37), including miliary TB in 18.9% (7/37) [14, 18, 26, 32, 33, 35, 36]. Chylothorax developed in association with chylous ascites in 10.8% (4/37) of the cases [14, 26, 35, 38]. Chylothorax developed on the right side or bilaterally in the majority of cases (78.3%; 29/37). Accompanying parenchymal infiltrates and lymphadenopathy were seen in 48.6% (18/37) and 70.3% (26/37) of the cases, respectively, leading to suspicion of associated TB. However, 45.9% (17/37) of the cases did not have any thoracic infiltrate or mediastinal adenopathy, including 13.5% (5/37) that presented with tubercular empyema alone [10, 21, 27, 29, 31]. The mechanism of development of chylothorax in association with TB was presumed to be due to interruption of lymphatic flow by mediastinal nodes in 51.4% (18/35), abdominal nodes in 14.3% (5/35), extensive pleural disease in 14.3% (5/35), constrictive pericarditis in 2.8% (1/35) [19], and erosion of a spinal abscess into the thoracic duct in 5.6% (2/35) of the cases [8, 12]. The diagnosis of TB was made concurrently with the diagnosis of chylothorax in 72.2% (26/36) of the cases. Chylothorax developed subsequent to a diagnosis of TB on ATT in 27.8% (10/36) of the cases at a median of 6.75 weeks (IQR 4–9) following the initiation of treatment [7, 12–14, 25, 26, 32, 36, 38, 40]. Chylothorax occurred along with an immune reconstitution syndrome (IRS) in 6 (60%; 6/10) of these cases [12, 25, 26, 32, 36, 40], including 3 in immunocompetent individuals [32, 36, 40].

The vast majority of chylothoraces were suspected because of a milky appearance of the pleural fluid (94.4%). Pleural fluid analysis showed exudative effusion in all cases described (mean protein 4.70 ± 0.37 g/dL; median LDH 177 U/L). About 88.9% of the effusions were lymphocytic predominant, with a median of 90% lymphocytes (IQR 67–97). The median triglyceride value observed was very elevated at 678 mg/dL (280.25–1,154). Consequently, chylomicrons were reported in only 11.1% (4/36) of the cases, including the index case [9, 24, 40].

The diagnosis of TB was established microbiologically in 72.2% (26/36) of the cases, with a positive pleural fluid or sputum, bronchoalveolar lavage, gastric aspirate, or tissue mycobacterial culture, or a positive nucleic acid amplification test. Tuberculous empyema was associated with chylothorax in 25% (9/36) of the cases, including the index case [10, 13, 21, 24, 27–29, 31, 35]. Pathologic biopsies of the involved organ alone established the diagnosis of TB in a further 27.8% (10/36) [6, 7, 16, 18–20, 31, 34, 37, 39].

ATT was administered for a median of 7.57 months (IQR 6–9). A fat-free or medium-chain fatty acid diet was administered in 62.9% (22/35) of the cases. Steroids were given in 22.9% (8/35) of the cases, often for suspected IRS (37.5% [3/8]) or endobronchial TB. Chylothorax increased or developed on ATT alone in 25% (9/36) of the cases, including in 16.7% (6/36) with IRS. However, tho-

racic duct ligation [12, 14, 20, 24, 36, 40] and octreotide [22, 26, 36] were required in only 17.1% (6/35) and 8.6% (3/35) of the cases, respectively. In all, 94.4% (34/36) of the cases had good resolution of chylothorax and completed treatment successfully; only 5.6% (2/36) died [18, 27].

Discussion

A wide variety of etiologies can cause nontraumatic chylothorax (Table 2). In a large series of patients with chylothorax ($n = 203$), none were reported to have chylothorax due to TB [55]. Our systematic review suggests that chylothorax is a very rare but well-described complication of TB [6–40]. The occurrence of an acute effusion with smooth unthickened pleural surfaces along with demonstration of elevated triglyceride (≥110 mg/dL) and low cholesterol levels (pleural/serum cholesterol <1) or demonstration of chylomicrons by lipoprotein electrophoresis differentiates a chylothorax from a pseudochylothorax [3]. The absence of long-standing pleural effusion prior to the current illness and clear biochemical evidence and definitive demonstration of chylomicrons along with radiological features suggestive of TB *and* microbiologic demonstration of MTB established the association of chylothorax with TB in the index case. Pleural thickening was due to TB and *Candida albicans*-related empyema; it has been reported earlier in association with TB-chylothorax [31, 40].

Several mechanisms have been described for the development of chylothorax in TB. These include (1) mediastinal adenopathy with occlusion or erosion into the thoracic duct and leakage of chyle into the pleural space, (2) abdominal lymphadenopathy with occlusion of the cisterna chyli and opening of lymphaticovenous anastomosis, and (3) constrictive pericarditis associated with elevated left subclavian venous pressures leading to increased production and reduced drainage of lymph. The observation of exudates in all cases of TB-related chylothorax reported in the present systematic review, however, suggests a direct involvement of the pleura and/or lymphatic ducts due to TB or host-immune responses as the primary cause in most patients. Other mechanisms are also evident from this systematic review; these include erosion of the thoracic duct by spinal abscesses, extensive pleural disease with lymphatic exudation, and duct damage due to IRS. The occurrence of chylothorax subsequent to initiation of ATT in 27.8% (10/36) of the patients, the absence of any associated mediastinal or abdominal adenopathy in 35%, the very high proportion of cases with disseminated TB (45.9%; 17/37) in apparently immunocompetent individuals presenting with chylothorax, including miliary TB (18.9%; 7/37), and the development of chylothorax during immune reconstitution suggest direct or host-immune damage to the thoracic duct as a major mechanism for the development of chylothorax. The median time to development of chylothorax observed in our systematic review was 6.75 weeks (IQR 4–9), which is the most common time period of immune reconstitution; IRS can occur in 2.4–28% of immunocompetent individuals with lymph nodal [40] or pulmonary TB [56].

The occurrence of chylothorax was suspected due to obvious milky pleural fluid, suggesting an underrecognition of chylothorax in TB. Tuberculous empyema was associated with chylothorax in 25% (9/36) of the cases, including 13.9% (5/36) where this was the sole manifestation. Given the disseminated paucibacillary disease in a significant majority, biopsies of involved tissues like nodes and the pleura were needed in 50% (18/36) of the cases, with 22.2% (10/36) being diagnosed only by pathology. Lymphangiograms were reported only for 8.6% (3/35) [6, 14, 37], and the site and cause of leakage of chyle was presumptive in most reported cases.

Steroids were administered in 22.9% (8/35) of the cases for IRS, bronchial stenosis, and severe disseminated TB with variable responses in reduction of chylothorax. The need for thoracic duct interruption was reported only for 17.1% (6/35) of the cases, with success in 83.3% (5/6) of these, indicating that chylothorax may resolve with a fat-free diet and ATT in the majority of cases. TB-chylothorax is associated with good prognosis with conservative treatment despite the higher proportion with disseminated disease at diagnosis and associated comorbidities. The survival rate was 94.4%.

Conclusions

Chylothorax is a very rare but well-described complication of TB. It develops with extensive mediastinal or abdominal lymphadenopathy and extensive pleural disease, but it may also develop without any obvious lymphadenopathy and as part of an IRS. ATT and dietary manipulation – followed by duct ligation if needed in a small minority of cases – are associated with good outcome and low mortality.

Acknowledgements

The authors would like to thank R. Jagadeshwari, research coordination, PSG Institute of Pulmonology, for her help in rechecking the tables of the systematic review and proofreading the manuscript. The authors also thank the Senior Librarian, PSG IMS&R, for help in procuring previously published manuscripts.

Author Contributions

All authors were responsible for patient care and initiated manuscript preparation. S.R. and R.K. performed the systematic review, retrieving the articles of our systematic search and abstracting data. S.R. and R.K. take responsibility for the content of the paper, including the data and analysis.

Financial Disclosure and Conflicts of Interest

No funding was utilized for this manuscript and the authors have no conflicts of interest to disclose.

Pulmonary Nocardiosis Presenting as Exacerbation of Chronic Pulmonary Disease

Roopa Kancherla[1], Ramanathan Palaniappan Ramanathan[2], Bobbe Appalaraju[3], Srinivas Rajagopala[4]

Abstract

Background: Pulmonary nocardiosis (PN) occurs in chronic pulmonary disease (CPD) in the absence of traditional risk factors. Clinical features that differentiate bacterial exacerbations (AE-CPD_b) from PN-related exacerbations (AE-CPD_{PN}) are not well described.

Objectives: To describe a series of AE-CPD_{PN} without traditional risk factors and compare clinical features, radiology and outcomes with age, gender and CLD-type matched AE-CPD_b.

Materials and methods: Single-center retrospective review and case-control study.

Results: AE-CPD_{PN} had longer duration of symptoms and more leukocytosis at hospitalization. AE-CPD_b patients were sicker with more chronic respiratory failure (OR 33.3, $p = 0.01$), cardiac disease and pulmonary hypertension (OR 6.2, $p = 0.008$) at diagnosis. More patients with AE-CPD_b were discharged on domiciliary oxygen (OR 5.27, $p = 0.01$). On logistic regression, AE-CPD_{PN} was independently associated with mechanical ventilation (OR 22.3, $p = 0.01$), length of hospital stay (median difference, 4 days, $p = 0.016$) but not to hospital mortality. 22.7% of AE-CPD_{PN} died. Respiratory failure requiring oxygen, NIPPV or mechanical ventilation was associated with mortality in AE-CPD_{PN}.

Conclusion: PN is a rare cause of AE-CPD and can be suspected by longer symptom duration, more leukocytosis, consolidation and cavitation. AE-CPD_{PN} is associated with longer hospital stay and mechanical ventilation. Respiratory failure is associated with mortality in AE-CPD_{PN}.

Key messages:

- Pulmonary nocardiosis can present in advanced chronic lung disease as an exacerbation in the absence of traditional risk factors like immunosuppression.
- Bronchiectasis, followed by chronic obstructive pulmonary disease are the most common chronic lung disease risk factors.
- Pulmonary nocardiosis is a rare cause of acute exacerbation of chronic pulmonary disease (CPD).
- Compared to exacerbations of CPD due to bacterial infections, nocardiosis-related exacerbations (CPD_{PN}) were independently related to need for mechanical ventilation and length of hospital stay.
- Respiratory failure requiring oxygen, noninvasive ventilation and mechanical ventilation are associated with mortality in AE-CPD_{PN}.

Indian Journal of Critical Care Medicine (2019): 10.5005/jp-journals-10071-23270

Introduction

Acute exacerbation of chronic pulmonary disease (AE-CPD) leads to substantial worsening in quality of life, need for additional therapies, morbidity, mortality and costs.[1] Severe exacerbations are associated with respiratory failure, need for mechanical ventilation and mortality.[2] Pulmonary nocardiosis, the most frequent presentation of human infection by *Nocardia* spp, is increasingly being recognized in patients with CPDs, including chronic obstructive pulmonary disease (COPD).[3] Predisposing factors include bacterial colonization of lower airways with advanced lung disease, oral steroid use for exacerbations and structural lung disease in the form of associated bronchiectasis in severe COPD.[4] Most series of PN in CPDs include patients with associated traditional predisposing factors like steroid therapy, solid-organ or hematopoietic cell transplantation, human immunodeficiency virus infection or malignancy; mortality determinants were thus affected by these associated risk factors.[4] The clinical features, radiologic findings, laboratory clues that should suggest the presence of PN in AE-CPD (AE-CPD_{PN}) and its outcomes are not well described. We describe a series of AE-CPD_{PN} in the absence of traditional risk factors to determine clinical features that can distinguish it from bacterial exacerbations of CPD (AE-CPD_b) and determine the association of AE-CPD_{PN} with need for mechanical ventilation, hospital length of stay and mortality.

Materials and Methods

This is a retrospective study of patients ≥18 years and a final diagnosis of PN and AE-CPD from a large tertiary care hospital in southern India over 10 years between January 2008 and December 2017. All cases with PN were identified by an electronic search of our records and cross-referenced by a simultaneous manual search of the nocardiosis register in the department of microbiology. Clinical records of all identified cases were retrieved. Only PN presenting

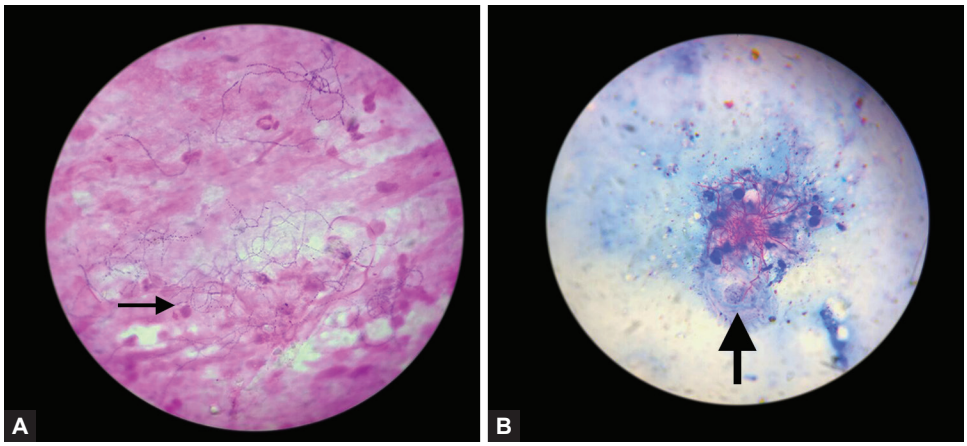
Flowchart 1: Number of enrolled patients in the study

with worsening of underlying CPD was included. PN associated with long-term steroid therapy, immunosuppressive therapy, human immunodeficiency infection (HIV) and malignancy and PN in the absence of CPD was excluded (Flowchart 1).

Study Subjects

Case Series



CPD was defined by the presence of one of the following conditions; COPD, bronchial asthma, bronchiectasis, interstitial lung disease (ILD) and post-tuberculosis lung disease. The diagnosis of COPD, bronchial asthma, bronchiectasis and ILD was made according to standard guidelines.[1,5,6] The diagnosis of obstruction and restriction on spirometry was according to ATS/ERS guidelines.[7] An exacerbation of CPD was defined as worsening of respiratory symptoms that resulted in additional therapy.[1] If the initial diagnosis of CPD was made during an exacerbation of CPD, spirometry performed subsequently during stable disease, where available, was taken for data abstraction. PN was diagnosed on the basis of (i) presence of compatible respiratory symptoms and (ii) isolation of *Nocardia* spp. in smears and/or cultures of respiratory samples or (iii) histopathology of transthoracic or bronchoscopic biopsies showing organisms consistent with *Nocardia* spp.[8] Respiratory samples included sputum, endotracheal aspirates, bronchoalveolar lavage fluid (BALF) and pleural fluid. Nocardiosis was diagnosed as "disseminated" if there was isolation in blood culture or demonstrable infection in other organs, including skin and central nervous system in association with respiratory infection.[8] Recent steroid intake was defined as steroid intake in the 3 months prior to diagnosis of PN. We excluded any patient with steroid intake >7.5 mg in 3 months prior to the diagnosis of pulmonary nocardiosis to eliminate oral steroid as a confounding factor for AE-$CPD_{PN.}$ Chronic respiratory failure was defined by an arterial blood gas (ABG) with PaO_2 ≤55 mm Hg or <60 mm Hg in the presence of pulmonary hypertension; $PaCO_2$ ≥45 mm Hg with or without pH ≤7.36 in the absence of symptoms suggestive of an acute deterioration.[1,9]

Controls

Controls were patients with COPD, bronchiectasis, post-tuberculosis lung disease and ILD without any Immunocompromising condition, including receipt of steroids in 3 months prior to study inclusion. Only exacerbations that were microbiologically proven or clinically presumed to be due to bacterial infection (AE-CPD_b) were included. Receipt of antibiotics was taken as a surrogate for clinical presumption of infection; any controls with suspected or proven exacerbations due to viral infections, heart failure or pulmonary embolism were excluded. Patients with a presumed bacterial infection were included only if they had a complete clinical response to antibiotics and supportive care alone; outpatient follow-up notes and radiology were retrieved and reviewed for all controls for confirmation. Controls with exacerbations and radiological infiltrates were included in an attempt to match illness severity between cases and controls. Three controls were identified for each case and matched by age, gender and type of chronic lung disease.

Microbiological Identification

Samples collected included sputum, endotracheal aspirates, BALF and pleural fluid under sterile precautions. The samples were examined by direct microscopy after Gram's staining to establish specimen quality. Modified Kinyoun's stain was also done if nocardiosis was suspected clinically or if Gram's stain showed organisms compatible with *Nocardia* spp. All samples were then homogenized with sterile glass beads in a test tube and incubated in blood agar and Sabouraud's dextrose agar at 37°C in an aerobic atmosphere for up to 4 weeks and examined every alternate day for growth. The presumptive identification of *Nocardia* spp. was based on the microscopy showing branching gram-positive thin filamentous rods (Fig. 1A), partially acid-fast with modified Kinyoun's stain (Fig. 1B) and the macroscopic morphology of buff or pigmented waxy cerebriform colonies. Identification at the species level was done using biochemical testing. From 2019 onwards, 16s rRNA based-DNA sequencing was implemented for speciation (outside study period).

Figs 1A and B: Composite image with Gram's staining of sputum sample. (A) Branching of gram-positive thin filamentous organisms consistent with *Nocardia* spp; (B) Modified acid-fast staining confirmed that these organisms were acid-fast

Treatment Protocol for PN

All admitted patients received meropenem 1 g every 8 hours for 2–4 weeks, along with oral or parenteral cotrimoxazole (15 mg/kg trimethoprim equivalent in three divided doses); cotrimoxazole alone was then continued for the remaining duration of 6 months. All patients with PN were admitted only till clinical stabilization as defined by absence of fever, normal hemodynamics and need for minimal or no oxygen; parenteral antibiotics were continued on ambulatory basis or arranged at a center of convenience for the prescribed period. In mild PN treated as outpatient basis, cotrimoxazole alone (10 mg/kg trimethoprim equivalent in three divided doses) was administered. In cases of suspected or proven disseminated nocardiosis, amikacin 15 mg/kg was added for the initial period and the initial intensive phase was extended from four to 6 weeks.[10,11]

Data Extraction

Data was abstracted in a predefined data extraction form. From the selected cases, the following data were gathered: (a) demographic details of each case including age and gender, (b) duration of symptoms, (c) symptoms at presentation, (d) type of chronic lung disease, (e) body mass index, (f) co-morbidities and their details, including smoking, alcohol abuse, diabetes, chronic kidney disease, steroid receipt in the last 6 months before diagnosis and concurrent malignancy, (g) diagnosis of chronic respiratory failure before the diagnosis of PN, (h) spirometry values, (i) laboratory investigations, including total leukocyte counts, arterial blood gas analysis, (j) radiologic findings and echocardiography, (k) microbiologic isolates, (l) treatment administered, including details of steroids, antimicrobial therapy and their duration, oxygen use, noninvasive or invasive ventilation and its duration, and (m) outcomes; discharge on domiciliary oxygen and hospital mortality.

Outcome Measures

The duration of symptoms prior to presentation, symptoms, laboratory findings, radiologic findings, treatment administered and outcomes were compared between patients with AE-CPD_b and AE-CPD_{PN}

Statistics

Statistical analyses were performed using SPSS version 14. Continuous variables were described in a descriptive fashion (mean ± SD, median, IQR) and discrete variables were described as frequency proportions. Comparisons for continuous variables were performed using the independent T test or Mann–Whitney test and proportions using the Chi-square test or Fisher's exact test, where appropriate. Statistical significance was assessed at the 2-sided $p \leq 0.05$ level. The independent association of AE-CPD_{PN} with the need for noninvasive or invasive mechanical ventilation and mortality was tested by logistic regression.

Ethics

The Research Ethics Committee of our Hospital approved this study. All data abstracted was anonymized, thus ensuring confidentiality and patient privacy.

Results

There were a total of 32 cases of PN over a 10-year period. We excluded 10 cases, including five with disseminated nocardiosis without coexisting CPD. There were a total of 22 cases of AE-CPD_{PN}, including 13 men and 9 women; all had localized pulmonary disease. The type of CPD was most commonly bronchiectasis (59%, 13/22), followed by COPD (36.4%, 8/22) and ILD (1/22, 4.5%) (Table 1A). Bronchiectasis was cystic (CB) and multilobar in all and the etiology was idiopathic, post-tuberculosis or allergic bronchopulmonary aspergillosis (ABPA)-related. 21/22 of AE-CPD_{PN} had inhaled corticosteroids (ICS) use compared to 63/66 of the controls; these were patients with advanced airway disease and were on triple therapy and ICS use was not different in cases compared to controls. The final 22 AE-CPD_{PN} included did not have any oral steroid intake in the 12 months prior to the diagnosis of PN. The patient with AE-CPD_{PN} related to ILD was steroid-naïve and the diagnosis of ILD was made concurrent with the diagnosis of PN. Two patients with AE-CPD_{PN} received steroids for severe bronchospasm with a diagnosis of AE-CPD_b before the diagnosis of PN; in both, steroids were discontinued after diagnosis. Among patients with AE-CPD_b, *Pseudomonas aeruginosa* was the most common organism isolated. 27.2% (6/22) of the patients with AE-CPD_{PN} had a presumed or proven bacterial coinfection. All patients with AE-CPD_{PN} were treated with cotrimoxazole for a median (IQR) duration of 6(2) months. Two patients were subsequently treated with other regimens after discontinuation of cotrimoxazole; reasons included inability to tolerate cotrimoxazole due to persistent severe hyperkalemia and in another, the isolate was reported as *N. farcinica* resistant to cotrimoxazole in association with clinical failure.

Table 1A: Comparison between patients with exacerbations of chronic lung disease due to Nocardia and bacterial exacerbations of chronic lung disease

Characteristics	*Nocardia related exacerbation (n = 22)*	*Bacterial exacerbations (n = 66)*	*P value, **OR 95% CI*
Age years, mean ± SE	61.36 ± 2.9	60.5 ± 1.7	0.79

There was no difference in body-mass index, lung function at baseline, presence of obstruction on spirometry, presence of risk factors like smoking, alcohol abuse, recent steroid intake, diabetes or prior tuberculosis between AE-CPD_b, and AE-CPD_{PN} (Table 1B). When compared to age, gender and type of CPD-matched AE-CPD_b, AE-CPD_{PN} had longer symptom duration (median difference 5 days, $p = 0.014$) prior to presentation. There was more leukocytosis (mean difference 5559/µL, $p = 0.002$), neutrophilia (mean difference 4373/µL, $p = 0.01$) and higher erythrocyte sedimentation rate (mean difference 25.1 mm/hour, $p < 0.001$) at hospitalization. Patients with AE-CPD_b had higher proportion with dyspnea at presentation (OR 4.57, $p = 0.02$), chronic respiratory failure prior to diagnosis of bacterial exacerbation (OR 33.3, $p = 0.01$), and more respiratory acidosis (pH difference –0.04, $p = 0.016$, $PaCO_2$ difference 12.7 mm Hg, $p = 0.01$) at diagnosis. More patients with AE-CPD_b had acute kidney injury (AKI, O.R 5.0, 95% CI 1.07–23.3, $p = 0.04$) at diagnosis, with 22.7% (5/22) requiring dialysis. Two patients with AE-CPD_{PN} had renal failure, with both requiring dialysis. There was also higher proportion of left ventricular systolic or diastolic dysfunction (OR 5.27, 95% CI 1.34-20.7, $p = 0.01$) and pulmonary hypertension (OR 6.2, $p = 0.008$) in patients with AE-CPD_b.

On imaging, AE-CPD_{PN} had higher proportion of consolidation (95.5%) and cavitation (27.3%). Consolidation was mass-like, multilobar or multifocal in all patients with AE-CPD_{PN}. (Figs 2 and 3). On univariate analysis, there was no difference in the need for oxygen, noninvasive ventilation or mechanical ventilation between

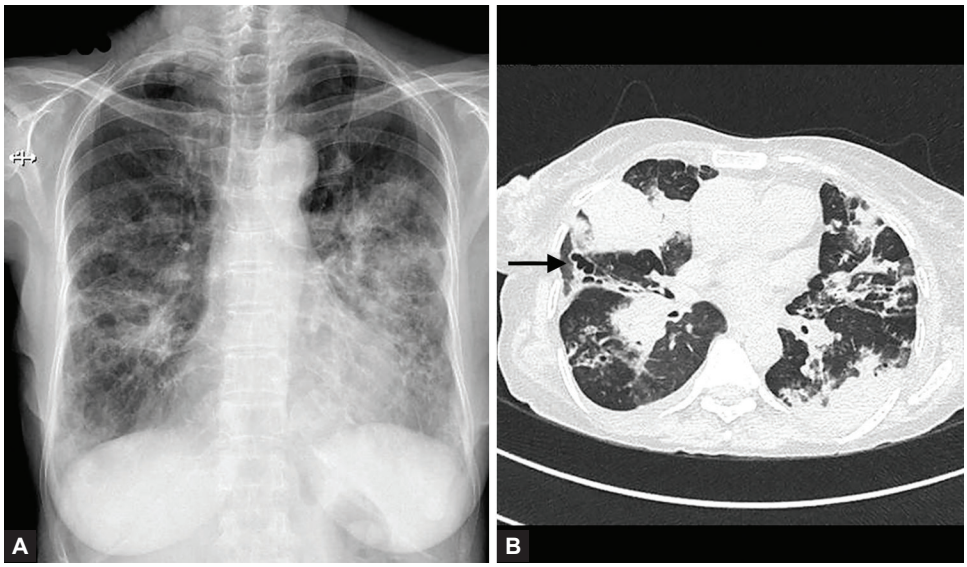
AE-CPD_{PN} and AE-CPD_b. Patients with AE-CPD_{PN} had a longer stay for clinical stabilization ($p = 0.016$) and more patients with AE-CPD_b were discharged on domiciliary oxygen (O.R 5.27, $p = 0.01$). On multiple logistic regression, after adjusting for higher illness severity of AE-CPD_b, AE-CPD_{PN} was independently related to need for mechanical ventilation (OR 22.3, $p = 0.01$), length of hospital stay (median difference, 4 days, $p = 0.016$) but not to hospital mortality (Table 2).



AE-CPD_{PN} was associated with a 22.7% (5/22) mortality. There was no difference in recent receipt of steroids prior to diagnosis of PN, renal failure at diagnosis, pH or hospital stay between survivors and nonsurvivors (Table 3). Respiratory failure requiring oxygen, NIPPV or mechanical ventilation was associated with mortality in AE-CPD_{PN}.

Discussion

Pulmonary nocardiosis is a rare thoracic infection predominantly affecting immunocompromised hosts.[8] The traditional risk factors for PN include long-term steroid therapy, malignancy, chemotherapy and HIV infection.[11] However, one-third of cases reportedly occur in immunocompetent patients.[12] There is increasing recognition that COPD is a risk factor for PN.[13] Data are mostly from case reports and small series, given the rarity of PN.[3,4,14-16] Notably, several of these cases have COPD associated with bronchiectasis and this is an important but under-recognized risk-factor for PN as well.[3,13] In our series, bronchiectasis was the most common underlying CPD. No clustering of cases was noted and only five of the 22 cases were diagnosed and managed in the outpatient non-CF bronchiectasis

Figs 2A and B: Composite image with chest radiograph (A) of a patient with pulmonary nocardiosis-related chronic pulmonary disease exacerbation showing multilobar consolidation, with a dense mass-like consolidation in the left lingula. Bronchoscopic biopsy from lingula confirmed nocardiosis; (B) Repeat chest radiographs at 6 months of cotrimoxazole showed resolution with a small area of residual fibrosis

Figs 3A and B: (A) Composite image with chest radiograph of a patient with pulmonary nocardiosis-related chronic pulmonary disease exacerbation showing multilobar consolidation; (B) Computed tomography confirmed extensive consolidation and also showed bronchiectasis (thin arrow)

clinic. None of the cases with AE-CPD$_{PN}$ had received long-term steroids before diagnosis, including all the patients with ABPA. In one-third of the cohort, the diagnosis of CPD was made when they presented with AE-CPD.

Thoracic involvement is the most common presentation of PN and is seen in 85% of cases at presentation. Symptoms are nonspecific and this is especially true with PN presenting in patients with CPD.[4,8] PN in CPD presents with an exacerbation of the underlying respiratory symptoms and is often similar to bacterial exacerbations of CPD (AE-CPD$_b$).[17] In fact, two cases of PN in our series were initially diagnosed as AE-CPD$_b$ and improved with antibacterials for AE-CPD; early relapse of symptoms after discontinuation of antibiotics for AE-CPD$_b$ (typically seven days in our practice) prompted extensive microbiological evaluation, yielding a diagnosis of AE-CPD$_{PN}$. This study was conducted in this background to identify clinical features that can distinguish AE-CPD$_{PN}$ from AE-CPD$_b$.

Table 3: Comparison of clinical features of AE-CPDPN between survivors and nonsurvivors

Characteristic	*Survivors (n = 17)*	*Nonsurvivors (n = 5)*	*Statistics*

Hospital length of stay days Median, IQR	10 (9)	5 (13)	0.25

SD, standard deviation; IQR, interquartile range

We did not find additional risk-factors independent of CPD predisposing to PN in our series (Tables 1A and 1B), again establishing the independent risk of CPD for PN.[13] AE-CPD_{PN} occurred in patients with advanced lung disease (mean FEV1 1.01 ± 0.05 L, 53.6 ± 2.4% predicted) who presented with longer symptom duration, more leukocytosis and inflammatory markers when compared to AE-CPD_b. Extensive consolidation or cavitation prompted suspicion for PN in AE-CPD and cavitation was seen in 27.3% at diagnosis. Four patients with AE-CPD_b had an initial diagnosis of cavitation; one was related to an exacerbation of COPD related to previous tuberculosis and in another three, underlying bronchiectasis had not been diagnosed and consolidation around cystic bronchiectasis spaces was initially misdiagnosed as cavitation.

The cohort of AE-CPD_b was sicker with a higher proportion of cardiac disease, pulmonary hypertension, chronic respiratory failure on long-term oxygen therapy, respiratory acidosis and AKI at presentation. Consequently, more patients with AE-CPD_b were treated with oxygen, NIPPV (though statistically non-significant) and were discharged on domiciliary oxygen. After adjustment for the higher illness severity of AE-CPD_b, AE-CPD_{PN} was independently related to the need for mechanical ventilation and duration of hospital stay. The in-hospital mortality of 22.7% in AE-CPD_{PN} is similar to previous published reports of PN.[4] Respiratory failure requiring oxygen therapy, NIPPV or mechanical ventilation was associated with mortality in AE-CPD_{PN}.

Our study has several strengths. This is one of the largest series of PN in immunocompetent CPD till date. In another large series of 30 patients with PN-CPD, 23% (7/30) were related to chronic steroid therapy, chemotherapy and malignancy. Associated immune-compromise was associated with mortality and this masked the mortality associations of PN-CPD *per se*.[4] We also identified a matched cohort of AE-CPD_b to identify clinical features that could help in early diagnosis of PN in AE-CPD. There are several limitations of this study. The retrospective nature of the study resulted in an imbalance in the baseline characteristics between cases and controls; controls had more preexisting respiratory failure than cases. PN is a rare disease and conducting prospective studies is not always feasible. Second, we included patients with consolidation in the control group of AE-CPD_b. While this is debatable,[1,18] we aimed at a control group with similar severity of illness to AE-CPD_{PN} and including AE-CPD_b with consolidation was considered appropriate as most patients with AE-CPD_{PN} had consolidation at diagnosis. While some reports of AE-CPD exclude those with consolidation, this would have prevented us from identifying clinical features that help in early diagnosis of AE-CPD_{PN}. Third, data on speciation of *Nocardia* spp. is being revised with 16sRNA studies and our data is currently not available. It is well described that extensive discrepancy between biochemical testing and 16sRNA testing occurs and leads to re-speciation.[19] Fourth, most of the cases of PN (22/32, 68.75%) in the current series were related to CPD; this is possibly because of high index of suspicion in our unit and the absence of hemato-oncology and organ transplant specialty service till 2016 in our hospital. Finally, the absence of spirometry reports for the five patients who died may have lead to over-estimation of values in the AE-CPD_{PN} arm. As has been described, 29% were diagnosed with CPD when they presented with AE-CPD and it was not always feasible to do spirometry.

Conclusion

In conclusion, PN is a rare cause of AE-CPD and can be recognized by a longer symptom duration, leukocytosis, extensive consolidation and cavitation. Early recognition is important, given the high short-term mortality. AE-CPD_{PN} is independently associated with longer duration of hospital stay and mechanical ventilation. Respiratory failure requiring oxygen, NIPPV and mechanical ventilation is associated with mortality in AE-CPD_{PN}.

Abstract

Lymphangioleiomyomatosis (LAM) is a cystic lung disease frequently associated with reduced exercise capacity, mostly affecting young women. The disease is characterized by progressive pulmonary cystic change, recurrent pneumothorax, chylous pleural collections, and in most cases, progressive respiratory failure. Diagnosis is made by a combination of clinical features and computed tomography scanning or, with lung biopsy. We present a case report of a young woman who suspected of LAM and diagnosed with cystic lung disease, admitted to the intensive care unit in view of worsening hypoxia associated with pneumothorax. She was on ventilator support and placement of repeated intercostal drains and had a tracheostomy to step down to bilevel positive airway pressure support, after the medical stabilization. She was referred for pulmonary rehabilitation, in which she showed good outcomes and recovered well.

Keywords: Hormonal therapy, lymphangioleiomyomatosis, pulmonary rehabilitation

Introduction

Lymphangioleiomyomatosis (LAM) is a rare disease of the lungs and lymphatics, which can occur sporadically or in association with tuberous sclerosis. LAM almost exclusively affects young women, generally developing before menopause. The disease is characterized by progressive pulmonary cystic changes with the accumulation of LAM cells, recurrent pneumothorax, and chylous pleural collections and, in most cases, progressive respiratory failure.[1] Along with chest X-ray changes (pneumothorax and effusions), high resolution computed tomography (HRCT) findings of multiple, small, diffusely distributed cysts, an elevated serum vascular endothelial growth factor-D (VEGF-D) testing are the most diagnostic measures. Lung biopsy is indicated only when HRCT findings and VEGF-D testing are nondiagnostic.[2]

Most patients with LAM complain of impaired quality of life and reduced exercise capacity, secondary to airflow obstruction, abnormal diffusion capacity, dynamic hyperinflation, peripheral muscle dysfunction (deconditioning), and pulmonary hypertension.[3] Available medical management like Sirolimus and hormonal therapy (Medroxyprogesterone, Gonadotropin-releasing hormone agonists) may slow down disease progression; however, the disease remains incurable. Pulmonary rehabilitation (PR) is a safe intervention and improves exercise capacity, dyspnea, daily physical activity, muscle strength, and quality of life in LAM.[4,5] After obtaining appropriate consent from the patient, we present a case report of a young female patient who suspected of LAM and diagnosed with cystic lung disease and the outcomes of PR.

Case Report

A 25-year-old female, health-care worker, reported to the emergency room with sudden onset of breathlessness and hypoxemic shock. In view of worsening conditions, she was shifted to the intensive care unit (ICU) and intubated with

mechanical ventilation. Initial chest X-ray [Figure 1a] showed a bilateral pneumothorax with subcutaneous emphysema and it was treated by bilateral intercostals drainage (ICD). There was persistent air leak for a prolonged duration, along with inadequate lung expansion. Initial HRCT-chest [Figure 2a and 2c] showed extensive fibro-bronchiectatic changes with few cystic changes noted in bilateral lower lobes and also bronchopleural fistula (BPF). Since she was diagnosed with pulmonary tuberculosis 3 months ago with sputum positive (sputum Gene expert positive, Rifampicin sensitive), and she was started on treatment; however, Ziehl-Neelsen stain was negative after the 3 months. She had developed multiple episodes of nosocomial infection during the period of ICU. It was treated with appropriate antibiotics, and infection settled down. Repeated blood and tracheal cultures were sterile; however, her respiratory distress persisted due to recurrent pneumothorax.

A repeat HRCT-thorax was done, which showed extensive bilateral cystic changes with a right-sided loculated pneumothorax with 2 ICDs *in situ* on the right side and one on the left side, and very poor lung reserve. A possible diagnosis of Sporadic LAM was suspected with HRCT; hence cardiothoracic surgeon opinion was obtained for open lung biopsy but deferred in view of high risk. Autologous blood patch was attempted twice to seal the BPF but was a failure. In view of the difficulty in weaning from the ventilator, tracheostomy was done after 2 weeks. In view of constant ICD site pain, thoracic epidural analgesia was given. Gradually, she was weaned off the ventilator and was maintained on bilevel positive airway pressure support.

In view of possible LAM, high dose of medroxyprogesterone and doxycycline were administered with informed consent. Gradually bilateral air leak stopped, and bilateral ICDs were removed. The repeated chest X-rays [Figure 1b-d] and HRCT [Figure 2b and 2d] showed multiple cysts with surrounding multiple large bullae replacing the left upper lobe sparing the lingular segment-bulla have increased in size. Multiple cysts in the right upper lobe, right middle lobe, and anterior right lower lobe. Cysts have increased in size/parenchymal strands, small areas of pneumonitis in the right lower lobe and upper lobe [Figure 2c].

Due to prolonged ICU stays along with worsened disease condition, she developed ICU acquired critical illness myoneuropathy, and systemic deconditioning associated with proximal muscle atrophy. With the low lung reserve and cystic lung disease, the team planned and advised her family to get ready for lung transplantation. Meanwhile, PR was initiated to achieve fitness for surgery. Hence, she was enrolled in PR program with exercise-based intervention. Nutritional status was improved with dietary correction and psychological support was given, which helped her to come out of her anxiety.

Pulmonary rehabilitation program

The PR program was initiated after getting informed consent. PR program was conducted with two interventional programs; ICU-based intervention, and inpatient. The ICU-based intervention outcomes were measured by using the Standardized 5 Questions (S5Q) for assessing patients' ability to cooperate, Modified Medical Research scores for muscle strength, and Berg Balance Scale for balance. The ICU based intervention was started with the use of the Leuven protocol from "start to move."[6] It is a six-level assessment and treatment protocol, which includes basic assessment of S5Q (1). Open and close your eyes, (2). Look at me, (3). Open your mouth and stick out your tongue, (4). Shake yes and no nod your head, (5). I will count to 5, frown your eyebrows) and Modified Medical Research score (0 = no visible contraction, 1 = visible contraction without limb movements, 2 = movements of the limb in the eliminated gravity, 3 = movement against gravity

in full range, 4 = movement against gravity with resistance, 5 = normal strength). If the patient passed in S5Q then go for muscle strength test (muscles to be tested deltoid, biceps, wrist extensors, quadriceps, dorsiflexors, and the total score; 60 if the score <48/60-significant muscle weakness). Berg balance scale components include sitting with back unsupported but feet supported on the floor, sitting to standing, standing unsupported (scores from 0-unable to do for 10 s to 4-able to do for 2 min comfortably). According to this assessment, the treatment protocol was administered in ICU and explained in Table 1.

In-patient PR program was initiated after shifting to the ward. Baseline assessment was collected. It was followed by 1 min sit to stand test, 6 min walk test,[7] activity questionnaire's functional independence measure (score; self-care domain), which includes eating, grooming, bathing, dressing upper and lower body and toileting (scoring starts with 1-total assistance to 7-complete independence), physical activity index (which includes poor to high active category) and modified sphygmomanometer,[8] was used to the measured hand grip. The PR program consists of exercise training (flexibility training, endurance training, strength training, airway clearance technique, and breathing retraining), educational support (about her condition, program, nutrition, advantages, and guidance to family members), psychological counseling, and nutritional intervention as per need. The detailed PR program is explained in Table 1. The PR program was continued from the day shifted from ICU and 4–6 days/week to till discharge (4 weeks). Home care program was advised to do regular exercises such as

Table 1: Protocol of pulmonary rehabilitation program

Phase I: ICU based Intervention started after hemodynamic stability (6 weeks)
Goals in the ICU
Optimizing lung expansion and secretion clearance, breathing pattern retraining, to maintain upper and lower extremity ROM, strength and basic bed mobility and transfers
Exercise program in acute phase
Assessment criteria (Level-0: No cooperation, Level-2: Moderate cooperation)
Basic assessment S5Q=0-3/5, MRC sum=36, BBS sitting=1[6]
Airway clearance
Gentle chest percussion, vibration & shaking manoeuvres, suctioning on need basis, along with manual hyperventilation
Breathing retraining
Synchronizing the breathing with abdomino thoracic movement with ventilator, 15–20 repetition/3–4 times/day, after tracheostomy with BIPAP, 10–15 times of diaphragmatic and thoracic expansion exercise with manual resistance (manual resistance was applied with hands over the xiphisternal and abdomen of the patient by the physical therapist and the patient were asked to inspire against hand resistance. Followed by sand bag with ranges from 0.5 kg to 2 kg was used for resistance)
DVT prophylaxis and ROM
Pneumatic compression device applied during night and sleep time, active ankle pump exercise, calf stretching, squeezing and other ROM exercises when the patient awakes, 15–20 repetition/3–4 times/day
Exercise program in acute maintenance phase
Assessment criteria (Level-3 close to full cooperation-Level 5 Full cooperation) Basic assessment S5Q=4–5/5, MRC sum=36, BBS sitting=1–3, standing=0–2, sit-to standing=0–1[6]
Early mobilization
Initially long sitting, bed side dangled sitting with caution about all tubes and drains 10–30 min/daily, chair sitting after drain removal done up to extubation from ventilator, and on BiPAP
Cardiopulmonary endurance training
Leg cycling with mini pedal exerciser 10–20 min once/daily, standing march 10–15 times once/daily up to weaned from ventilator. Same continued twice daily after weaning
Walking training
Initially 5–10 min with 2–4 L/min oxygen with BiPAP to maintain SpO_2 above 90%, then progressed up to 20 min, twice daily with 2–3 L/min oxygen support with BiPAP
Phase II: Inpatient rehabilitation program till discharge, 5–6 days/week (4 weeks)
Endurance training
Level walking as much as tolerated (10–20 min, according to patients walking speed or with 6MWT distance or intensity of modified Borg scale 4–6/10). Arm and leg cycle ergo meter: 10–20 min/5–6 weekly. Borg's scale 4–6/10
Strength training
Target muscles trained with dumbbells, weight cuffs (up to 2 weeks we avoided upper limb weight lifting due to repeated pig tail and ICD insertion)
Upper limb: Biceps, triceps, deltoid, pectorals. Lower limb: quadriceps, hamstrings, gluteus muscles, calf and dorsi flexors with 1–3 kg/10 rep/2 sets/ alternate days
Breathing retraining exercises
Breathing control through diaphragmatic breathing and localized thoracic expansion exercise with 15–20 rep/2–3 h once, trained breathing exercise in sitting, semi Fowler's position and side lying and supine gradually, paced breathing was trained during activities

S5Q: Standardized 5 questions, MRC: Medical research council score for muscle testing, BBS: Berg's Balance score, BiPAP: Bi-level Positive airway pressure, ICD: Intercostals drainage, 6MWT: 6-min walk test, ROM: Range of motion, ICU: Intensive care unit, DVT: Deep-vein thrombosis

walking, breathing exercises, resistance exercises with the use of simple object such as water bottles and sandbags. Outcome measures are explained in Table 2.

Discussion

Our patient showed significant improvements in exercise performance and quality of life following PR from day one to till discharge. Initially, the patients were hopeless towards exercise-based intervention due to long-term ventilation, repeated ICD tubes insertion, painful events during procedures, being transferred for different tests such as computed tomography and long-term ICU stay. Repeated psychological counseling, and appropriate hormone therapy with medroxyprogesterone and doxycycline the symptoms of pneumothorax and air leaks in ICDs were settled, along with adjustment of analgesics the graded mobilization was initiated. She accepted the changes and gave her full effort during the sessions. Initially, she was mobilized with maximal assistance then reduced to supervised mobilization; initially, she could participate 15–30 min in exercise sessions, while before discharge, she tolerated up to 2 h. She had showed a noticeable improvement in exercise capacity, observed in both endurance exercise time, during walking, reducing the level of dyspnea, increased daily physical activity, enhanced muscle strength, and improved quality of life. A positive trend toward symptoms of depression was also observed. The program was safe, well-tolerated and had a high rate of adherence. Her family members also showed high interest during the PR sessions and advised to follow the same at home.

This report clearly shows the importance and benefit of a PR program, even though it shows changes in patient recovery from physical illness rather than the disease state. PR program can be a good adjunct therapy to pharmacological treatment. In addition, serves as a bridging aid before lung transplantation in such chronic respiratory diseases such as LAM.

Abstract

Context: Majority of the Indians live in rural areas where resource constrained settings depend on cheaper and less invasive tests to diagnose extrapulmonary tuberculosis (TB). The decline in prevalence of TB in the country could affect the validity of the diagnosis. The aim was to measure validity of the pleural fluid study of proteins, lactate dehydrogenase (LDH), and cell counts in diagnosis of tuberculous pleuritis. **Materials and Methods:** This was a cross-sectional study conducted in a 300 bedded secondary care hospital in rural Tamil Nadu. Exhaustive sampling was performed during April 2013 to March 2014. Pleural fluid study of 54 patients with exudative pleural effusion was conducted. Diagnosis was established by closed needle pleural biopsy. Receiver operator curves were plotted and area under curve (AUC) was calculated for various parameters. Sensitivity, specificity, and predictive values were calculated for different cut-off values of the parameter with significant AUC. **Results:** Prevalence of tuberculous pleural effusion was 56% (95% confidence interval [95% CI] - 42.5–69.5%). Lymphocyte predominance in pleural fluid was the only valid test, and cut-off >80% had sensitivity of 70.0% (95% CI - 53.3–86.7%) and specificity of 70.8% (95% CI - 52.2–89.4%). Pleural fluid pH, protein or its ratio with serum protein, sugar, total leukocyte count, LDH or its ratio with serum LDH; erythrocyte sedimentation rate were not valid screening tests. **Conclusions:** Lymphocyte predominance > 80% can be used as a marker of tuberculous pleuritis. Since the prevalence of tuberculous pleuritis in India has come down considerably, newer tests need to be included to make a valid diagnosis.

Keywords: Extrapulmonary tuberculosis, pleural tuberculosis, tuberculosis, tuberculous pleuritis

Introduction

In India, one-fifth of new tuberculosis (TB) cases notified in 2014 were extrapulmonary.[1] Pleural effusion is the second common form, constituting about 28% of extrapulmonary TB (EPTB).[2,3] In 12th 5 years plan, new objective of early detection and treatment of at least 90% of all types of TB cases including EPTB was stated for Revised National Tuberculosis Control Program.[4] EPTB is known to be associated with delayed diagnosis.[5] Invasive or costly investigations are often required to diagnose EPTB.[6] In a rural area, healthcare settings are not well-equipped to diagnose EPTB. In India, 68.8% population live in rural area.[7]

In resource-constrained settings, pleural fluid study of protein and lymphocyte counts were suggested by World Health

Organization (WHO) to diagnose pleural TB.[8] In our institution, we had been using pleural fluid cell counts and simple pleural fluid biochemical tests to diagnose tuberculous pleuritis. In the context of falling prevalence of TB in India, the validity of using these tests were questionable in diagnosing tuberculous pleuritis.[1] Adenosine deaminase (ADA) assay or pleural biopsy were not available in our setting. Hence, this study was undertaken to measure validity of the pleural fluid study of protein, lactate dehydrogenase (LDH), and cell counts for diagnosing tuberculous pleuritis which had been in use in our hospital.

Materials and Methods

Study design

The study design was cross-sectional.

Study setting

The study was carried out in Internal Medicine Department of a 300 bedded secondary care level hospital in Dindigul district of Tamil Nadu. For 1 year, we had service of a pulmonologist in our hospital when this study was conducted. Since our institution did not have facilities for histopathological examination, special arrangements were made for the purpose of the study to transport the biopsy specimen to a tertiary care teaching hospital nearly 400 km away.

Study participants

The study period was April 2013 to March 2014. Patients presenting with evidence of pleural effusion on chest X-ray and were exudative by Light's criteria were included in the study.

Sample size and sampling technique

We expected sensitivity of 93.5% for differential lymphocyte count cut-off more than 80%.[9] We expected prevalence of TB among exudative pleural effusion to be 43.8%.[10] For alpha error of 5% and precision of 10%, we needed sample size of 53. With exhaustive sampling done during the study period, we obtained a sample size of 54.

Study tools

A semi-structured performa was used to collect information regarding symptoms and co-morbidities from the patient interview as well as from hospital records. Cell counts and biochemical parameters of pleural fluid were studied. Diagnosis was established by pleural biopsy.

Pleural biopsies were performed by pulmonologist by closed needle technique. Pleural biopsy was conducted under strict aseptic conditions. The affected side of the chest was cleaned thoroughly with antiseptics and draped. Under local anesthesia, a 23-gauge needle was passed and pleural fluid aspirated to confirm the site for incision. Just above the upper border of the rib in the selected site, a 0.5 cm incision was made. Through this incision, Tru-Cut needle was introduced, and multiple biopsies were taken by multiple passes. The pleural tissue obtained was put into a formalin bottle. Biopsy specimens were sent for histopathological examination to Pathology Department of a tertiary care center.

Analysis

Data entry was carried out using EpiData software, version 3.1 (The Epidata Association, Odense, Denmark) and analysis was performed using SPSS software, version 20 (IBM corporation, New York). Mean and standards deviation (SD) were calculated for continuous variables. Proportions were calculated for categorical variables. Histopathology of pleural biopsy was considered gold standard. Receiver operator curve (ROC) was plotted for various laboratory parameters. Sensitivity, specificity, and predictive values for various cut-offs of parameter with a significant area under curve were calculated.

Ethical aspects

The study was approved by Ethical Committee of the Institution. Participants were explained possible complications of pleural biopsy procedure in detail, and an information sheet also was provided. They were informed that institution would bear the expense for the management of complication if any. Voluntary written informed consent was given by the study participants. Privacy was ensured for an interview. Confidentiality of the information is maintained.

Results

Characteristics of the study participants

There were 54 study participants. All of them had unilateral and exudative pleural effusion. Males comprised 35 (65%) of the study participants and females the rest. Mean age was 47.7 years (SD = 16.4), and 31 (57%) were above 60 years. Fourteen (25.9%) participants were tobacco smokers, 5 (9.3%) were diabetic, and 6 (11.1%) were hypertensive. None of them had cardiac failure or renal failure. Majority had one or the other of the following symptoms such as a cough, breathlessness, loss of appetite, loss of weight, or fever.

Laboratory parameters

Among hematological parameters, 42 (77.7%) had anemia, all had raised erythrocyte sedimentation rate (ESR), 18 (33.3%) had leukocytosis, 32 (59.2%) had neutrophilia, 3 (5.5%) had band forms, 34 (62.9%) had lymphocytopenia, none had lymphocytosis, 4 (7.4%) had eosinophilia and 10 (18.5%) had monocytosis. In pleural fluid study, mean LDH was 898.2 (SD = 551.2), mean total protein was 4.7 g/dl (SD = 0.9), and mean pH was 7.5 (SD = 0.4). Forty-two (77.7%) had lymphocyte dominance more than 50% in pleural fluid.

Validity of laboratory parameters

The diagnosis was established by pleural biopsy. Among the study participants, 30 (56%, 95% confidence interval [95% CI] - 42.5–69.5%) had tuberculous pleuritis, 7 (13%) had malignancy and 17 (31%) had other inflammatory conditions.

ROCs were plotted to explore valid laboratory parameters to diagnose tuberculous pleural effusion. The parameters studied were pleural fluid pH, protein, LDH, sugar, total leukocyte count, lymphocyte predominance, ratio of LDH in pleural fluid to serum, ratio of protein in pleural fluid to serum and ESR. Among these parameters shown in Table 1, only the pleural fluid differential lymphocyte count had a diagnostic value with an accuracy of 80.1% (95% CI - 67.8–92.4%, $P < 0.001$).

WHO criteria for diagnosing pleural effusion in resource-constrained settings (pleural fluid protein >3 g/dl and lymphocytes >50%) was 90% sensitive but specificity was 45.8%. Table 2 shows sensitivity, specificity, and predictive value of different cut-offs of lymphocyte predominance. With pleural fluid lymphocyte count > 50% as cut-off for TB, sensitivity was 93.3% (95% CI - 83.9–100%) and specificity was 41.7% (95% CI - 21.6–61.8%); with pleural fluid lymphocyte count >80%, sensitivity was 70.0% (95% CI - 53.3–86.7%), specificity was 70.8% (95% CI - 52.2–89.4%), positive predictive value was 75% (95% CI - 58.6–91.4%), and negative predictive value was 65.4% (95% CI - 46.7–84.1%), respectively [Table 2]. We had explored combinations of laboratory parameters for better sensitivity and specificity but, none emerged.

Discussion

Differentiating the pleural effusion as exudative or transudative using the Light's criteria was the first step toward diagnosis. The 54 samples identified as exudative may include some transudates as we know the specificity of Light's criteria can be as low as 71%.[11] The gold standard for diagnosis of tuberculous pleuritis is the demonstration of *Mycobacterium tuberculosis* in pleural fluid or biopsy specimen or demonstration of caseating granuloma in the biopsy specimen.[12] Tuberculous pleuritis was diagnosed in 30 (56%) samples, by closed needle biopsy. However, the sensitivity of closed biopsy is lower than biopsy taken by diagnostic thoracoscopy.[12]

Among the biochemical parameters and cell counts of pleural fluids, only pleural fluid differential lymphocyte count had a diagnostic value for tuberculous pleuritis. The WHO criteria of lymphocytes >50% and protein >3 g/dl in pleural fluid had high sensitivity (90%), but specificity was poor (45.8%). Pleural fluid lymphocytes >80% as a cut-off, sensitivity was 70.0%, and specificity was 70.8%. However, these estimates were not very precise. According to Pettersson and Riska, lymphocyte predominance >80% was characteristic of tuberculous pleuritis but also of malignant pleural effusion.[9]

The criteria recommended by WHO for diagnosing tuberculous pleuritis in resource-constrained setting was based on studies done in settings where 95% of the pleural effusions were tuberculous.[8] It is known that, in India, prevalence of TB had halved by 2013 compared to 1990.[1] In our study, only 56% (95% CI - 42.5–69.5%) of the pleural effusion were tuberculous. Similarly, in a tertiary care setting in Tamil Nadu, only 43.8% (95% CI - 29.5–58.1%) were tuberculous.[10] With low prevalence, false positive rates increase.

In this context, newer markers need to be considered for the diagnosis of tuberculous pleuritis. Burgess *et al.* had recommended to combine pleural fluid lymphocyte-neutrophil ratio and ADA, which would give sensitivity of 88% and specificity of 95% for tuberculous pleuritis diagnosis.[13] A meta-analysis estimate of sensitivity and specificity of ADA levels in pleural fluid were 92% and 90%, respectively.[14] Polymerase chain reaction for mycobacterial DNA had poor sensitivity.[15] Interferon-gamma, interleukin 12 (IL-12), IL-18 were identified as markers of tuberculous pleuritis.[16] Interferon-gamma is highly efficient marker of tuberculous pleuritis but costly.[15] Detection of free and immune complexed mycobacterial antigens ES-31 and EST-6 were suggested as an adjunct test to diagnose tuberculous pleuritis.[17]

Table 1: Area under the receiver operating curve of laboratory parameters for diagnosis of tuberculous pleuritis (*n*=54)

Laboratory parameters	AUC* with 95% CI	*P*
PF† pH	0.541 (0.383–0.699)	0.608
PF protein	0.603 (0.451–0.755)	0.198
PF LDH	0.535 (0.373–0.696)	0.663
PF sugar	0.559 (0.396–0.722)	0.459
PF total leukocyte count	0.431 (0.269–0.592)	0.384

Ratio of PF protein to serum protein	0.550 (0.395–0.705)	0.531
Ratio of PF LDH to serum LDH	0.492 (0.335–0.648)	0.917
ESR	0.542 (0.388–0.697)	0.614

*AUC: Area under curve; †PF: Pleural fluid. LDH: Lactate dehydrogenase; CI: Confidence interval; ESR: Erythrocyte sedimentation rate

Table 2: Sensitivity, specificity and predictive values of lymphocyte predominance in pleural fluid for tuberculous pleuritis (*n*=54)

Differential lymphocyte count (%)	With 95% CI (%)			
	Sensitivity	Specificity	Positive predictive value	Negative predictive value
Above 50	93.3 (83.9–100)	41.7 (21.6–61.8)	66.7 (52.2–81.2)	83.3 (61.8–100)
Above 60	86.7 (74.3–99.1)	45.8 (25.5–66.1)	66.7 (51.6–81.8)	73.3 (50.5–96.1)
Above 70	80.0 (65.4–94.6)	66.7 (47.5–85.9)	75.0 (59.7–90.3)	72.7 (53.7–91.7)
Above 80	70.0 (53.3–86.7)	70.8 (52.2–89.4)	75.0 (58.6–91.4)	65.4 (46.7–84.1)
Above 90	60.0 (42.1–77.9)	91.7 (80.4–100)	90.0 (76.6–100)	64.7 (48.3–81.1)

CI: Confidence interval

Conclusions

Pleural fluid protein is not a valid test to diagnose TB. Lymphocyte predominance >80% in pleural fluid is a valid marker but, because of low prevalence of TB among pleural effusion, predictive values are compromised. Newer tests need to be included in pleural fluid studies with due to consideration of cost and logistics to improve validity of the diagnosis of tuberculous pleuritis in resource-constrained settings.

ABSTRACT

We describe a 21-year-old male with a history of smoking and subacute onset of breathlessness with normal cardiorespiratory examination. The presence of "track marks" and digital infarcts prompted evaluation for infective endocarditis and confrontational history taking revealed anorexia, weight loss over 3 months along with intravenous drug abuse of reconstituted tablets of tapentadol. Echocardiography was normal and blood cultures were sterile; computed tomography showed bilateral, diffuse, small centrilobular nodules with "tree-in-bud" appearance. In this clinicopathologic conference, we discuss the clinical and radiological differential diagnosis of centrilobular nodules, lung biopsy findings, and management options for patients with such a presentation.

KEY WORDS: Excipient lung disease, intravascular talcosis, pulmonary foreign body angiogranulomatosis, talc granulomatosis

PRESENTATION OF THE CASE

A 21-year-old college student presented with breathlessness and left-sided chest pain for a week. Breathlessness was insidious in onset and persisted on walking at own speed at level. Chest pain was left-sided, intermittent, pricking and non-exertional. There was no history of fever, rhinitis, headache, hemoptysis, cough, or joint pains. He did not raise pets but admitted to smoking 7–8 cigarettes/day and consuming whisky (192 g of alcohol weekly). He denied any recent worsening of educational performance. He did not report any significant prior medical illness or pertinent illness in family or occupational dust exposure. He was initially seen in cardiology and evaluation showed normal cardiac and respiratory examination without any pallor, clubbing, or organomegaly. Body mass index was 18.6 kg/m^2. The examination also showed extensive track marks over both arms with evidence of multiple peripheral digital infarcts [Figure 1], raising suspicion for infective endocarditis (IE). On confronting, he disclosed daily intravenous self-injections of three–four powdered and reconstituted 50 mg tablets of Tapentadol (Tydol, Sun Pharma) in sterile distilled water two–three times a day over the last 2 years. He also admitted to using inhaled cannabis twice weekly over the last 2 years. There was associated anorexia and unquantified weight loss over the last 3 months. Three sets of blood cultures were sterile. Electrocardiography showed T-wave inversions in leads V3–V6 and II, III, and aVF. Transthoracic echocardiography (TTE) showed normal valves without any evidence of vegetations or pulmonary hypertension and normal left ventricular function. Serum creatinine

Figure 1: Composite image of the clinical photographs (left) of the right forearm showing "track marks," indicating healed superficial septic thrombophlebitis and (right) both hands showing multiple bilateral distal digital pulp infarcts. Similar findings were also seen in both plantar surfaces (not shown)

was 0.6 mg/dL; urine microscopy was normal without any albuminuria. Hemoglobin was 14.2 g/dL with normal leukocyte and platelet counts. He remained afebrile. Transesophageal echocardiography (TEE) was planned; in the meanwhile, review of his chest radiographs showed diffusely scattered fine nodules bilaterally [Figure 2, left]. Spirometry showed mild restriction with reduced diffusion capacity for carbon monoxide (forced expiratory volumes at 1 s 2.25 L [65%]%, forced vital capacity 2.87 L [71%], DLco 62%). There was desaturation to 92% while walking 6 minutes, with preserved walk distance (545 meters, 89% predicted). Human immunodeficiency virus (HIV), anti-nuclear antibodies, hepatitis B, and hepatitis C antibodies were negative by enzyme-linked immunosorbent assay. Immunoglobulin E levels were 9 IU/mL (normal <100 IU/mL). High-resolution computed tomography (HRCT) of the thorax showed bilateral profuse evenly distributed micronodules with "tree-in-bud" [Figure 2, right]. There was no sputum production on induction with 3% saline. A procedure was planned for diagnosis.

DIFFERENTIAL DIAGNOSIS

Important features of this case

This HIV-negative young adult with significant smoking history, cannabis use, and intravenous drug abuse with reconstituted tablets over 2 years has breathlessness, anorexia, and weight loss with radiological findings of micronodules. There is evidence of distal embolic infarcts, but initial evaluation for endocarditis was negative. The reduced DLco, restriction on spirometry and unexpectedly low walk distance in a young individual with desaturation on walking implies extensive parenchymal and/or pulmonary vascular disease. The differential diagnosis of profuse bilateral micronodules is extensive [Table 1] but can be narrowed by careful history and analysis of HRCT findings in conjunction with the expected pulmonary complications of intravenous drug abuse [Table 2].[1] The first step is to characterize the

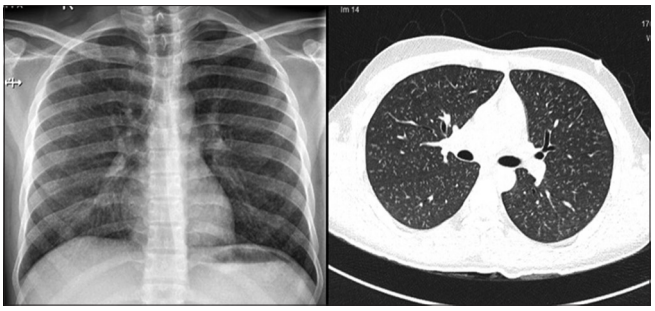

Figure 2: Composite image of the chest radiograph (left) showing small nodular opacities and high-resolution computed tomography of the thorax (right) showed bilateral profuse evenly distributed micronodules with tree-in-budding; pulmonary artery was normal in size, and there were no associated lymphadenopathy. Expiratory computed tomography did not show any air trapping (not shown)

distribution of the micronodules spatially within the lung and also the secondary pulmonary lobule. These nodules were uniform in size and were distributed evenly in a cephalocaudal direction, without any preferential lobar involvement. None of the nodules abut the pleural surface or the fissures [Figure 3]; there is clear evidence of extensive bilateral branching nodules in centrilobular distribution. There is no evidence of bronchiectasis; while no contrast was administered, in conjunction with echocardiography, there is no dilated pulmonary artery or lymphadenopathy. These findings limit the radiological differentials to causes of micronodules in a centrilobular distribution and extensive uniform "tree-in-bud" appearance. "Tree-in-bud" indicates the presence of dilated centrilobular bronchioles with lumen impacted by mucus, fluid, or pus and associated with peribronchiolar inflammation. "Tree-in-bud" indicates small airway disease and is associated with airway infection in the large majority but can also be rarely caused by arteriolar disease.[2] Its presence makes three common causes of centrilobular nodules unlikely: hypersensitivity pneumonitis, follicular bronchiolitis, and respiratory bronchiolitis.

Endobronchial tuberculosis

Mycobacterium tuberculosis is endemic in India, with more than 2.2 million new cases each year. Delayed recognition

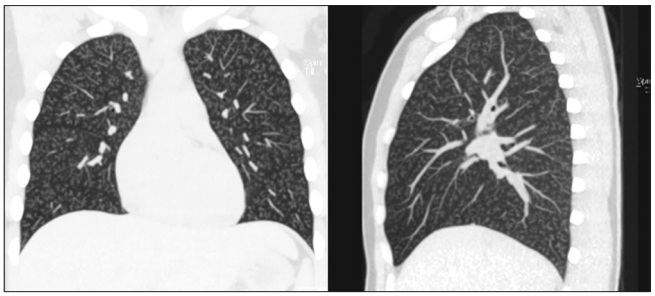

Figure 3: Coronal and sagittal reconstruction of the maximum intensity projection formatting of the high-resolution computed tomography images of the thorax showing diffuse, extensive, bilateral centrilobular nodules with branching and without any lobar predominance

and extensive disease are related to associated substance abuse, poverty, and malnutrition, all of which were present in this patient. Extensive endobronchial spread of tuberculosis can cause extensive tree-in-bud opacities although asymmetry is usually seen.[3] Tuberculosis is also the most common cause of micronodules with a random pattern (miliary). Even though the "pretest probability" of tuberculosis is high in this patient, the marked symmetry and the absence of any cavitation or consolidation is odd; digital infarcts are unusual but could be caused by an associated immune complex phenomenon that can occur with tuberculosis. *Mycobacterium avium*-intracellulare infection can also cause centrilobular nodules with "tree-in-bud," bronchiectasis, and consolidation. While it can be seen in immunocompetent patients, the classic phenotype is a middle-aged woman with slender build and without any constitutional symptoms.

Bronchopneumonia and viral bronchiolitis

Infectious bronchiolitis due to viruses, *Mycoplasma*, and chlamydia is a common cause of profuse and symmetric centrilobular nodules with "tree-in-bud;"[3] however, the prolonged illness and associated embolic phenomenon are unusual.

Allergic bronchopulmonary aspergillosis

Centrilobular nodules with "tree-in-bud" or miliary nodules can be caused by allergic bronchopulmonary aspergillosis but the absence of asthma, central bronchiectasis, and normal IgE levels rule out this diagnosis.[2,4]

Diffuse panbronchiolitis

Diffuse panbronchiolitis (DPB) is a rare disease of unknown cause presenting in males between the second and fifth decade with productive cough, diffuse bilateral centrilobular nodules with "tree-in-bud" and sinusitis. While reported in Indians,[5] it is extremely rare in our population but can explain all the clinical and radiological features.[6] Cold agglutinins are frequent in DPB and pulp infarcts may be due to an associated connective tissue disease. The absence of productive sputum, obstruction on spirometry, sinusitis, and air trapping on expiratory CT are unusual in DPB and necessitate further evaluation with surgical lung biopsy to establish the diagnosis.[6]

Excipient lung disease

Centrilobular nodules are usually caused by bronchiolar disease but can rarely be caused by arteriolar disease. Arteriolar causes include pulmonary edema and hemorrhage, excipient lung disease (ELD), granulomatosis with polyangiitis (GPA), plexogenic arteriopathy (PH), veno-occlusive disease (VOD), pulmonary capillary hemangiomatosis (PCH), and metastatic calcification.[2] There was no evidence of heart failure, renal failure or anemia and hemoptysis to suggest alveolar hemorrhage. The absence of pulmonary hypertension makes centrilobular nodules due to PH, VOD, and PCH very unlikely. Nodules due to GPA are larger, fewer, and associated with cavitation. Excipients are insoluble inert particulate filler materials that bind and protect the active drug during production as well as shape and lubricate tablets for easy swallowing. Excipients include talc (hydrated magnesium silicate), microcrystalline cellulose, crospovidone, and starch. Typically, excipients constitute 5% of a tablet's mass. On intravenous injection, excipient particles lodge in pulmonary arterioles and trigger an angiogranulomatous reaction; progressive disease is associated with dyspnea and pulmonary hypertension.[7] However, the presence of finger pulp infarcts, "tree-in-bud" appearance and absence of pulmonary hypertension are unusual in ELD.

CLINICAL DIAGNOSIS

In summary, the differential diagnosis of extensive centrilobular nodules with "tree-in-bud" without bronchiectasis or pulmonary hypertension in this young adult with smoking, cannabis use, and intravenous drug abuse of reconstituted tablets can be narrowed down to extensive endobronchial tuberculosis, diffuse panbronchiolitis, and ELD.

Dr. RM. PL. Ramanthan: With these clinicoradiological possibilities in mind, this patient underwent fundus examination and bronchoscopy with bronchoalveolar lavage (BAL) and transbronchial lung biopsy, with a plan for surgical biopsy if evaluation was inconclusive. Can we now have the findings?

Dr. K. Divya: Dilated fundus examination confirmed refractile particles scattered along both the retinal arteries and retinal veins [Figure 4], confirming systemic embolization of small (<5 μm) talc particles, consistent with intravenous talcosis. Inhalational talc exposure does not cause such marked retinal deposition as the inhaled particles are larger and are restricted by bronchioles and pulmonary circulation.[8,9]

Dr. Nidhya Ganesan: BAL was negative for acid-fast bacilli and for *M. tuberculosis* by Xpert MTB/RIF; occasional needle-shaped crystals were seen on cytology. The transbronchial lung biopsy specimen confirmed perivascular granulomatous reaction to talc particles [Figure 5, left] that appear as birefringent needle-shaped crystals within the granulomas under polarized light [Figure 5, right]. Review of the composition of Tydol confirmed the presence of talc as excipient. Microcrystalline cellulose appears rod like while starch has a maltese cross pattern and crospovidone is nonbirefringent on polarization.[7]

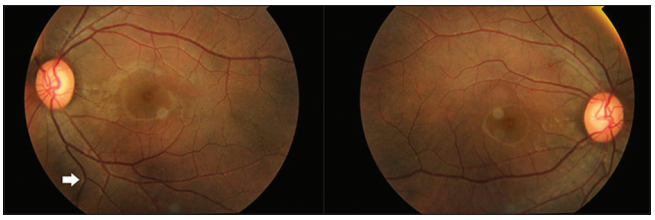

Figure 4: Fundus photograph of both eyes showing refractile particles scattered along both the retinal arteries and retinal veins, confirming the diagnosis of intravenous talcosis

Dr. Srinivas Rajagopala: A diagnosis of ELD (talc granulomatosis) was made. Psychiatry services were involved, and the patient underwent counseling, arrangement for family supervision, and daily-observed methadone replacement. He has successfully discontinued intravenous drug abuse and remains stable at 3 months of follow-up. Serial spirometry, DLco, and radiographs have been advised at 6 monthly intervals. Three unusual findings need an explantation; 1) The presence of "tree-in-bud" in a process that is hematogenous in origin 2)The absence of pulmonary hypertension in ELD and 3)The cause of the bilateral digital infarcts observed.

Dr. B. Devanand: Diseases involving pulmonary arterioles can cause centrilobular nodules as arterioles run in the peribronchovascular interstitium adjacent to bronchioles. Talcosis associated with intravenous abuse is most commonly associated with diffuse fine centrilobular nodules, ground-glass abnormalities or a combination of nodules and lower-lobe emphysema (Ritalin lung with methylphenidate).[9,10] The "tree-in-bud" pattern is unusual for arteriolar disease; it can be caused by intra-arteriolar accumulation of talc with associated adjacent perivascular granulomatous reaction giving the appearance of branching centrilobular nodules and has been described in a few cases of ELD earlier.[11]

Dr. Srinivas Rajagopala: What is the course of ELD? Can the disease progress despite cessation of abuse?

Dr. Kancherla Roopa: Lung fibrosis and pulmonary hypertension are related to the extent of vascular obstruction and granulomatous inflammation and are usually irreversible with talc, cellulose, and crospovidone as these cannot be mobilized; starch can be removed by metabolism and pulmonary hypertension can be reversible to a large degree. Disease progression can occur despite cessation due to ongoing granulomatous foreign-body reaction to the deposited, unmobilizable talc. The initial series of patients described all had progressive symptoms leading to death over 9 months to 5 years.[10,12] The index

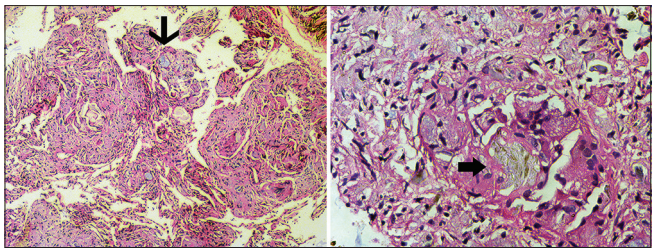

Figure 5: Photomicrographs of the transbronchial lung tissue biopsy specimen (left) demonstrating perivascular foreign body granulomatous reaction to the talc particles (thin arrow, H and E, ×100). Under polarized light, birefringent 20–95 μm needle-shaped crystals were seen in the granuloma, consistent with talc (block arrow, H and E, ×400)

patient has a large load of perivascular disease and is at risk for pulmonary hypertension and disease progression despite cessation of further abuse.

Dr. Srinivas Rajagopala: How common is systemic embolization of talc given that the lung acts as an effective filter?

Dr. K. Divya: The talc that is trapped in the pulmonary arterioles is typically around 10 μm, but smaller particles can escape to the systemic circulation and be detected in the retina, spleen, and virtually every organ on autopsy.[12] Finding excipient crystals in fundoscopy is a rapid noninvasive method to confirm intravenous talcosis.

Dr. Srinivas Rajagopala: Given the presence of digital infarcts, is TEE needed to exclude IE in this patient?

Dr. G. Rajendiran: The first consideration in this patient with possible unsafe needle practices, no murmurs, weight loss, breathlessness, and digital embolic manifestations was subacute native valve IE. TTE has low sensitivity compared to TEE (46% vs. 93%) although both are highly specific (96%).[13] Embolic manifestations are seen in about half of patients with IE.[14] He was not administered any antibiotics, three sets of blood cultures were sterile, and TTE showed all valves clearly without any vegetations. TEE is restricted in our practice to high probability for IE or in whom TTE is rendered less sensitive due to obesity, lung hyperinflation, or prosthetic valves. The index patient met only 2 minor Modified Duke's criteria and was considered low risk for IE after the initial evaluation and TEE deferred.[15] Furthermore, a clear alternative explanation for the observed distal infarcts in the form of talc deposition in the distal microcirculation with thrombosis is available and corroborated by fundoscopy. While this physical finding has not been described in ELD previously, it is consistent with the distal digital embolization and subsequent microthrombosis caused by talc.

Dr. Srinivas Rajagopala: What are the options for those with progressive breathlessness despite cessation of intravenous drug abuse?

Dr. RM. PL. Ramanthan: There are previous small series of lung allografts after a careful selection process in ELD with excellent outcomes.[16] Cadaveric bilateral sequential lung transplantation is a reality in our country today, and he can be listed for the same at our center if he meets criteria and remains free of substance abuse for at least 6 months with adequate psychiatry counseling.

SUMMARY

Clinical examination findings continue to have relevance in this era of investigation-driven medicine. Excipient lung disease can result from intravenous injection of reconstituted tablets and can present with ground glass opacities, small nodules, and emphysema. Pulmonary arteriolar diseases must be considered in the differential diagnosis of centrilobular nodules on CT.

Miliary Sarcoidosis: does it exist? A case series and systematic review of literature

Srinivas Rajagopala[1], Sakthi Sankari[2], Roopa Kancherla[1], Ramanathan Palaniappan Ramanathan[1], Devanand Balalakshmoji[3]

[1]Department of Pulmonary Medicine, [2]Department of Pathology and [3]Radiodiagnosis, PSG Institute of Medical Sciences and Research, Peelamedu, Coimbatore, India

Abstract. *Background and Objectives:* Sarcoidosis typically presents with peribronchovascular and perilymphatic nodules on high-resolution computed tomography (HRCT); a miliary pattern is reported but not well described. *Design, setting:* We describe four patients with miliary sarcoidosis and results of a systematic review of all previously reported cases from 1985 onwards. *Results:* We identified only 27 cases of "miliary" sarcoidosis in the HRCT era. These patients were older (85.2% older than 40 years), had more co-morbidities (72.7%) and were symptomatic compared to "typical" sarcoidosis. Respiratory symptoms were present in 61.9% at diagnosis. Hypercalcemia was seen in 28.5%. On review of HRCT images, only 34.6% (9/26) had a "true miliary" pattern without fissural nodules. In our series, prominent perivascular granulomas were seen on histopathology in all. 44.4% (12/27) had tuberculosis preceding or concurrent to miliary sarcoidosis. Of the eight true associations, tuberculosis preceded sarcoidosis by 52 (median, IQR 36) weeks in six and occurred concurrently in another two. The diagnosis of tuberculosis was clinical in all with concurrent diagnosis of tuberculosis and sarcoidosis. Treatment with steroids had 100% response and 14.2% relapse. *Conclusions:* A true miliary pattern in the HRCT era is very rare in sarcoidosis and subtle perilymphatic pattern is nearly always seen; this should be labeled "pseudo-miliary". Prominent perivascular granulomas are associated with true miliary pattern. Miliary sarcoidosis patients are older and symptomatic, needing treatment at diagnosis. "Miliary" sarcoidosis may follow treatment for tuberculosis; concurrent cases possibly indicate the difficulty in differentiating both or a "tuberculo-sarcoid" presentation. *(Sarcoidosis Vasc Diffuse Lung Dis 2020; 37 (1): 53-65)*

Key words: sarcoidosis, miliary, micronodules, miliary tuberculosis

Introduction

Miliary sarcoidosis has been described as a rare presentation of sarcoidosis and was reported in <1% of all cases in the pre-computed tomography (CT) era on chest radiography (1). With the advent of high-resolution-CT (HRCT), peribronchovascular and perilymphatic nodules in relation to the secondary pulmonary lobule are recognized as classic of sarcoidosis (2). However, random micronodules (miliary pattern) have been described and sarcoidosis is included in the differential diagnosis of a "miliary" pattern on HRCT (3, 4). There are no well-described series or systematic reviews of "miliary" sarcoidosis in the high-resolution CT (HRCT) era. On the other hand, tuberculosis continues to be a global pandemic with an estimated 10 million cases worldwide in 2016 (5). Miliary tuberculosis accounts for 1-2%

of all cases of new cases of tuberculosis and 8% of all extra-pulmonary tuberculosis (6). The relationship between tuberculosis and sarcoidosis continues to be enigmatic; tuberculosis can precede, follow or present concurrently with sarcoidosis (7). In patients with miliary tuberculosis, the clinical symptoms of night sweats, weight loss and fatigue are non-specific and overlap markedly with sarcoidosis. Respiratory symptoms are often minimal in either forms of miliary disease and microbiological evidence of *M.tuberculosis* is only present in 20-30% of miliary tuberculosis (8). Sarcoidosis has a characteristic perilymphatic pattern on histopathology and radiology (2); the co-relation of random nodules seen on radiology with pathology in "miliary" sarcoidosis is unclear. We describe a series of patients with miliary sarcoidosis and the results of our systematic review on miliary sarcoidosis in the HRCT era.

Materials and methods

We describe four patients with miliary nodules and proven sarcoidosis that was managed in the authors' institution over three years and performed a systematic search of literature for miliary sarcoidosis.

Systematic search of literature

Two of the authors (R.S and R.K) conducted a systematic search of literature in PUBMED independently using the MeSH term "miliary" *AND* "sarcoidosis" limited to title/abstract and restricted the search from the year 1985 onwards (9). The choice of the year was defined by the first description of the current HRCT protocols and detailed description. This was further supplemented by search of IndMed using the same terms, the references of retrieved articles, our personal records and the Internet search engine GOOGLE. These articles were screened without blinding, by title and abstract review to identify relevant studies. Any discrepancy was resolved by consensus. Full texts or abstracts were then retrieved to identify the type of lung involvement in reported cases with miliary sarcoidosis. Only those articles that included patients with HRCT according to established protocols (9), included representative images or detailed descriptions and had a histological diagnosis compatible with sarcoidosis (10) were included for analysis. For the purpose of this systematic review, we included all descriptions that were accepted as "miliary" in published cases but reanalyzed the images independently. The diagnosis of sarcoidosis was according to previous published guidelines (10).

Data extraction

Data was abstracted from selected cases in a predefined data extraction form (Supplementary Table).

Statistical analysis

Continuous data are presented as mean (standard deviation (SD), median [range or Interquartile Range (IQR)] and categorical data as percentages and proportions. All statistical analysis was done using the Statistical software SPSS Version 14.

Ethics

The Human Ethics Committee of PSG IMS&R, Coimbatore, approved the study. All data was anonymized to maintain patient confidentiality.

Case reports

Case 1

A 65-year-old lady presented with cough, night sweats and exertional breathlessness of two months' duration. There was no history of weight loss or fever. Her past history was significant for hypertension and non-productive cough two years before that was evaluated at another center. CT had shown right paratracheal and bilateral hilar lymphadenopathy along with upper lobe-predominant micronodules. Tuberculin skin testing was negative and endobronchial ultrasound-guided needle aspiration (EBUS-FNA) and transbronchial lung biopsy (TBLB) were performed. EBUS-FNA showed few non-caseating granulomas and TBLB was non-contributory. A presumptive diagnosis of tuberculosis was made and four-drug anti-tuberculosis treatment (ATT) was administered for six months with improvement in cough. Examination was unremarkable during current evaluation. There was no exposure to pets, drugs

or occupational dusts. Chest radiography was normal. Spirometry was normal and diffusion capacity showed mild reduction. HRCT showed profuse random micronodules without lymphadenopathy and an upper-lobe and peripheral predominance that was visualized better with maximum intensity projection (MIP, Figure 1). Renal function tests, serum calcium and angiotensin-converting enzyme (ACE) levels were normal. Fibreoptic bronchoscopy (FOB) was done with bronchoalveolar lavage (BAL) and TBLB; BAL Fluid was negative for acid-fast bacilli and Xpert MTB/RIF and TBLB showed interstitial inflammation only. Surgical lung biopsy was performed and showed extensive perivascular non-caseating granulomas (Figure 2). BAL mycobacterial cultures were subsequently reported as negative. She was started on steroids with resolution in cough and breathlessness by second month of treatment. She remains asymptomatic and off steroids after one year of treatment.

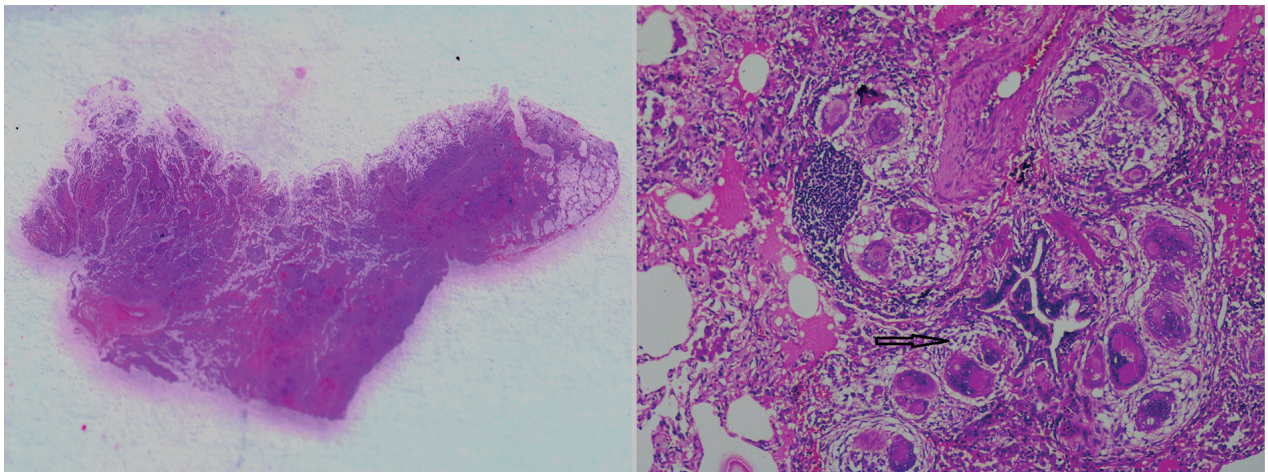

Fig. 2. Composite image of photomicrographs of surgical lung biopsy specimen of Patient 1 with left [Gross Pathological specimen, transverse plane] showing subpleural sparing and (right, Hematoxylin and Eosin stain (H & E), x 4) showing peribronchial and perivascular granulomas (arrow)

Case 2

A 40-year old gentleman presented with polyuria, fatigue and nausea of 20 days duration. There was also history of unquantified weight loss and exertional dyspnea. He did not smoke and did not raise pets, abuse drugs or have exposure to occupational dusts. Physical examination showed raised papulonodular skin lesions over hands and legs. Renal function tests showed serum creatinine of 2.65 mg/dL (normal <0.8 mg/dL); Urine microscopy showed 2+ albumin with bland sediments. Hemoglobin was 10.9 g/dL with normal leukocyte and platelet counts. Ultrasound showed normal kidney size with preserved corticomedullary distinction. Chest radiographs showed miliary nodules. Serum ionized calcium was 1.8 mg/dL (normal 1.1-1.3 mg/dL) with suppressed parathyroid hormone (1.9 pg/mL, normal 15-65) and normal vitamin D levels (23.6 ng/mL). ACE levels were elevated (98 U/mL, normal 8-53). Tuberculin skin testing was negative. CT-Chest showed random micronodules without zonal preponderance and bilateral hilar lymphadenopathy (Figure 3, left). FOB was done with BAL and TBLB; BAL was negative for acid-fast bacilli and Xpert MTB/RIF. TBLB showed perivascular non-caseating granulomas with Schaumann and asteroid bodies (Figure 4). Punch biopsy of the skin also showed non-caseating granulomas in the dermis**.** He was started on steroids with resolution of hypercalcemia and normalization of renal function. His subsequent course was complicated by steroid-aggravated diabetes presenting with hyperosmolar coma; methotrexate was added and steroids were tapered. He remained asymptomatic with near-complete radiologic clearing (Figure 3, right) after one year of stopping methotrexate but relapsed by 18 months and remains on methotrexate.

Case 3

A 55-year old gentleman with moderately controlled diabetes mellitus presented with exertional breathlessness, cough, right-sided shoulder pain and weight loss of one month's duration. There was no anorexia or expectoration. He was a farmer by occupation and did not have exposure to poultry or occupational dusts and chemicals. Physical examination showed fine bilateral crepitations without clubbing. Renal function tests, serum calcium, urine microscopy, ACE levels and hemogram were normal. Chest radiographs showed miliary nodules (Figure 5, left). Human Immunodeficiency virus was negative by enzyme-linked sorbent assay. Tuberculin skin testing was strongly positive (18 mm, 1 TU). CT-Chest showed random micronodules without lymphadenopathy (Figure 6, left). FOB was done with BAL

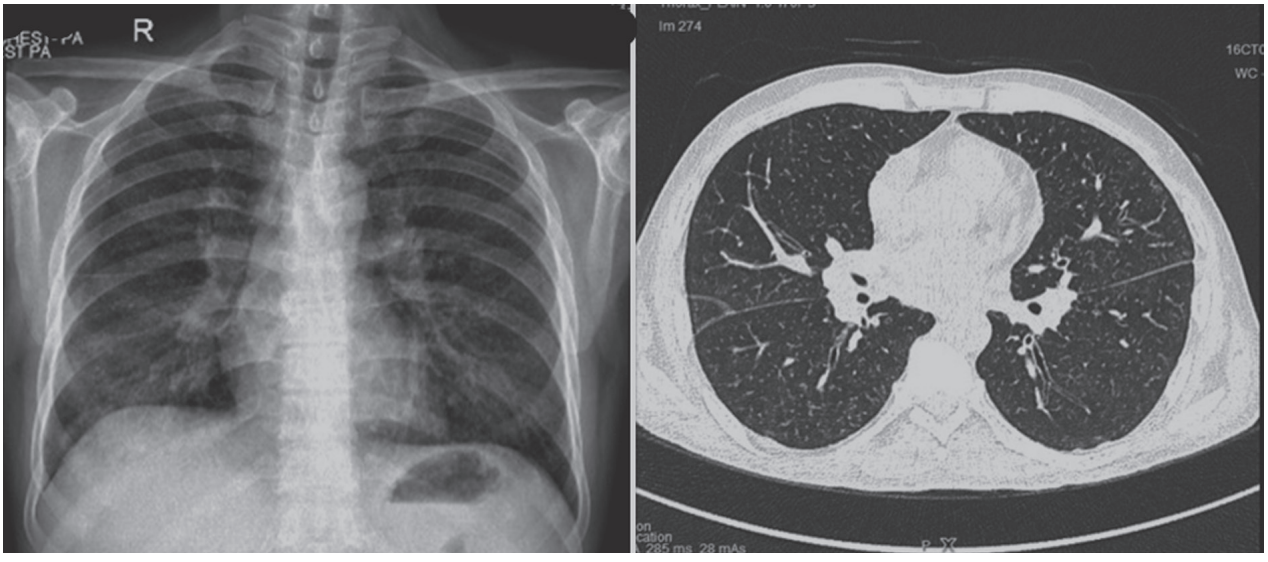

Fig. 3. Composite images of chest radiography of patient 2 showing miliary nodules (left) and HRCT images (major fissure level) showing upper lobe-predominant random nodules. No involvement of the fissure or "beading" of the fissure is seen

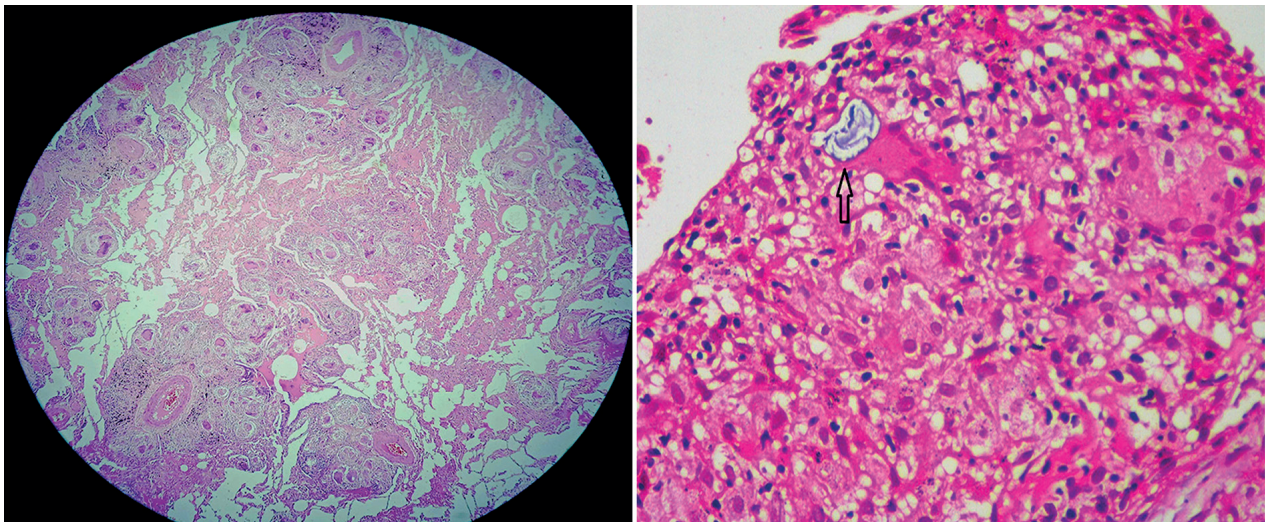

Fig. 4. Composite image of Photomicrographs of lung biopsy sample of Patient 2 with left, [Hematoxylin and Eosin stain (H & E), x scanner power] showing multiple non-necrotizing perivascular granulomas, and right, [H & E stain, x 40) showing a Schaumann body within a giant cell (arrow)

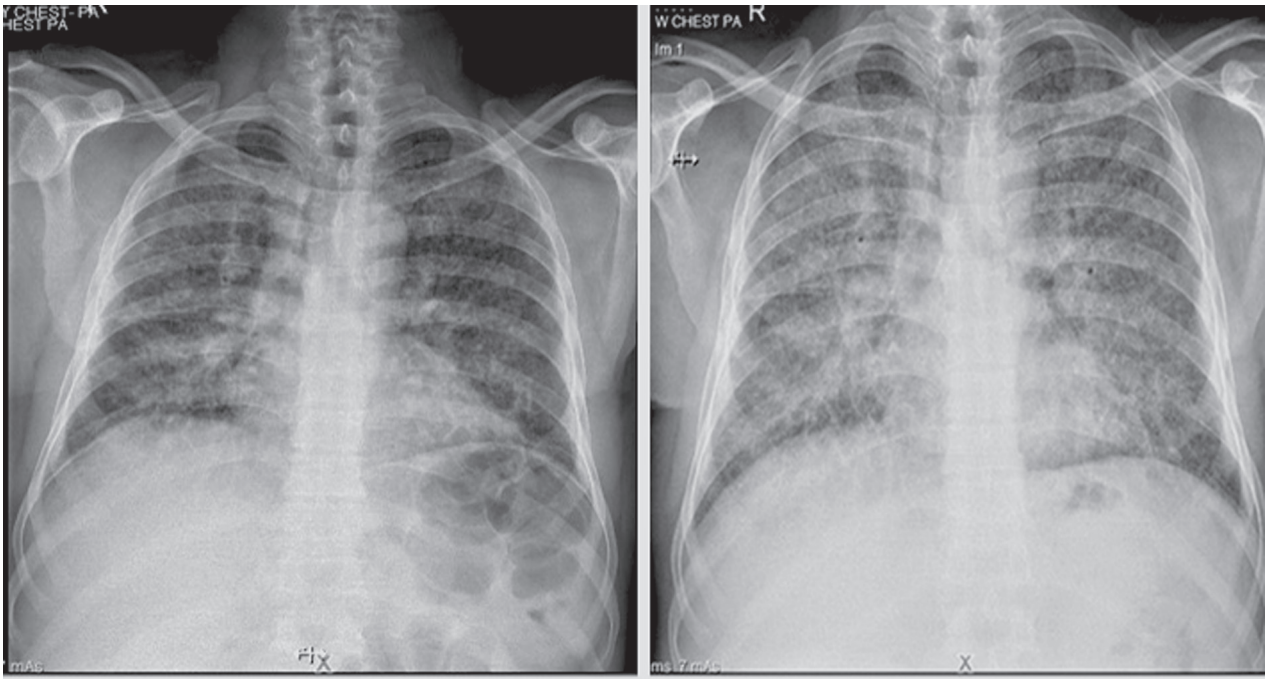

Fig. 5. Composite image of the Chest Radiographs of Patient 3 at initial evaluation (left) showing extensive miliary nodules. Subsequent Chest radiograph (right) after six weeks of anti-tuberculosis treatment alone show profusion of nodules with diffuse ground-glass opacification. Worsening hypoxemia was clinically noted

and TBLB; BAL was negative for acid-fast bacilli and Xpert MTB/RIF. TBLB showed well-formed perivascular granulomas with Langhans' giant cells, occasional fibrinoid necrosis and lymphocytes rimming (Figure 6, right). A diagnosis of miliary tuberculosis was made and four-drug weight-based ATT was started. However, his symptoms continued to worsen with worsening nodules and development

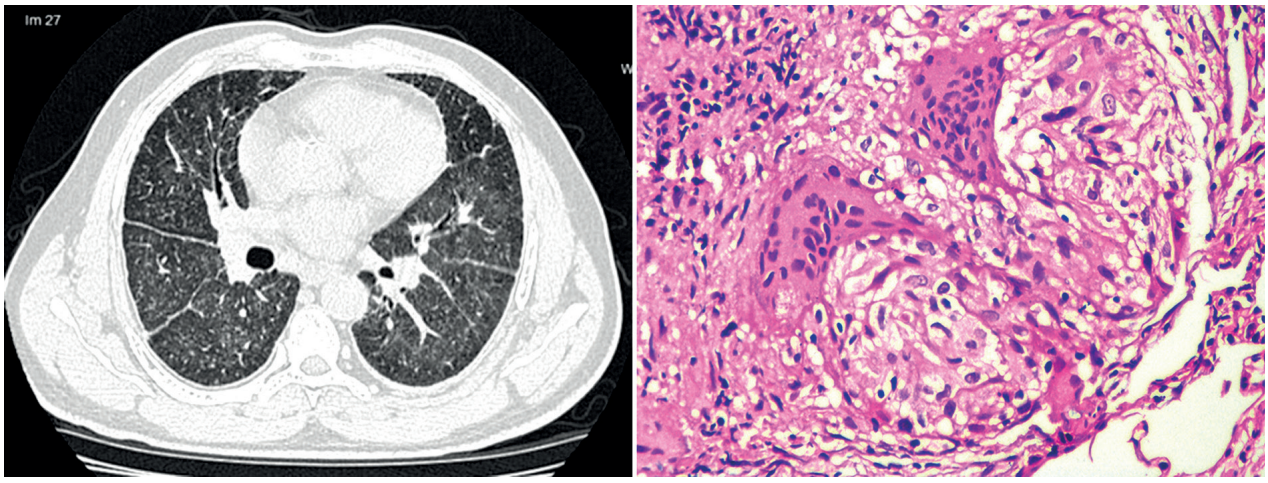

Fig. 6. Composite image of the HRCT image of Patient 3 at the level of major fissure during worsening hypoxemia corresponding to right-side of Figure 5 (left), showing random nodules with fissural prominence, with beading in both oblique fissures; some interlobular septal thickening and diffuse ground glass opacity can be seen and right, (Hematoxylin and Eosin stain, x 40) showing a non-necrotizing granuloma with peripheral lymphocyte cuffing

of hypoxemia needing oxygen at four weeks (Figure 5, right). BAL mycobacterial cultures were negative in the meantime. Steroids were added with a presumptive diagnosis of immune reconstitution syndrome, with resolution of hypoxemia and symptoms. Symptoms recurred after stopping steroids at four weeks; right-sided vision loss due to uveitis occurred. After a clinico-pathological review, a possibility of concurrent miliary tuberculosis with sarcoidosis was considered. ATT was continued and low-dose tapering steroids and methotrexate (in view of poorly controlled diabetes) were added, with complete resolution of symptoms by eight weeks. He remains asymptomatic after two years of cessation of ATT and methotrexate.

Case 4

A 48-year-old gentleman presented with fatigue for two weeks. There was no history of night sweats, weight loss or fever. He did not smoke, did not raise pets, abuse alcohol or drugs and did not report exposure to occupational dusts. Physical examination was normal. Renal function tests, urine microscopy and hemogram were normal. Serum calcium was elevated (1.43 mg/dL, normal 1.1-1.3). Chest radiographs showed miliary nodules (Figure 7, left). ACE levels were elevated (76 U/mL, normal 8-53). Tuberculin skin testing was negative. CT-Chest showed upper lobe predominant random micronodules and lower-lobe interlobular septal thickening (Figure 8, left & right). FOB was done with BAL and TBLB; BAL was negative for mycobacterial cultures and Xpert MTB/RIF. TBLB showed prominent perivascular non-necrotizing epitheloid granulomas with asteroid bodies (Figure 7, right). A diagnosis of miliary sarcoidosis was made and steroids were initiated. His symptoms and hypercalcemia resolved by four weeks and steroids were tapered over the next nine months. He remains asymptomatic on follow-up.

Results of the systematic search

Our systematic search identified 27 reports of miliary sarcoidosis in 21 reports (3, 11-30); this included 16 men and 9 women (Table 1, supplementary Table). This cohort of "miliary sarcoidosis" was older, was mostly symptomatic and had high co-morbidity burden. The mean age of the included patients was 47.5±13.2 years; 85.2% were older than 40 years. 72.7% reported at least one associated co-morbidity (11, 12, 16, 18, 21, 27, 30).

The median time to presentation was 8 (IQR 12) weeks. The majority had symptoms at the time of presentation (90.9%, 20/22); only two patients recognized by surveillance transbronchial lung biopsies post-lung transplantation were asymptomatic

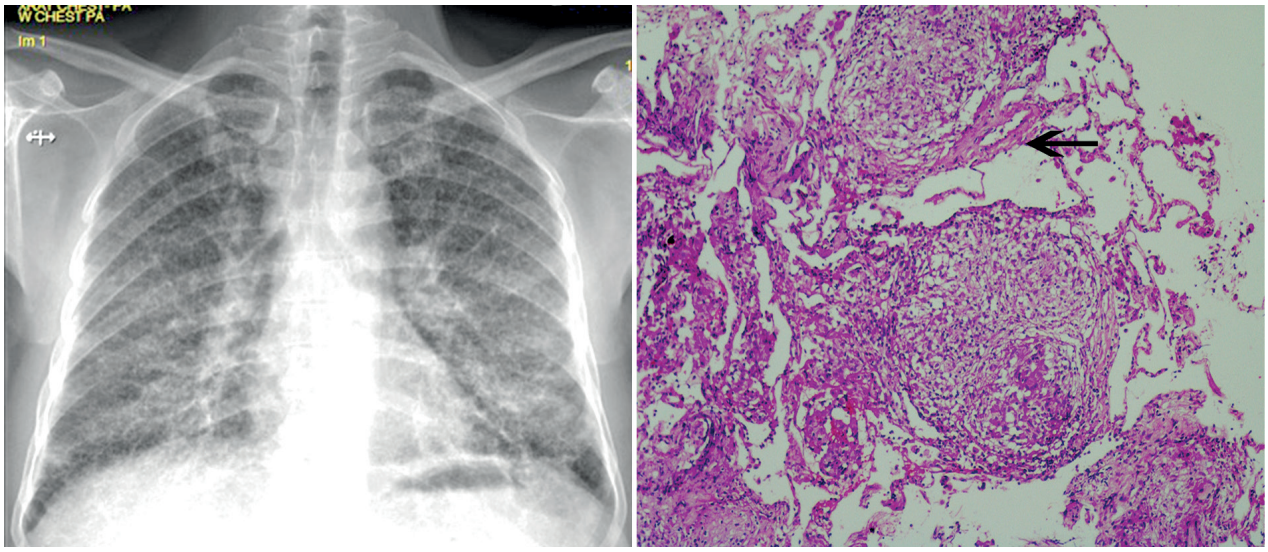

Fig. 7. Composite image of chest radiography images (left) of Patient 4 showing miliary nodules at diagnosis and photomicrographs of the lung biopsy specimen [right, Hematoxylin and Eosin stain (H & E) x 4] showing multiple perivascular granulomas (arrow)

Fig. 8. Composite image of the HRCT image of Patient 4 showing (left, upper lobes) random nodules with perilymphatic predominance, beading of the right oblique fissure and perivascular nodules and (right, lower lobes) marked interlobular septal thickening in the lower lobes associated with random nodules

at diagnosis (11, 12). Respiratory symptoms, however, were present in 63.6% only at diagnosis (13, 14, 16, 20, 21, 23-25, 28-30). In those with respiratory symptoms, breathlessness and cough were present in less than 50% (45.4%). Fever (27.3%) (13, 21-23, 29), night sweats (11.1%) (22, 27) and weight loss (22.7%)(18, 22, 27) were all seen in a significant percentage at diagnosis.

Symptomatic multi-systemic disease in association with miliary sarcoidosis was seen in 36.4%.(17, 19, 20, 23, 30) Hypercalcemia was seen in 27.3% (19, 20, 23, 27) and acute kidney injury was seen in 9.1% (19) at diagnosis. None needed dialysis but chronic kidney disease occurred in association with nephrocalcinosis (19). Ocular (13.6%, 3/22) involvement (25), bone (4.5%, 1/22) disease (17), sicca syndrome

Table 1. Summary of clinical features of all reported cases of thoracic sarcoidosis with miliary nodules on High-resolution Computed Tomography (N=27) [$]

Characteristic	Description
Age, Mean ± S.D, N=24	47.5±13.2 years; Age >40 years 85.2%
Gender (Male: Female), N=25	16:9
	In those >40 years, Male: Females O.R 0.26, p=1.00 (61.9% vs 75%)
Country of description	India (10/26), United States (7/26), Greece (5/26), Japan (3/26), Germany (1/26)
Symptoms at presentation	
Any symptoms, N=22	None, asymptomatic (9.1%, 2/22)
Symptom duration prior to presentation, Median, IQR N=19	8, (12) weeks
Symptoms	Any respiratory symptom (63.6%, 14/22)
	Dyspnea (45.4%, 10/22), cough (45.4%, 10/22)
	Fatigue (30.4%, 7/23), fever (27.3%, 6/22), weight loss (22.7%, 5/22), night sweats (11.1%, 3/22)
Acute kidney injury	9.1%, 2/22
Hypercalcemia	27.3%, 6/22
Co-morbidities, N=22	Any 72.7% (16/22)
	Smoking (18.2%, 4/22), diabetes (13.6%, 3/22), hypertension (18.2%, 4/22), lung transplantation (9.1%, 2/22), dust exposure (13.6%, 3/22)
Symptomatic disseminated sarcoidosis	8/22 (36.4%)
Other site involvement	Ocular (13.6%, 3/22), pleural effusion (9.1%, 2/22), bone (4.5%, 1/22), sicca syndrome (4.5%, 1/22), pancreas (4.5%, 1/22)
Radiological findings (N=26)	
True miliary pattern on HRCT	17/26 (65.4%) only
Perilymphatic nodules on HRCT in miliary CT	8/17 (47.1%); Truly random nodules total 9/26 (34.6%)
Zonal predominance seen	Upper & middle (7/26, 26.9%), central (7.7%, 2/26), peripheral (19.2%, 5/26)
Fissural nodules	65.4% (17/26)
Peripheral subpleural predominance	69.2% (18/26)
Interlobular septal thickening	23.1% (6/26)
Intralobular septal thickening	11.5% (3/26)
Ground glass opacity	11.5% (3/26)
Mediastinal adenopathy	Yes (50%, 13/26); Right paratracheal (23.1%, 6/23), bilateral hilar (23.1%, 9/23), others (8.7%, 2/23)
Generalized lymphadenopathy	8.7% (2/23)
Steroid treatment	Yes 21/22 (95.2%), Response 100% (21/21)
Relapse	14.2% (3/21)
Tuberculosis and miliary sarcoidosis	
Both tuberculosis and sarcoidosis	Both tuberculosis and sarcoidosis 44.4% (12/27)
	Definite or probable tuberculosis followed by sarcoidosis 29.7% (8/27)
	Probable misdiagnosis of tuberculosis 33.3%, (4/12)
	Microbiologically proven 37.5% (3/8) of all cases only
	Sequential (87.5%, 7/8), concurrent (25%, 2/8)[@@]

(continued on next page)

Characteristic	Description
Time to sequential miliary sarcoidosis in those with tuberculosis preceding sarcoidosis, (Median, IQR) N=7	52 (36) weeks
Site of tuberculosis	Pulmonary 87.5% (7/8), spinal 12.5% (1/8)
Yield of TBLB, N=21	85.7% (18/21)
Miliary tuberculosis preceding or concurrent with miliary sarcoidosis	5/8 (62.5%), 2/5 with miliary TB preceding miliary sarcoidosis
ATT-induced hepatitis	2/8 (25%)

Abbreviations: S.D standard deviation, IQR Inter-quartile range, HRCT High-resolution Computed Tomography, TBLB transbronchial lung biopsy, ATT Anti-tuberculosis treatment
[@@]One patient had both sequential and concurrent diagnosis of tuberculosis and sarcoidosis

(4.5%, 1/22) (20) and pancreatic mass (4.5%, 1/22) (28) were the other manifestations seen. Pleural effusion was seen in association in 9.1% (2/22) (24, 28).

On review of the HRCT images, a "true miliary" pattern was seen in 65.4% (17/26) of the reported cases only. In these cases, fissural nodules and prominence could still be seen in 47.1% (8/17); only 34.6% (9/26) of reported cases could be classified as random micronodules on radiologic review (12-14, 17, 18, 24, 26, 28, 30). An upper and middle lobe distribution of nodules (11-13, 15, 16, 25-27) was seen in 26.9% (7/26) and a peripheral distribution was seen in 69.2% (11, 12, 15, 24, 28). Perilymphatic clustering of nodules (3, 11-18, 22, 24-26, 28) or a perivascular dominance (3, 13, 15, 19, 22, 26-28) of nodules was seen in 65.4% and 42.3% respectively. Interlobular septal thickening, often lower-lobe in distribution, was seen in 23.1% (Table 1) (12, 14, 15, 18). Mediastinal adenopathy was observed in 50% in association with micronodules and generalized systemic lymphadenopathy was seen in 8.7% of patients (19, 20).

44.4% (12/26) of the reported patients had tuberculosis preceding or concurrent to the diagnosis of miliary sarcoidosis (13-17, 20-22, 29). In four of these patients, this was likely a misdiagnosis (13, 14, 30). In eight patients, tuberculosis occurred preceding (15-17, 21, 22) sarcoidosis in six (62.5%), concurrently in one (37.5%) (29) and both in one (23). In those with tuberculosis preceding sarcoidosis, a microbiological confirmation was made in 42.9% (15-17, 22); Others were diagnosed based on pathology and clinical response (21). In patients with concurrent diagnosis of tuberculosis and sarcoidosis, the diagnosis of tuberculosis was clinical in all; in all these patients, clinical and pathological findings, including caseous necrosis, were consistent with tuberculosis but clinical resolution occurred on initiation of steroids only (23, 29). The time to subsequent diagnosis of miliary sarcoidosis after treatment for tuberculosis was a median of 52 (IQR, 36) weeks. Miliary tuberculosis followed or concurrent with miliary sarcoidosis was reported in four patients (Table 2) (15, 16, 23, 29).

TBLB was the most common modality used for diagnosis and was reported as diagnostic in 85.7%. As most patients were symptomatic, treatment with steroids was offered in 95.2%, with 100% response. Methotrexate was administered in two patients for steroid-related severe adverse effects, with good response in both. Three patients (14.2%) relapsed after steroid taper; prompt response was noted on re-institution without further relapse.(21)

Discussion

The description of "miliary" refers to small, well-defined, 1 to 3 mm nodules on chest radiography and is derived from Latin miliarius, meaning millet seed (8). This pattern implies hematogenous dissemination of disease and is classically associated with hematogenous spread of tuberculosis, fungal infections and malignancy (31). However, more than 40 diseases have been associated with this pattern on chest radiography (Table 2). The importance of quickly establishing the diagnosis, especially in high prevalence areas of tuberculosis, is that miliary tuberculo-

Table 2. Reported causes of miliary nodules on High-resolution Computed Tomography

Classification	Cause of miliary Nodules	Site of micronodules in SPL
Infectious	Mycobacterium tuberculosis	Random
	Disseminated Bacillus-Calmette-Guerin infection	Random
	Bacterial: Mycoplasma pneumoniae, Hemophilus influenzae	Centrilobular
	Fungal: Histoplasmosis, Coccidioidomycosis, hematogenous Candida infection	Random
	Viral: Varicella-zoster, cytomegalovirus	Centrilobular
	Parasitic: Tropical pulmonary eosinophilia	Centrilobular
Immunologic	Pneumoconiosis: Silicosis	Perilymphatic
	Pneumoconiosis: Coal worker's pneumoconiosis	Perilymphatic
	Hypersensitivity pneumonitis	Centrilobular
	Sarcoidosis	Perilymphatic
	Idiopathic pulmonary hemosiderosis	Centrilobular
	Pulmonary alveolar microlithiasis	Centrilobular
	Diffuse panbronchiolitis	Centrilobular
	Allergic bronchopulmonary aspergillosis	Centrilobular
Malignancy	Secondaries from bronchogenic carcinoma	Perilymphatic
	Others: melanoma, papillary thyroid carcinoma, renal, breast, Trophoblastic tumor, osteosarcoma	Random
	Pulmonary Langerhans' cell histiocytosis	Random
	Metastasizing leimyoma	Random
	Lymphoma	Perilymphatic
Substance abuse	Excipient lung disease	Centrilobular

Table 3. High-resolution computed tomography findings in Thoracic Sarcoidosis (Modified from Criado et al)

Typical features	
Lymphadenopathy	Site (hilar, right paratracheal), bilateral, symmetrical, well defined. May show "cluster of black pearls" sign. If calcified, patchy or egg-shell
Nodules	Micronodules 2-4 mm, bilateral, well-defined, upper and middle zone and peri-hilar predominant. Peri-bronchovascular, subpleural, interlobular septal (peri-lymphangitic pattern)
Fibrotic changes	Interlobular septal thickening, Reticular opacities, architectural distortion, traction bronchiectasis
Atypical features	
Lymphadenopathy	Unilateral, isolated, anterior or posterior mediastinal
Nodules	Miliary
	Lower-lobe predominant, unilateral, "Halo" sign or "Atoll" sign
Consolidation	Mass-like opacities, conglomerate masses, solitary pulmonary nodules, confluent alveolar opacities and ground-glass opacities
Linear opacities	Intra-lobular septal thickening
Airway	Mosaic attenuation, trachea-bronchial abnormalities, atelectasis
Pleural	Effusion, chylothorax, pneumothorax, pleural thickening, calcification, plaque-like lesions

sis is the most common cause, has 25-30% mortality in adults and is invariably fatal if untreated (8).

The finding of a miliary pattern on chest radiographs was noted in early roentgenologic series of thoracic sarcoidosis; 1.3% (2/150) had "miliary" disease (1). Thoracic sarcoidosis has been reported to have several typical and atypical findings on HRCT; miliary is classified as an atypical finding (Table 3) (3). The description of micronodules by their distribution in relation to the "secondary pulmonary lobule" on HRCT along with the clarity of margins and attenuation further helps in narrowing the differential diagnosis of diffuse pulmonary micronodules. Micronodules can be accurately classified as having a centrilobular, perilymphatic or random distribution with their characteristic disease associations (Table 2) (4). Miliary nodules have a random distribution and can be seen in relation to pleural surfaces, small vessels and interlobular septa but do not have a consistent or predominant relationship to any of these (31). Given the reported prevalence of sarcoidosis varies from 4.5-36 per 100,000, the very small number of cases of "miliary" sarcoidosis reported in literature in the HRCT era (Table 1) suggests that this is a very rare occurrence. Most series of computed tomographic findings in sarcoidosis and a review on atypical findings in thoracic sarcoidosis did not report "miliary" sarcoidosis (32, 33).

Our systematic review suggests that this small reported number is an overestimate as a true miliary pattern was seen only in 34.6% (9/26) of the published cases of "miliary" sarcoidosis; and subtle perilymphatic pattern is nearly always seen and the term "pseudo-miliary" may be more appropriate. Distinct perilymphatic clustering of nodules or a perivascular dominance of nodules was seen in 65.4% and 42.3%; fissural nodules leading to the "beaded fissure sign" was prominent and seen in 65.4% of cases. Further, unlike true miliary nodules that lack any zonal predominance, an upper lobe and peripheral clustering was seen in 30.8% and 19.2% respectively. In all our patients with random micronodules, we observed a prominent perivascular distribution of micronodules on histopathology (Figures 2, 4, 6 and 8); two of these had associated "beaded fissure sign" on HRCT. Pathologically, sarcoidosis causes perilymphatic clustering of granulomas; hematogenous or airway spread has not been postulated (34). Profuse clustering of micronodules along the centrilobular and perilymphatic compartments gives rise to an appearance of random nodules in the majority with a "pseudo-miliary" appearance. In the few patients with a true random pattern, prominent perivascular granulomas or drainage into the pulmonary lymphatics and subsequent dissemination by hematogenous route could be postulated.

The link between mycobacteria and sarcoidosis continues to be an enigma (7, 35). In the original descriptions, about 5% of sarcoidosis had tuberculosis preceding them. Polymerase chain reaction analyses of lung biopsies of sarcoidosis have shown mycobacterial DNA in 26.4%.(35) Tuberculosis may present concurrently and confound the diagnosis and management of these patients (23, 36, 37). It has been hypothesized that the immunological responses in sarcoidosis are analogous to "tuberculoid" or "pauci-bacillary" leprosy (38); persisting immunological responses to mycobacterial antigen can explain the extraordinarily high rates of tuberculosis preceding the diagnosis of pseudo-miliary sarcoidosis in the present systematic review.

The diagnosis of sarcoidosis rests on a constellation of clinical, radiological, histopathological and laboratory findings (39). Constitutional features including significant weight loss can occur in up to 25% of patients (Table 2). Fibrinoid necrosis and rarely, caseation can occur in sarcoidosis on histopathology (40, 41). Caseation may sometimes be absent in tuberculosis (41). Radiology can help in the differentiation of sarcoidosis from tuberculosis (26). The presence of hypercalcemia, skin involvement, negative tuberculin skin-testing, upper and middle-lobe distribution of nodules, a peripheral distribution of nodules when present and interlobular septal thickening all point to the diagnosis of "pseudo-miliary" sarcoidosis alone (42). However, sarcoidosis can precede, occur concurrent with or follow tuberculosis and differentiating tuberculosis from sarcoidosis remains a major challenge, especially in high prevalence areas of tuberculosis (43, 44). When the constellation of findings are non-conclusive, a trial of anti-tuberculosis treatment is appropriate in high prevalence areas given the very small number of true miliary sarcoidosis reported in literature. Steroids could be added when there is no clear response at 4-6 weeks (39, 43).

Conclusion

A true miliary pattern in the HRCT era is very rare in sarcoidosis and subtle perilymphatic pattern is nearly always seen; this pattern should be labeled "pseudo-miliary". Prominent perivascular granulomas are associated with true miliary pattern. Miliary sarcoidosis patients are older and symptomatic and mostly need treatment at diagnosis. "Miliary" sarcoidosis may follow treatment for tuberculosis; concurrent cases possibly indicate difficulty in diagnosis or a "tuberculo-sarcoid" presentation. Transbronchial lung biopsy had a good yield for diagnosis. Most patients were symptomatic and treated with steroids, with 100% response and 14.4% relapse.

ABSTRACT

Background: Urinary tract infection (UTI) is one of the most common bacterial illnesses and hence one of the most important indications for antibiotic treatment. Current knowledge of the common organisms implicated in causing UTI in the local community and surveillance to monitor the changes in susceptibility of uropathogens are imperative to ensure appropriate therapy. The study objectives were to assess the proportion of UTI caused by each of the common urinary pathogens, to study the antibiotic drug sensitivity patterns by analyzing the culture and sensitivity reports and to identify the drugs which would be potentially favourable candidates for empirical therapy in the study locale.

Methods: This hospital based cross sectional study was done by collecting the data from case records of patients who attended OPD or were admitted with diagnosis of UTI during the study period.

Results: *Escherichia coli* was the single most important cause of UTI, accounting for 70% of the infection among the studied subjects, amongst which 55% was extended spectrum beta-lactamase producing organisms. A pattern of increased susceptibility to higher antibiotics like ertapenem, tigecycline and decreased sensitivity to fluroquinolones was evident. In addition, nitrofurantoin was found to be one of the antibiotics to which most of the organisms were susceptible (85%) favouring its use in empirical therapy of UTI.

Conclusions: The pattern of accentuated susceptibility to higher antibiotics in the face of declining trend in the sensitivity to commonly used antibiotics necessitates promoting awareness on the need for rational prescribing of antibiotics among clinicians.

Keywords: Antibiotics, Culture and sensitivity, *Escherichia coli*, Urinary tract infection

INTRODUCTION

Urinary tract infections (UTI) remain one of the commonest infections diagnosed in out-patients and hospitalized patients. An in-depth knowledge on antimicrobial susceptibility pattern is essential for appropriate therapy, particularly with increasing resistance resulting from repeated use of the same antibiotic.[1] It is also essential to be aware of the changing patterns of antibiotic resistance in a locale.[2] Published data may not always represent the scenario prevailing in a particular location as the studies done elsewhere could vary in the pattern of microorganisms involved in causation, their sensitivity and resistance to different antibiotics which in turn depends on the antibiotic prescribing pattern in that region. This indicates that there is a need for studying the existing antibiotic sensitivity patterns in the local population.[3] Resistance significantly varies by region and the highest antibiotic resistance has been observed in developing countries. Similarly a significant rise in resistance over time is seen in studies reporting on community acquired *E. coli* UTI.[3]

Hence this study was designed to evaluate the drug sensitivity patterns to some of the commonly used antimicrobials in UTI like the beta lactams, fluroquionolones and aminoglycosides. In addition, the

antibacterial drugs commonly used in UTI like nitrofurantoin, cotrimoxazole were also studied for the sensitivity patterns. Thus, the study was done to provide an insight into the drug sensitivity patterns of common urinary pathogens to antibiotic therapy by analyzing the culture and sensitivity reports.

Our study was designed to identify the proportion of UTI caused by each of the urinary pathogens prevalent in the study locale and the likely drug candidates with the potential of being used as empirical therapy in community acquired pathogens by evaluating their sensitivity pattern, thereby enabling identification of the drugs which can effectively be used in the management of UTI.

METHODS

This was a hospital based study done at a tertiary care teaching hospital after the approval from Institutional Human Ethics Committee. The study was a cross sectional one, done using case records. The data from case records of the patients who attended OPD or admitted with diagnosis of UTI during the study period were included for the study based on inclusion and exclusion criteria.

The data from the case records of adult patients above the age of 20 years, of both sexes, diagnosed with UTI were included for the study. Patients with asymptomatic bacteriuria, those with complicated UTI, upper UTI or known malformations, paediatric and pregnant patients, immunocompromised patients like patients with HIV, on corticosteroids or immunosuppressant therapy, organ transplant recipient were excluded.

The culture and *in vitro* sensitivity testing report data were collected in addition to demographic data, co morbid conditions, symptoms and duration of symptoms and drug therapies. In addition, data on history of hospitalizations, catheterizations and frequency of recurrences were also obtained from the case sheets. Also, the details recorded on the review date regarding cure or continuing symptoms, repeat culture reports, if any, was made note of from the case record.

RESULTS

A total of 20 patients whose case records indicated that they had been diagnosed with UTI were included for the study. All these patients were urine culture positive. In our study 30% of patients were in the age group 20 -40 years and a large majority of about 45% were in the age group of 41-60 years and 25% of the patients were aged 61 -80 years (Figure 1). Male female ratio in our study population was 65:35.

Catheterization was done in 20% of the study subjects. The duration of catheterization was variable with one patient having a history of prolonged catheterization of 12 days. Concomitant renal disease was found in a high proportion of the UTI patients. Amongst the studied population, 10% had renal failure, 10% nephritis and 5% pyelonephritis with renal calculi. One patient manifested with lupus nephritis as she was a known case of systemic lupus erythematosis. One patient was a case of neurogenic bladder. About10% patients had presented with concomitant prostatitis and a similar 10% with UTI had history of recurrent episodes (Figure 2).

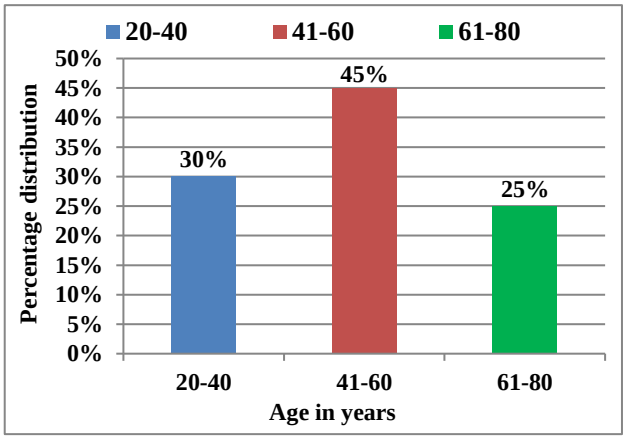

Figure 1: Frequency distribution of age in the study population.

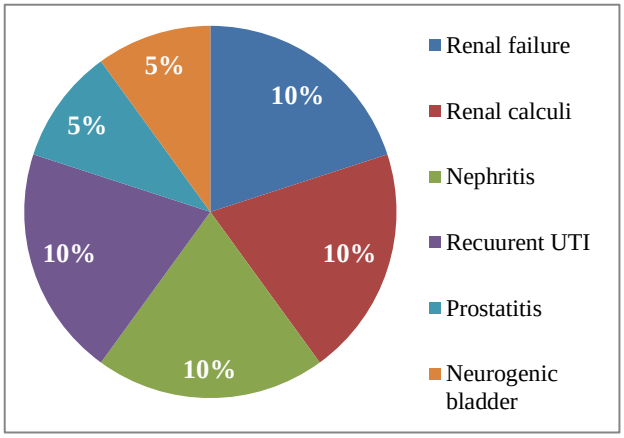

Figure 2: Frequency distribution of concomitant renal disease.

Data also demonstrated that concomitant systemic diseases were found in a significant proportion of the patients whose records were evaluated. A total of 40% had diabetes mellitus and 30% patients were hypertensives. Interestingly, amongst the 30% with hypertension, 83% were both diabetic and hypertensives. Heart disease was seen in 10%, one with diastolic dysfunction and the others with coronary artery disease. Amongst those whose data were studied, it was found that there were about five patients with other chronic systemic illnesses like chronic calcific pancreatitis, pituitary ademona, hypothyroidism, SLE, liver disease with cholelithiasis (Figure 3).

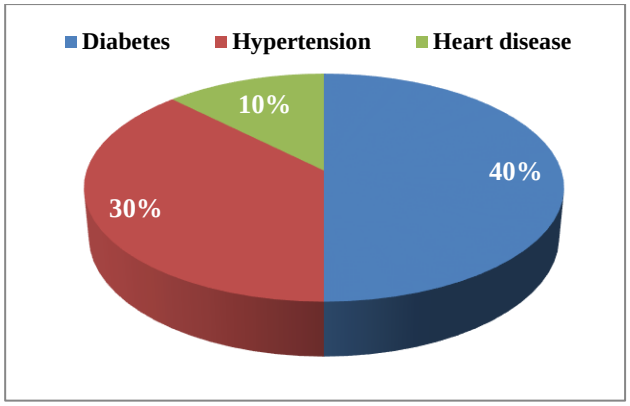

Figure 3: Frequency distribution of concomitant systemic diseases.

Escherichia coli was the single most important microorganism found to implicated in causation of UTI, accounting for 70% of the infection among the studied subjects (Table 1).

Table 1: Percentage distribution of organisms isolated in culture.

Organisms grown in culture	Percentage
Escherichia coli (ESBL)	55%
Escherichia coli	15%
Pseudomonas aeroginosa	10%
Enterococcus fecium	10%
Enterococcus fecalis	5%
Klebsiella pneumoniae	5%
Infection with dual organisms	10%

Organisms grown in urine culture in the study population revealed a high proportion of *E. coli* being Extended spectrum beta-lactamase (ESBL) producing organisms. Next in frequency was *Pseudomonas aeroginosa* and *Enterococcus fecium*, responsible for 10% each whilst *Enterococcus fecalis and Klebsiella* contributing 5% each. Co-infection with two of these organisms (dual infection) was seen in 10% (Figure 4).

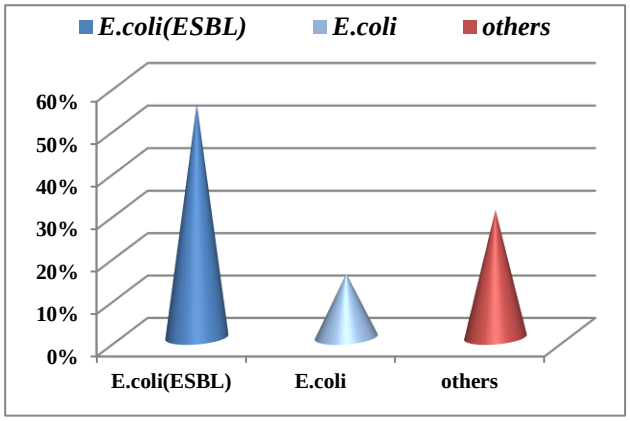

Figure 4: Frequency distribution of the urinary pathogens isolated in culture.

The sensitivity of the cultured organisms was also evaluated based on their susceptibility to different groups of antibiotics.

Aminoglycosides

The sensitivity to amikacin was found to be highest (60%) followed by netilmycin (40%) and the sensitivity for tobramycin and gentamycin were equal, each with 30% (Figure 5).

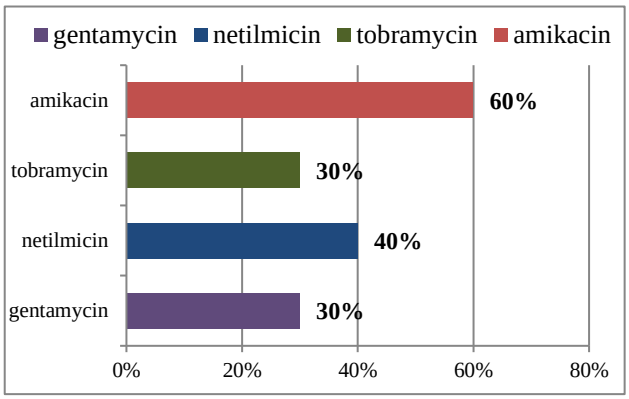

Figure 5: Frequency distribution of sensitivity to aminoglycosides.

Fluoroquinolones

The overall sensitivity to quinolones was found to be lower than that of aminoglycosides and among the quinolones, the greatest sensitivity percentage was recorded for ofloxacin (Figure 6).

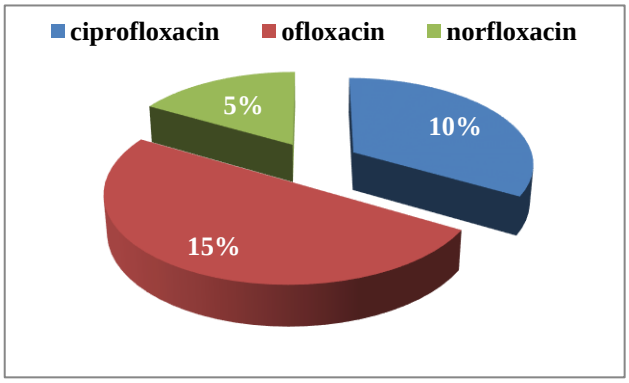

Figure 6: Frequency distribution of sensitivity to fluoroquinolones.

Beta lactams

Analyzing beta-lactams demonstrating high sensitivity, it was found that remarkably higher sensitivity was seen for beta lactams when combined with beta-lactamase inhibitors. It is quite obvious that the greater susceptibility can be accounted by the high proportion of ESBL organisms cultured. 60% of all culture reports studied revealed sensitivity of the cultured bacteria to

cefaperazone in combination with sulbactam and the next highest being piperacillin tazobactum combination with 45% and a slightly lower percentage of 40% was recorded for amoxicillin clavulanate (Figure 7).

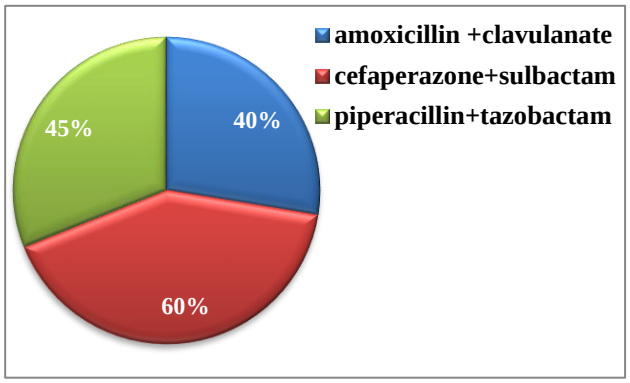

Figure 7: Frequency distribution of sensitivity to commonly used beta lactams in combination with beta-lactamase inhibitors.

Amino-penicillins

The aminopenicillins were one of the drug groups studied for bacterial sensitivity apart from ureidopencillins in the penicillin group of beta-lactam antibiotics and among the two amino-pencillins used commonly, organisms showed a marginally higher sensitivity to ampicillin (20%) as compared to amoxicillin (10%).

Cephalosporins

In the cephalosporin group, cefaperazone in combination with sulbactum was the antibiotic to which most organisms (60%) were sensitive. Apart from it, the other cephalosporins found to be useful in 10 -20% of infections based on culture and sensitivity pattern are cefepime, ceftriaxone, cephalothin and cefuroxime respectively with 30%, 20%, 15% and 10%. It was evident that sensitivity for the first and second generation was lower in comparison to third and fourth generations of cephalosporins (Figure 8).

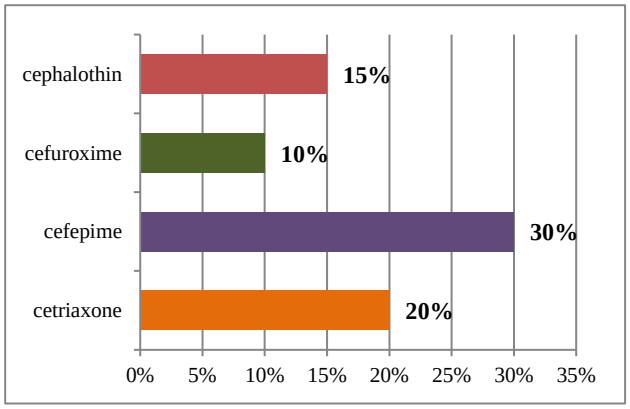

Figure 8: Frequency distribution of sensitivity to cephalosporins.

Carbapenems

Among carbapenems, greatest sensitivity was recorded for ertapenem (70%) (Figure 9).

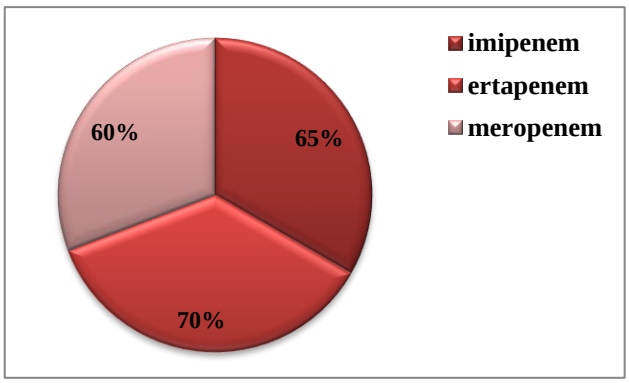

Figure 9: Frequency distribution of sensitivity to carbapenems.

Tetracycline and glycylcycline

Tigecycline was found to be the antibiotic to which 60% of the organisms studied were susceptible to and it matched that of cefaperazone combined with sulbactum in achieving the same percentage of sensitivity (Figure 10).

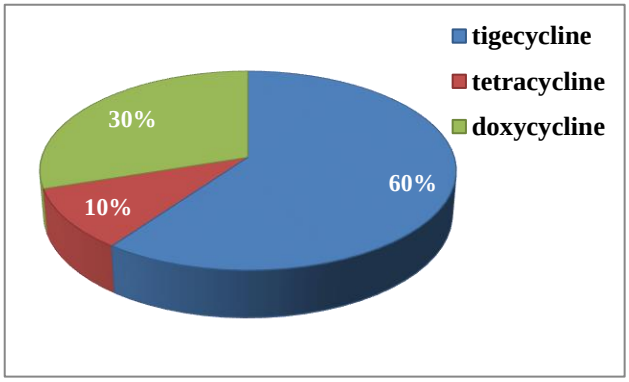

Figure 10: Frequency distribution of sensitivity to tetracyclines and glycylcycline.

Miscellaneous antibacterials

Interestingly, 85% of the cultures showed sensitivity to nitrofurantoin. Also, colistin was another antibiotic found to have similar percentage of sensitivity comparable with tigecycline and cefaperazone sulbactam combination. Sensitivity to cotrimoxazole was 40% and that for vancomycin and linezolid, with 20% each (Figure 11).

The pattern of antibiotic sensitivity of the UTI causing organisms was analyzed. Comparing the various drug groups with differential sensitivity percentages, the highest *in-vitro* sensitivity was to the beta lactam group followed by nitrofuantoin and colistin of the

miscellaneous antibacterial group and the least sensitivity was demonstrated by the fluoroquinolones (Figure 12).

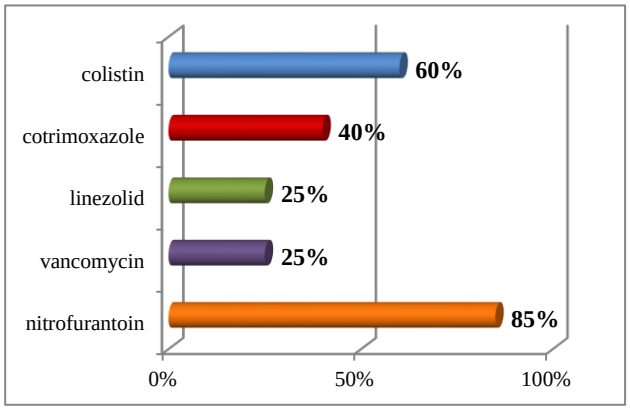

Figure 11: Frequency distribution of sensitivity to miscellaneous antibiotics.

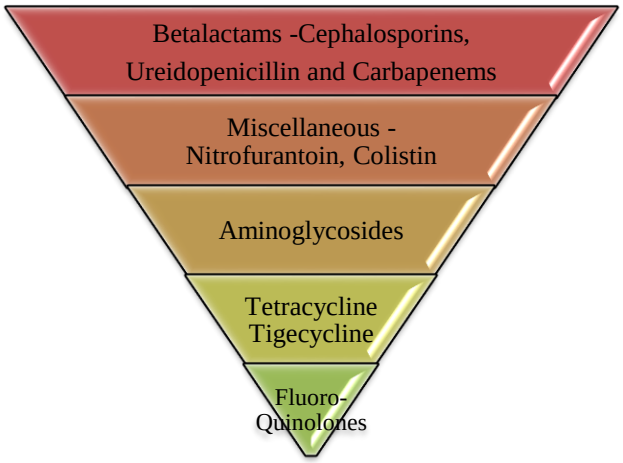

Figure 12: The pattern of drug susceptibility of urinary pathogens to different antibiotics.

DISCUSSION

Urinary tract infections (UTI) is the most common infection experienced by human after respiratory and gastrointestinal infections, accounting for 8.6 million visits (84% by women) in 2007 in the United States.[4,5] UTI is said to occur more commonly in females than in males; in males it is uncommon, but often associated with structural abnormality.[6] But in our sample, we found a greater percentage of males than females.

The highest co-morbidity noted in our study population was diabetes and hypertension. Diabetes plays a definitive role in increasing the occurrence of UTI because of the changes in immunological function and thereby increasing the susceptibility to UTI. Studies have demonstrated that the epidemiology of urinary tract infections (UTIs) among men and women with diabetes is similar to the epidemiology of those without diabetes with women having greater risk than men.[7] However, the bacteriology and antibiotic susceptibility patterns also do not, in general, differ from those without diabetes.[7,8] Our study results are well in line with these findings. In addition, a study has revealed that the virulence factors of *E. coli* affecting the diabetic individuals also remains the same as in the general population.[8]

Worldwide, the most frequent etiology is *Escherichia coli* and this is also reflected in our study results.[9] However the sensitivity and resistance patterns of *E. coli* strains causing UTI varies considerably between regions and countries.[10] In this study, we found that most *E. coli* isolated in culture were susceptible to cefaperazone-sulbactum, ertapenem, tigecycline, nitrofurantoin, colistin and amikacin. Among these nitrofurantoin and colistin are the drugs administered orally and the rest have to be administered by parenteral route. Interestingly, we found a decreasing sensitivity to fluoroquinolones which have been regarded as one of the first line drugs in UTI and therefore rampantly used which consecutively would have lead to a high degree of fluoroquinolone resistance in our population.

The study highlights the increasing trend of resistant Gram negative organism in culture necessitating the need for higher antibiotics. A study has highlighted that among tetracyclines, tigecycline has best in vitro susceptibility against ESBL producing Gram negative rods.[11] Likewise, a high cure rate, both clinical and microbiological has been recorded for ertapenem also, particularly for ESBL infections.[12] The indiscriminate use of such higher antibiotics like ertapenem and tigecycline will foster development of drug resistance, further complicating the management of urinary tract infection.

The vicious cycle wherein widespread use of newer antibiotics leading on to the organisms developing resistance to them and that in sequence, further necessitating the development of newer antibiotics ultimately results in difficult to treat infections. Such a situation can be overcome by implementing rational prescribing practices like the use of lower antibiotics with limited spectrum to which the organism is susceptible rather than resorting to prescribe higher antibiotics with a wide spectrum.[13]

This study has clearly delineated the emphatic role of nitrofurantoin in urinary tract infections. Our findings are in concordance with currently emerging trend in the use of nitrofurantoin as a key oral antibiotic option in the treatment of acute uncomplicated cystitis due to multi-drug resistant Gram negative bacilli causing UTI.[14] Studies also have acknowledged that the efficacy of nitrofurantoin for the empirical treatment is supportable from a public health perspective in an attempt to decrease uropathogen resistance.[15] Thus the current scenario based on drug sensitivity justifies the use of nitrofurantoin in the empiric management of UTI, not only due to the high susceptibility of *E. coli* to nitrofurantoin and the ease of oral administration but also owing to the fact that it lacks

cross-resistance with commonly prescribed antibiotics for UTI. However, nitrofurantoin is contraindicated in renal disease since most of it is really excreted.

Limitation

The limitation of the study is the small sample size. A larger study with a larger sample is needed to confirm the drug sensitivity pattern of UTI causing organisms in the study locale established through our study results.

CONCLUSION

The study highlights that *E. coli* contributes to the majority of the urinary tract infections diagnosed in our tertiary care hospital. In addition, the current drug sensitivity pattern signifies the need for higher antibiotics and this mandate implementing strategies of rational prescribing to avert forging resistance to these agents also. Nitrofurantoin, with good activity against a high percentage of the cultured organisms causing UTI, rationalizes its use for empirical treatment of UTI.

ABSTRACT

To compare the effectiveness of vitamin B12 and folic acid in comparison to N-acetylcysteine (NAC) as hepato-protective agent against liver damage in experimentally induced acute acetaminophen toxicity in Sprague dawley rats. 18 male Sprague dawley rats were randomly divided into three groups of six each. Group A was administered NAC, group B - vitamin B12 and group C - folic acid intraperitoneally one hour after an acute over-dosage of acetaminophen 3mg/kg. After 48 hours, 1.5 ml of blood was withdrawn and the animals were sacrificed for histopathological examination of liver. The mean AST and ALT of vitamin B12 group did not differ statistically from that of the NAC group. The folic acid group had higher mean AST though not statistically significant whilst the mean ALT was significantly higher compared to NAC group. The reduction in the mean ALP and GGT with vitamin B12 showed statistically significant reduction whereas the folic acid group did not. Histopathology of liver revealed that the tissue architect was totally disturbed with portal tract appearing hemorrhagic and congested in addition to centrilobular necrosis in the folic acid group. In vitamin B12 group, the architecture of tissue was preserved with only mild inflammation. Vitamin B12, unlike folic acid has proved to be an efficacious hepato-protective agent in animal model of acute acetaminophen toxicity.

Keywords: Acetaminophen toxicity, Folic acid, Vitamin B12, Liver enzymes, Histopathology.

INTRODUCTION

Acetaminophen or paracetamol is one of the commonly used non-steroidal anti-inflammatory drugs. Though considered as safe analgesic-antipyretic, an overdose can lead to hepatotoxicity. Each year in the United States, approximately 6% of adults are prescribed acetaminophen doses of more than 4 g/day and 30,000 patients are hospitalized for acetaminophen toxicity.[1] Acetaminophen overdose is clinically significant as it is the most common cause of drug-induced liver failure.[2] Liver

injury occurs in 17% of adults with unintentional acetaminophen overdose.[1]Acute tubular necrosis is yet another manifestation of acute acetaminophen toxicity and it can occur either isolated or along with hepatotoxicity.[3]

N-acetylcysteine (NAC) is used as the treatment of choice for acetaminophen overdosage.[4, 5] Intravenous and oral formulations of NAC are available for the treatment of acetaminophen overdose. Though the current standard of care involves NAC, the use of this drug has many adverse effects like allergy, anaphylaxis, angioedema, bronchospasm.These reactions are dose-dependent and preceded by release of histamine. Hypotension can occur due to the vasodilatory effect and in severe cases, there can be consequent oliguria which may lead on to the issue of pre-renal pathology for an acute renal failure.[6]Animal studies and previous case reports strongly suggest that massive NAC overdose can cause cerebral edema and seizures.[7]

Though it has been well established that NAC can reduce mortality in acute overdose toxicity of acetaminophen, it is important to understand that the risk of adverse reactions to NAC do exists as is the risk of its overdosage.[6, 8] Noteworthy, the preparation of NAC for intravenous administration is quite complex.[6] Cases of iatrogenic NAC overdose have been reported in literature and it is important as this could even lead to death of the patient due to progressive hemolysis, thrombocytopenia and acute renal failure.[6, 7]

A high incidence of more than 60% patients treated with NAC has been reported to develop ADR.[8] Vitamin B12 and folic acid have been demonstrated to possess hepato-protective effect in other models of liver injury. Though one animal study indicating the effectiveness of folic acid in liver injury induced by acetaminophen has been reported in literature,[9] there are no studies evaluating the protective role of vitamin B12 in this animal model and in addition, this is the first study comparing the hepato-protective activity of vitamin B12 with folic acid in experimentally induced acute acetaminophen toxicity in rats in order to identify the potentially less toxic alternative to NAC by evaluating the effects of vitamin B12 and folic acid on liver enzymes and histopathology of liver tissue in comparison to that of NAC.

MATERIALS AND METHODS

The institutional animal ethics committee approved the protocol of the study (Approval number: 289/2015/IAEC). 18 Adult, male Sprague dawley rats weighing 200-300g were housed at constant ambient temperature in 12hr light, 12hr dark cycle. They were group housed as 3 animals per cage in polypropylene cages. Pellet diet and tap water were provided *ad libitum*. The animals were randomly allocated into the following three groups of 6 rats per group.

Group A: 6 rats in which acetaminophen at a dose of 3g/kg was given and NAC at a dose of 150mg/kg once after 1 hour of acetaminophen toxic dose.
Group B: 6 rats in which acetaminophen at a dose of 3g/kg was given and vitamin B12 at a dose 10mg/kg once after 1 hour of acetaminophen toxic dose.
Group C: 6 rats in which acetaminophen at a dose 3g/kg was given and folic acid 8mg/kg administered once after 1 hour of acetaminophen toxic dose.

The animals are weighed and the drugs were orally gavaged based on the body weight. 48 hours later, 1.5ml of blood was collected from the tail vein of the rats and liver function test (LFT) was performed. Quantitative analyses of liver enzymes namely, aspartate-aminotransferase (AST) or serum glutamic-oxaloacetic transaminase (SGOT), alanine-aminotransferase (ALT) or serum glutamic-pyruvic transaminase (SGPT), alkaline phosphatase (ALP) and ã-glutamyl transpeptidase (GGT) were performed. The values of these enzymes thus estimated were indicative of the severity of liver damage and were statistically analyzed.

All the rats were then sacrificed and liver specimens were taken, fixed in 10% formaldehyde and embedded in paraffin. Sections were cut from the tissue blocks, mounted on slides, and stained with Van Gieson's stain. They were examined under microscope for liver cell damage and disruption of normal architecture. [Figure1]

Statistical analysis: The data was entered in Excel and analyzed using SPSS software version

19. Comparison of the mean of liver enzymes was done using one-way analysis of variance (ANOVA) followed by Fisher's least significant difference (LSD) test. The difference between the groups was considered statistically significant if $p<0.05$. Histopathological changes between groups were qualitatively analyzed.

RESULTS

The mean AST (260.2 ± 54.7) of vitamin B12 group was lower compared to that of the group which received NAC with mean AST (319.8 ± 57.6) and though the mean ALT for vitamin B12 group (114.3 ± 32.4) was higher than that of NAC

Table 1: Comparison of liver enzymes between groups using one way ANOVA

Parameter	Between groups comparison	Mean difference	p value
AST	Groups A and B	59.667	0.103
	Groups A and C	-30.167	0.393
ALT	Groups A and B	-27.167	0.348
	Groups A and C	-207.333*	0.000
ALP	Groups A and B	119.167*	0.001
	Groups A and C	-378.000*	0.000
GGT	Groups A and B	-0.400	0.372
	Groups A and C	-1.650*	0.002

*The mean difference is significant at the 0.05 level.

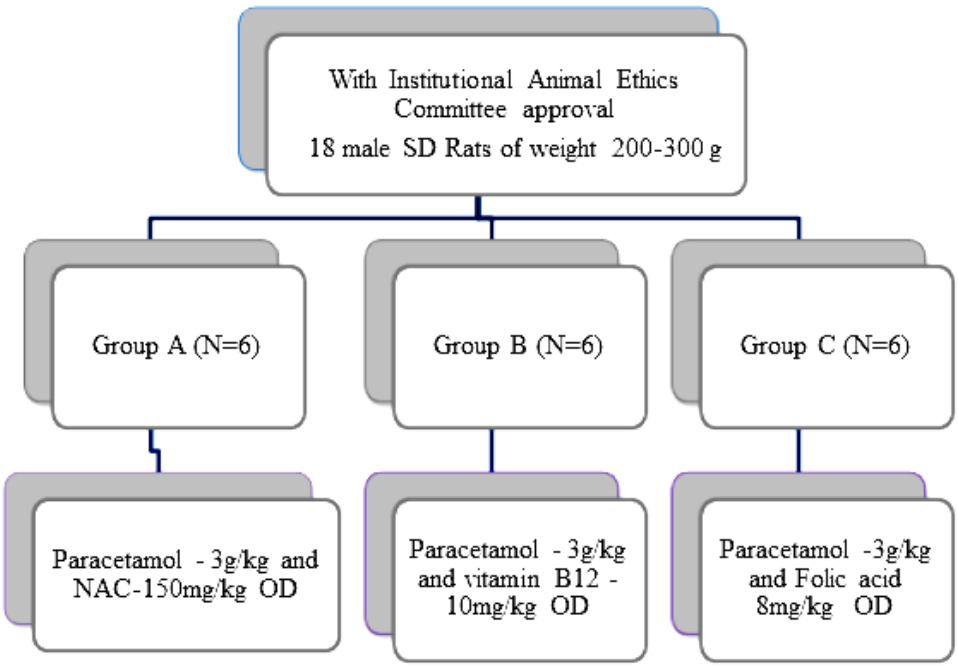

Fig. 1: Methodology

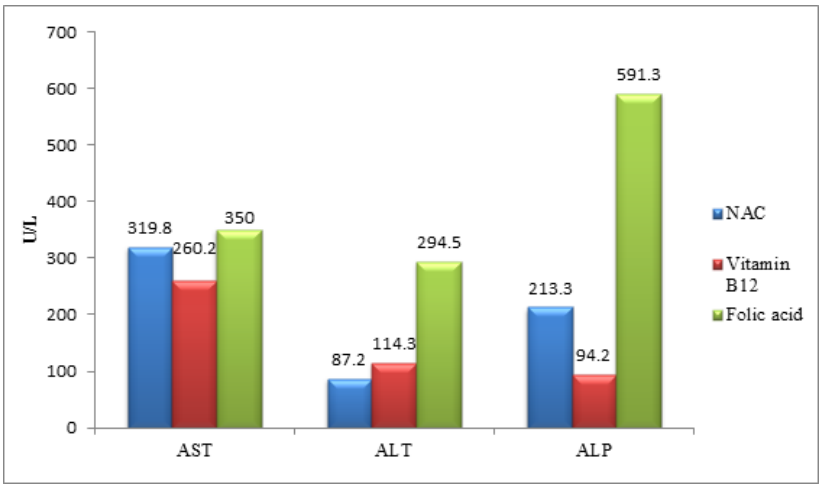

Fig. 2: Comparison of mean AST, ALT, ALP between groups

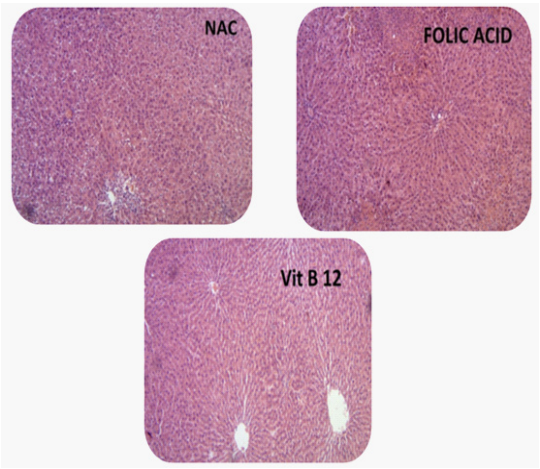

Fig. 3: Histopathology picture of the study groups

group (87.2 ± 41.5), [Figure2] the difference was not statistically significant by ANOVA with *post-hoc* LSD test either for AST (p=0.103) or ALT (p=0.348) between the two groups. [Table1]

On the contrary, folic acid group demonstrated a higher mean AST (350 ± 65.4) and mean ALT (294.5 ± 65.5) than NAC group. Comparison of the folic acid group with the group that received standard NAC treatment using ANOVA revealed that there was no statistical significance for the difference in the mean AST (p= 0.393) unlike that for mean ALT (p< 0.001). In addition, the vitamin B12 group had a significantly lower AST with mean difference of -89.8 ± 34.3 (p= 0.019) as well as for ALT with mean difference of -180.2 ± 28.0(p< 0.001) when compared to the group given folic acid. [Figure2 and table1]

Interestingly, there was a statistically greater reduction in mean ALP for vitamin B12 (94.2 ± 61.2) compared to NAC group (213.3 ± 48.2) whereas folic acid group (591.3 ± 44.8) had a statistically higher mean ALP (p< 0.001) indicating that folic acid did not demonstrate ALP reduction analogous to vitamin B12. [Table1]

Though mean GGT was slightly higher for the vitamin B12 group (1.18 ± 0.77) compared to the NAC group (0.78 ± 0.68), there was no statistical significance (p=0.372) for the difference in the mean values. However GGT for folic acid group (2.43 ± 0.79) mirrored the ALP wherein there was a statistically significant higher mean GGT (p=0.002) observed for folic acid group compared to the NAC group. [Table1]

Histopathological examination of the liver specimens revealed interface hepatitis, focal hepatic necrosis and thinning of sinusoidal plate in group A. In contrast, the group which received folic acid demonstrated tissue architect being totally disturbed with portal tract appearing hemorrhagic and congested in addition to centrilobular necrosis. Group B or vitamin B12 group had the architecture of tissue preserved with only mild inflammation. [Figure3]

DISCUSSION

This animal study has brought out the effective lowering of the liver enzymes by vitamin B12 in acute acetaminophen toxicity. The protective efficacy of vitamin B12 in reducing the liver damage after acetaminophen overdose is also evident from the histopathological changes observed in the study. It has been well established that acetaminophen induced liver damage causes centrilobular necrosis associated with a marked increase in AST, ALT activity.[10, 11, 12] Also, the increase in serum ALP activities is supported by the findings of earlier studies that, acetaminophen overdose is also accompanied by an increase in ALP activity due to hepatocellular injury. [10, 13] The reactive oxygen species-sensitive transcription factor namely nuclear factor-kappaB (NF-kappaB) is said to play a vital role in genesis of acetaminophen induced hepatotoxicity[12] and it has been reported that oxidative stress mediated by the metabolite N-acetyl-P-benzoquinone-imine (NAPQI) is considered to be the main cause of hepatic injury which involves depletion of cellular ATP, reduced Ca^{+2} ATPase activity with increased cytosolic Ca^{+2} levels, apoptosis and lipid peroxidation mediated by reactive oxygen species associated with a concomitant increase in AST, ALT, ALP.[14,15] It has also been hypothesized that reactive oxygen species induced lipid peroxidation generates peroxynitrite, a powerful oxidant and nitrating agent. Peroxynitrite can consequentially modify cellular macromolecules, aggravating mitochondrial dysfunction and ATP depletion, thus leading to cellular necrosis in hepatocytes and sinusoidal endothelial cells.[16]

The effectiveness of vitamin B12 parallels that of NAC since there is no significant difference in the mean AST, ALT and GGT values between the two groups [Table1]. In addition, the reduction in mean ALP was statistically greater for the vitamin B12 group than the NAC group. In comparison, folic acid did not demonstrate a similar effectiveness either in reduction of raised hepatic enzymes or reversal of histopathological changes induced by acute administration of high dose acetaminophen. [Figue3] This is in contrast to an earlier study which indicated lowering of liver enzymes and improvement in hepatocellular damage histopathologically following administration of folic acid in acetaminophen induced toxicity in rats. Folic acid, though has plausible hepato-protective effect attributed to its property of eliminating the changes that are related to the oxidative stress such as lipid peroxidation and oxidative DNA damage, [9, 17] our study did not replicate a similar efficacy and this can be ascribed to a lower dose of acetaminophen for induction of toxicity in the previous studies and disparity in the time duration of blood withdrawn for estimation of liver enzymes. Such hepato-protective property of folate supplementation regimens after induction of liver toxicity using either chromium in rabbits or folate deprivation with copper exposure in rats have been reported in literature.[18, 19] The contradiction in findings between different studies probably stems from the fact that there is some inherent variation in the pathways and diversity in the intensity of oxidative stress induced by different models.

On the other hand, our study has delineated a significant hepato-protective effect of vitamin B12 demonstrating its efficacy in acute acetaminophen toxicity rat model.[Table1 and Figure3] The potential mechanisms contributory to this beneficial effect is the ability of vitamin B12 to maintain the sulphydryl level under oxidative conditions despite lack of radical scavenging property.[20] Moreover, vitamin B12 has been shown to protect rat primary hepatocytes from hepatotoxin-induced cell death in *in-vitro* experiments.[20] Evidence suggests that the activity of glutathione reductase is significantly lower in B12 deficient liver[21] and that the interaction between vitamin B12 and glutathione could protect against disease related to vitamin B12 deficiency.[22] The presence of cobalt complex in vitamin B12 has been shown to effectively inhibit the hepatic inflammation and fibrosis.[20] Besides, protective effect of vitamin B12 in experimental liver injury by carbon tertrachloride[23, 24] has been well documented in literature wherein the beneficial effect has been primarily hypothesized as owing to the improvement in mitochondrial integrity and this could be another contributory factor in the hepato-protection in acetaminophen toxicity amelioration also.

CONCLUSION

This study highlights that vitamin B12 exhibits significant hepato-protective effect and hence can be considered as a potential therapeutic

agent, alternative to N-acetyl cysteine in acute acetaminophen over dosage after appropriate human trials.

Abstract Breast cancer is identified as the highest cause of death in women suffering from cancer. Early diagnosis is the key to increase the survival of breast cancer victims. Molecular diagnosis using biomarkers have advanced much in the recent years. The cost involved in such diagnosis is not affordable for most of the population. The concept being investigated here is to realize a simple diagnosis system for screening cancer by way of a blood test utilizing a miRNA based biomarker with a complementary molecular beacon probe. A microfluidic platform was designed and attached with a fluorescence reader, which is portable and cost effective. Experiments were performed with 51 blood samples of which 30 were healthy and 21 were positive for breast cancer, collected against institutional human ethical clearance, IHEC 16/180–7–9-2016. miRNA 21 was chosen as the biomarker because it is overexpressed 4-fold in the serum of breast cancer patients. This work involved design of an experiment to prove the concept of miRNA over expression followed by detection of miRNA 21 using the microfluidic platform attached with a fluorescence reader and validation of the results using quantitative Real Time Polymerase Chain Reaction (qRT-PCR). The results obtained from the microfluidic device concurred with qRT-PCR results. The device is suitable for point-of-care application in a mass-screening programme. The study also has revealed that the stage of the cancer could be indicated by this test, which will be further useful for deciding a therapeutic regime.

Keywords Screening · Breast cancer · Biomarker · miRNA-21

1 Introduction

The prevalence of breast cancer is the highest among cancers in women. The World Health Organization (WHO) has placed a paper on the screening procedure evaluation for breast cancer (BC) since breast cancer has been the highest cause of female mortality (World Health Organization 2014). Though advanced cancer regimes exist, the cause of high mortality rate is due to delayed diagnosis. In young women, societal and emotional insecurity

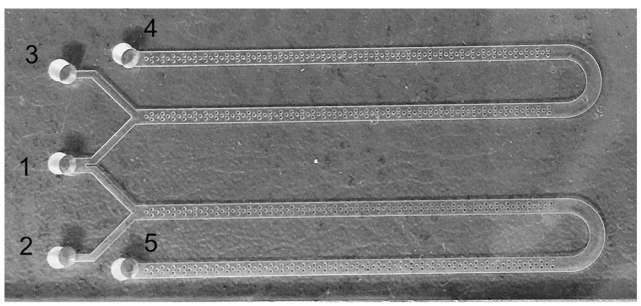
prevent them from disclosing the symptoms. Screening of high-risk population at regular intervals will reduce the mortality rate. Currently mammography is the screening tool which is not cost effective for a middle-income country(World Health Organization 2014). This scheme is not very convenient to address a population, since the mammogram facility is hospital centric. Histological diagnosis of cancer happens only when a symptom is reported. Biomarker based diagnosis is proved to compliment pathological examination and is capable of early detection (Emole 2012). In this work, a circulating biomarker identified is used to develop a screening tool by way of a blood test. miRNA 21 is reported to be overexpressed in the serum of breast cancer patients (Van Schooneveld et al. 2015). Molecular beacon probes are used for PCR to quantify miRNA. This molecular beacon probe is used with a microfluidic platform to read the overexpression of a specific miRNA (BETA et al. 2015). Microfluidic platform was used for detecting miRNA 18a from the serum of retinoblastoma patients (Salim 2015) which was a motivation to design a method for much prevalent and life threatening breast cancer. Based on this concept an objective for screening of breast cancer was derived which is the need of the day when breast cancer has taken highest position causing women mortality. Serum samples of BC patients were analyzed for miRNA-21 expression using qRT-PCR method (Asaga et al. 2011). Expression of miRNA-21 was found higher when compared with healthy controls as well as the level of miRNA-21 indicated difference based on cancer stages. The objectives of the study were (1) Detection of over expression of miRNA-21 in patients' sera using molecular beacon probe by allowing it to hybridize with miRNA-21 in serum (2) Development of a microfluidic platform to improve the hybridization efficiency compared to a well plate (3) Incorporation of a fluorescence reader to make the device portable. (4) Validate the test results using qRT-PCR.

Participants for this study were clinically confirmed for breast cancer. Healthy volunteers were included from master health checkup participants who were not having breast cancer. Inclusion of healthy and diseased individuals was based on need for Case-Control study to evaluate diagnostic accuracy (Rutjes et al. 2005). Diagnostic accuracy is the ability of the test proposed to distinguish between the targeted disease condition (case) and the healthy ones (control). Experiments conducted on serum of 21 breast cancer patients and 30 healthy individuals revealed that this device can be used for screening of breast cancer, which is validated against qRT-PCR results. 21 women included in the study were diagnosed with breast cancer at stage 2 or above. Statistical analysis was carried out based on the results for significance and sensitivity.



2 Materials and methods

2.1 Molecular beacon probe

Fluorescence based detection has taken molecular diagnosis to wider horizons due to its simplicity and sensitivity in quantifying molecules. Molecular beacon probes are oligonucleotides designed for target molecules with a reporter dye and a quencher (Braut-Boucher and Aubery 2010). They are hairpin shaped molecules with quenched fluorophore molecules which move away from the quencher, once the hairpin shaped molecule hybridizes with its complementary target nucleic acid molecule. While in quenched state, the excitation energy will be released through non-fluorescent means (Valeur 2001) like fluorescence resonance energy transfer (FRET) (Enderlein 2014). When the hybrid is formed, fluorophore molecules absorb excitation energy and emit fluorescence at a shifted wavelength from the exciting wavelength. miRNA-21 is the target nucleic acid in the serum. A custom miRCURY LNA™ microRNA detection probe hsa-miR-21-5p, (5TYE665/TCAACATCAGTCTGATAAGCTA) was used for the experiment with the excitation peak wavelength at 645 nm and the emission at 665 nm (Exiqon 2009) (Exiqon n.d.).

2.2 Sample collection

Ethical clearance was obtained from institutional ethical clearance committee to collect blood samples from confirmed breast cancer patients and healthy voluntary individuals as per IHEC No. 16/180 dated 07–09-2016. The inclusion criteria were based on consent by the individual with matching age group of 25–60 which is the most vulnerable age group for breast cancer. 5 ml of blood samples were collected in the BD Vacutainer SST tubes from twenty one BC patients and thirty healthy volunteers as reference or control. All the samples were in the age group of 25 to 60 years. Control blood samples were collected from healthy individuals who participated for the master health program diagnosed as non-

cancerous individuals. Collected blood samples were kept at room temperature for 15 min and then the serum was separated from the blood by centrifuging at 3000 rpm for 15 min and the supernatant (serum) was transferred and stored at -80^0 C.

2.3 Microfluidic platform

The proposed screening scheme is to measure miRNA-21 over expression by hybridizing the probe with target miRNA from the serum in a microfluidic platform. The microfluidic platform should provide efficient interaction of probe molecules with the RNAs in the serum. There are two parameters to consider while using a microfluidic platform. One of them is the volume of probe required to provide a result with significance of over expression in terms of fluorescence emitted, because lower the probe-volume, lower is the cost involved. This demands a thinner device where the Reynolds number becomes low of the order of 1 to 10 or lesser, resulting in laminar flow of fluid. Therefore, there is a possibility of mixing only by way of diffusion. The other contradictory parameter is that, for diffusion to be efficient a longer path should be provided for the fluids to interact in the channel, which in turn increases the volume. Comsol Multiphysics 5.2a was used for the design and simulation of single phase fluid flow. A microfluidic mixer is designed and developed for efficient mixing of two fluids [5]. The fluids flowing are serum and probe in this case. Diffusion coefficient of serum is 61 μ m^2/s and miRNA probe in water is 100 μ m^2/s (Milo et al. 2009). These diffusion coefficients are high enough for mass transport, but in a microfluidic channel since the flow is laminar, diffusion will happen only between lamella. There was the need to increase the interacting surface of the fluids to make diffusion better and at the same time to improve the mass transport by convection also. Active microfluidic mixers are useful in such applications, but are not cost effective for single use applications. Hence a passive microfluidic device with pillar structures along the channel was proposed for effective hybridization. The device was modified with two channels to allow mixing of sample under test in one channel and a control in the second channel with the probe. The dimensions are chosen such that the whole device is of a standard slide size as shown in Fig. 1. The device was fabricated on Poly(Methyl Methacrylate) (PMMA) using micromachining. Equally important was the compatibility of the material with biological sample. Also, the material chosen needed to be fabrication process compatible. PMMA was chosen as the material for fabricating the microfluidic device which matched the requirement compared to Polydimethylsiloxane (PDMS) or

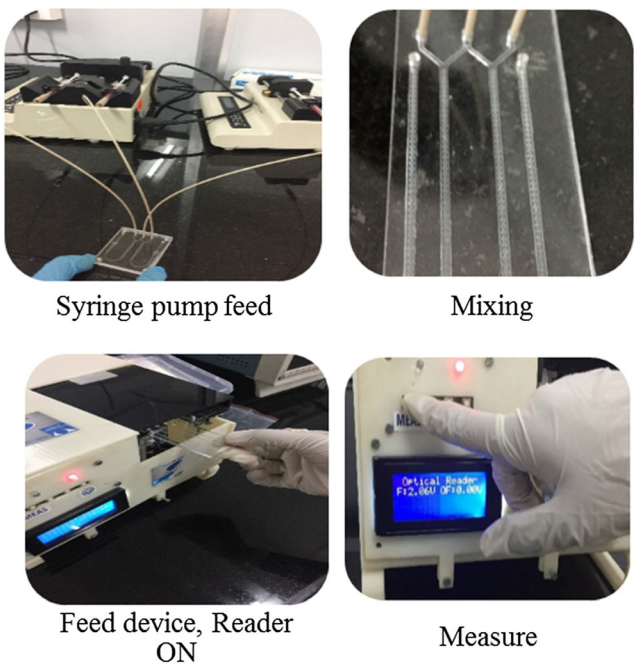

Fig. 3 Experiment set up for screening

Author's personal copy

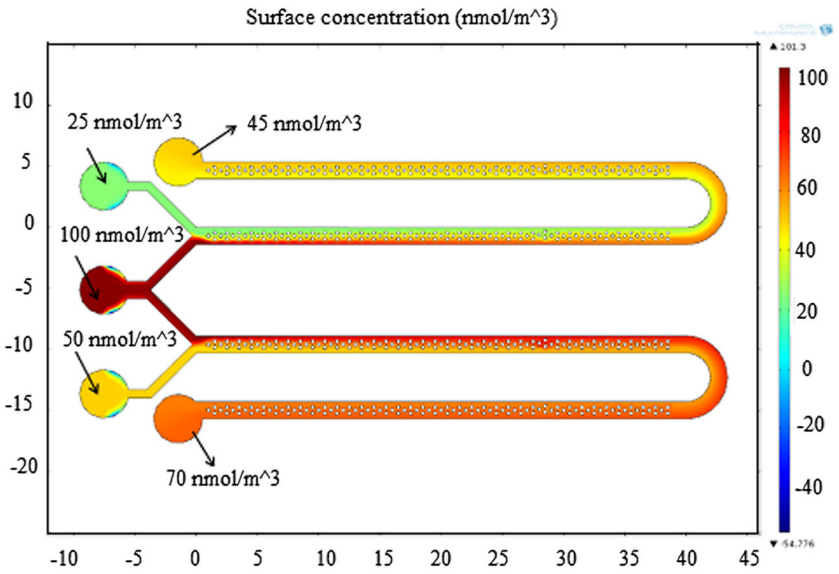

Fig. 4 COMSOL Simulated result of mixing efficiency with pillars in the channel (Salim 2015)

Polycarbonate. High transparency makes PMMA an ideal replacement for glass and is compatible with human tissue making it an important material for biomedical devices. PMMA is a clear, colorless polymer and is commonly called acrylic glass or simply acrylic (Ackermann et al. 2014). The device has 3 inlet wells - one for the molecular beacon probe, the second one for breast cancer serum (Case) and the third one for healthy serum (Control). There are two collection wells provided to measure fluorescence. The design and development of microfluidic device was done by one of the authors for a project to diagnose retinoblastoma from patients' serum using miRNA-18a (Salim 2015).

The dimensions of the microfluidic mixer are shown in Fig. 2. The overall device size is 53 mm × 25 mm as that of a standard slide. The channel depth is 0.235 mm. The inlet wells are of 4 mm diameter. The channel width is 1.4 mm. Length of the channel is 88 mm including the curved part resulting in a volume of approximately 26 μ liters. Sufficient entry length is provided so that the flow is fully developed before entering the channel. The pillars are of 300 μm diameter and placed in 3 rows spaced 1 mm apart horizontally. Vertically, split pillars are 300 μm spaced away from the channel wall and separated by 200 μm.

As the flow rate decreases, Reynolds number decreases and flow remains laminar. At the same time the mass transfer Peclet number, which is a ratio of mass transport by advection to mass transport by diffusion, decreases resulting in diffusion dominated mixing. The mass transfer Peclet number is directly proportional to hydraulic diameter and hence pillar structures added to the channel will reduce the hydraulic diameter and enhances diffusion (Madou 2002).

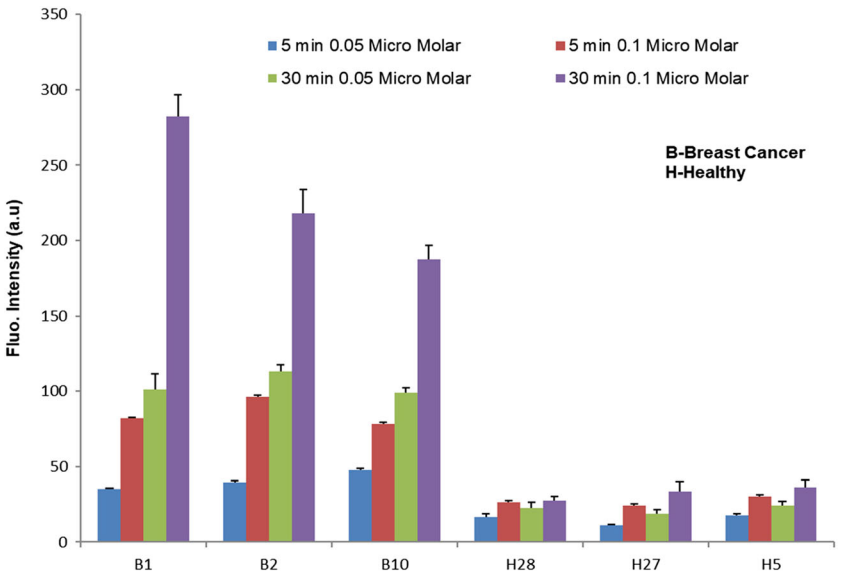

Fig. 5 Standardization of probe concentration and time

Author's personal copy

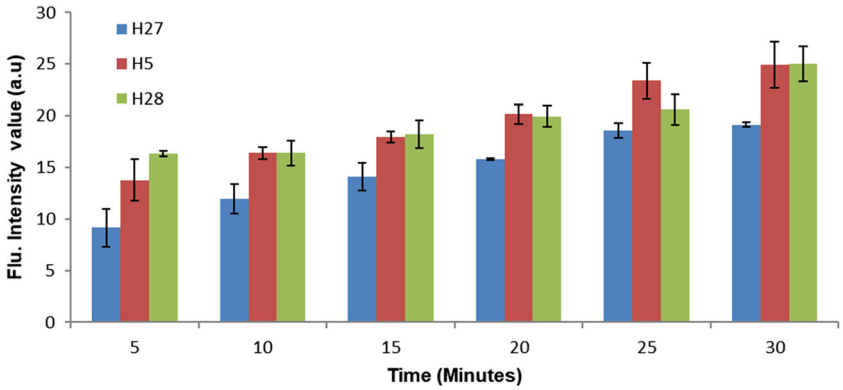

Fig. 6 Time standardization with 0.06 μM

2.4 miRNA-21 over expression using multimode fluorescence reader

Probe concentration Experiments were conducted to choose the molar concentration of probe to effectively utilize the probe, which in turn decides the cost of screening. Sensitivity was tested with probe concentration ranging from 0.1 μM to 0.5 μM initially and then molar concentration ranging from 0.01 μM to 0.09 μM. These experiments were conducted by simple mixing of serum and probe in microplate wells using a pipette. 50 μl of sample and 50 μl of probe at varying concentrations were experimented and the fluorescence was read using multimode scanning fluorescence reader. The results for 0.1 μM to 0.5 μM were discarded since 0.01 μM to 0.09 μM has proved good for measuring over expression of miRNA-21.

Fluid flow rate in microfluidic mixer To decide the flow rate in the microfluidic channel, fluorescence measurements were done at varying time interval starting from 1 min up to 30 min at an interval of 5 min with a probe concentration of 0.06 μM. This knowledge was required to design the channel length of the microfluidic mixer for effective hybridization.

Over expression of miRNA-21 Experiments were done on all the 21-breast cancer positive samples and 30 healthy samples, choosing 0.06 μM as probe concentration and 10 min as time for hybridization in the microplate wells to read the fluorescence.

2.5 Screening by microfluidic platform and built in fluorescence reader

Two micro syringe pumps were used to pump the fluids into the microfluidic platform; one of the syringe pump is dual and the other one single. The dual pump was used to pump serum and control to the inlet well at a flow rate of 1 μl/min and the single pump was pumping probe in the common inlet, feeding the channel for control and test sample. The flow rate was chosen as 2 μl/min. The designed device underwent slight modification in dimensions for the wells based on the fitting accessories used for the connecting syringe pump and due to fabrication limitations. The dimensions of the inlet wells were chosen to fit PEEK tubing to minimize the feed through volume. The fabricated device with the experiment set up is shown in Fig. 3. The microfluidic device fed to the fluorescence reader, which has a lens assembly to focus 645 nm wavelength light for exciting the hybridized sample and a photo diode to detect the emitted fluorescence at 665 nm. A dichroic lens was used to allow the excitation to the sample and return the emission on to the photo detector at an angle of 90 degrees with respect to the source. Fluorescence measurement requires low noise detection and hence a lock in amplifier in synchronous detection mode was used

Author's personal copy

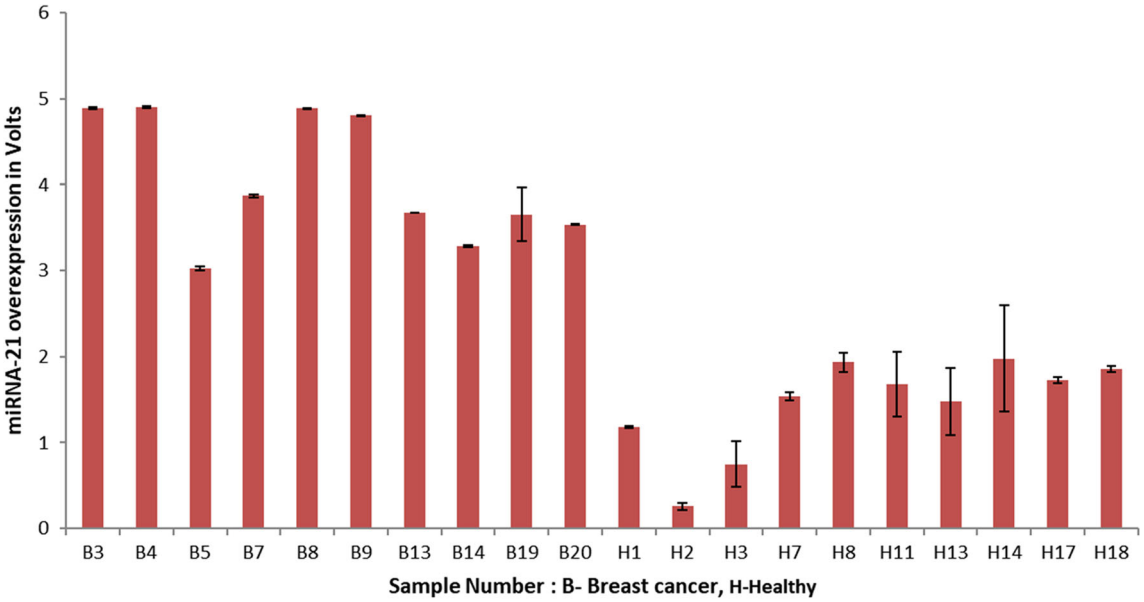

Fig. 8 miRNA 21 expression level measured on microfluidic device

(Bhagyajyoti et al. 2012) (PerkinElmer_Application_note 2000). The reader allows sliding of the microfluidic platform to read the collection wells of control and test by moving a lever. The fluorescence intensity is converted to voltage using optical detector (Transducer concept). A 16-bit analog to digital converter is used to obtain a resolution of 0.004 Volts which can represent 1026 levels of fluorescence intensity from 0 to 350 a.u, and is calibrated. The conversion to voltage is done for easy processing and developing user friendly display such as screened positive, negative etc. based on a threshold level.The result is displayed in Volts to compare the value of healthy control and BC sample under test which is calibrated for a range of 0 a.u to 350 a.u fluorescence value corresponding to 0 to 5 Volts from the fluorescence microscope.

2.6 Validation using qRT-PCR

The entire miRNA was isolated from the 10 BC and one healthy serum samples by miRNeasy plasma/serum kit (Qiagen, USA) according to the manufacturer's protocol. Healthy sample chosen was with mostly matching miRNA-21 level (36.91) corresponding to the average miRNA-21 level (35.73) obtained from 30 healthy samples. In the reverse transcription (RT) step, cDNA is reverse transcribed from total miRNA isolated from BC samples using a small RNA-specific, stem-loop RT primer from the TaqMan small RNA Assays and reagents from the TaqMan MicroRNA Reverse Transcription Kit (Applied Biosystems, USA). 5 ng of the miRNA from BC sample and Healthy sample were used for the synthesis of cDNA. The reaction parameters were 16 °C for 30 min, 42 °C for 30 min, 85 °C for 5 min and final hold at 4 °C. After the synthesis of cDNA, real time PCR (qRT-PCR) was carried out for analyzing the gene expression of the control and BC samples by using Taqman probes labeled with FAM dye. snRNA U6 was used as the internal control. The reaction parameters for the qRT-PCR were a hold at 95 °C for 10 min and 40 cycles of 95 °C for 15 s and 60 °C for 60 s.

2.7 Statistical validity test

Statistical analysis was performed to understand the significance, sensitivity and specificity of the method, confidence interval for miRNA level for true positive and true negative. When a screening regime is defined, the tool becomes stronger if the specificity is high which indicates the percentage of true negative out of a non-disease population. A 2-sample T test was done to check if the mean value of miRNA-21 expression of healthy individuals group differs from the mean value of miRNA-21 expression of a breast cancer patients' group. Correlation analysis was performed to check the concurrence of microfluidic device measurements with multimode reader measurements and the gold standard measurement using qRT-PCR.

Table 1 Patient demographics

Clinical Stage of Cancer	Sample number
Stage II	B1, B5, B8, B10, B11, B13, B16, B20
Stage II-after surgery	B17, B18
Stage III	B2, B3, B9, B12, B15, B19, B21

3 Results and discussion

3.1 Microfluidic mixer

Mixing efficiency of the designed device was verified using COMSOL Multiphysics 5.2a. Several designs were attempted for enhancing molecular interaction of serum and probe for efficient indication of miRNA over expression. The one with pillars arranged for split-and-recombine flow pattern showed better mixing and was chosen for fabrication. The result for simulation is shown in Fig. 4. The entry length was calculated as 0.56 μ meter. Pillars are incorporated to ease mixing otherwise the flow remains laminar due to very low Reynolds number of the order of 0.028 for a flow rate of 2 μ liter /min (effective flow rate in the channel) which corresponds to flow velocity of 121 μm/s. The mass flow rate is calculated as 20.5 μ gm/s. The pillars are arranged to achieve a split and recombine pattern for the flow which enhanced molecular interaction by way of increased surface interaction. The mass transfer Peclet number of 4.86e-4 is indicating that diffusion is dominant for mass transport. By introducing the pillar structures, effective area of interaction is enhanced and hence resulted in better diffusion.

3.2 miRNA-21 over expression using multimode fluorescence reader

Time and probe concentration standardization: Time and probe concentration for hybridization were performed choosing two values each for time and probe concentration as per

Healthy	30	35.7	13.2	2.4

Difference = μ (BC) - μ (Healthy)

Estimate for difference: 101.7

95% CI for difference: (68.2, 135.1)

T-Test of difference = 0 (vs ≠): T-Value = 6.34 *P*-Value = 0.000 DF = 20

Taguchi design of experiments. Two values each of time and concentration were chosen for understanding the trend. Fig. 5 shows that the time required for hybridization is more if probe concentration is higher. The change in fluorescence intensity corresponding to time change from 5 to 30 min is much less for 0.05 μM concentration compared to the change in time for 0.1 μM concluding that time is not an independent variable but depends on the concentration. Lesser molar concentration required lesser hybridization time.

Figure 6 shows all the fluorescence values for time varying from 5 min to 30 min in steps of 5 carried out for 0.06 μM concentration where moving average is seen to be levelled after 20 min. Hence a time of 10 min is suitable for a sensitive read of fluorescence. With this the channel length was designed for 12 μl volume so that a 1 μl/min flow rate will take 12 min to flow till the collection well.

Choosing the molar concentration for probe as 0.06 μM and time for hybridization as 10 min, fluorescence of all the 30 samples of healthy volunteers and 21 breast cancer patients were measured using multimode fluorescence reader which showed significant difference between the miRNA-21 level of healthy individuals from breast cancer patients as seen in Fig. 7. The average value of healthy samples was 35.7. The miRNA-21 level of breast cancer patients sample had variation in intensity based on their stage of diagnosis, with an average value of 137.4. In most of the cases, diagnosis is at advanced stage as indicated from the case sheet done as per the 7th edition of TNM staging of the Union for International Cancer Control (UICC) and American Joint Committee on Cancer (AJCC) in 2009. Two cases (B17, B18) with low miRNA-21 level seen in stage 2 had undergone surgery while blood samples were collected.

3.3 Screening experiment using microfluidic platform

Experiments conducted on microfluidic platform using 10 breast cancer samples showed difference in miRNA-21 level compared to 10 healthy samples as seen in Fig. 8. Healthy control samples have shown voltage levels below 2 V and all the breast cancer positive samples resulted in voltages of 3Volts and above. B4 was recorded as stage 4 and has shown highest level of miRNA-21. B3 was indicated as stage 3 but has shown higher level of miRNA-21 corresponding to stage 4 in all measurements. miRNA-21 level had been correlated with stage of breast cancer using qRT-PCR (Asaga et al. 2011). B17 and B18 were samples collected after surgery and showed miRNA-21 level corresponding to healthy volunteers as seen from Fig. 7. Demographics of BC patients is given in Table 1.

Figure 9 demonstrates a comparison of microfluidic device measurements with well plate measurement where mixing is done by pipetting. The readings are concurrent and hence miniaturization, which has reduced the probe

requirement from 50 μl in well plate to 12 μl in microfluidic mixer, has not affected the accuracy of test results. Pearson correlation study was performed using Minitab, which resulted in correlation coefficient of 0.894 and *p*-value of 0. With this we are also justifying that stage indication by miRNA measurements should be more accurate than the conventional imaging methods where the skill of the technician plays a major role. Fig. 10 shows the classification of stages of detection based on the patients' files and the miRNA 21 over expression measured using the fluorescence reader. There is a marked difference in the average values corresponding to stages but for stage 4 has a spread in values with 3 of the samples resulted in miRNA level corresponding to stage 3. Three of four samples of stage 4 presented values corresponding to stage 3 which has resulted in spread of miRNA level and low p-value in stage 4 as seen in box plot of Fig. 10.

3.4 Statistical analysis

3.4.1 Two-sample T-test for BC positive vs. healthy samples

Study on 30 healthy samples to find a range of miRNA level to screen the sample as negative revealed that miRNA levels in the range 30–40 have a 95% Confident interval. The mean values for hypothesis test are shown in Table 2. The distribution of data is normal. Probability of false positive is almost 0, hence significance is extremely good (>95%). The estimated difference in mean of breast cancer and healthy control is 101.7 as seen from Fig. 11. The probability density functions of healthy and BC miRNA-21 level measured using microfluidic device attached with reader for 10 samples each are depicted in Fig. 12. Statistical significance is given in Table 3.

3.4.2 Correlations between stage demographic and measured status

Correlation study was performed for stage demographics against microfluidic based measurements. Pearson correlation coefficient of 0.444 and *p*-value of 0.044 were obtained. Linear correlation coefficient of 0.444 indicates moderate strength in linear relationship, this is due to the discrete status of stage. The *p*-value of 0.044 indicates that there is only 4.4% risk in concluding that a linear correlation exists.

The samples collected after surgery and 2 samples designated as stage 4 which resulted in miRNA level corresponding to stage 2 were removed to get the correlation between demographic and measured stage as 0.579 correlation coefficient with a p-value of 0.015.

3.5 Validation using qRT-PCR

The results of qRT-PCR showed that gene expression of miRNA-21 for 10 BC positive blood samples and a control sample (H7) concurred with the results obtained using microfluidic device as given in Fig. 13. The highest

Table 3 Statistical significance of miRNA-21 expression for BC and healthy sera measured using microfluidic device

	N	Mean, μ	Std. Deviation	Std. Error
BC	10	3.848	0.611	0.193
Healthy	10	1.313	0.65	0.206

Difference = μ (BC) - μ (Healthy)

Estimate for difference: 2.535

95% CI for difference: (1.940, 3.130)

T-Test of difference = 0 (vs ≠): T-Value = 8.99 *P*-Value = 0.000 DF = 17

Author's personal copy

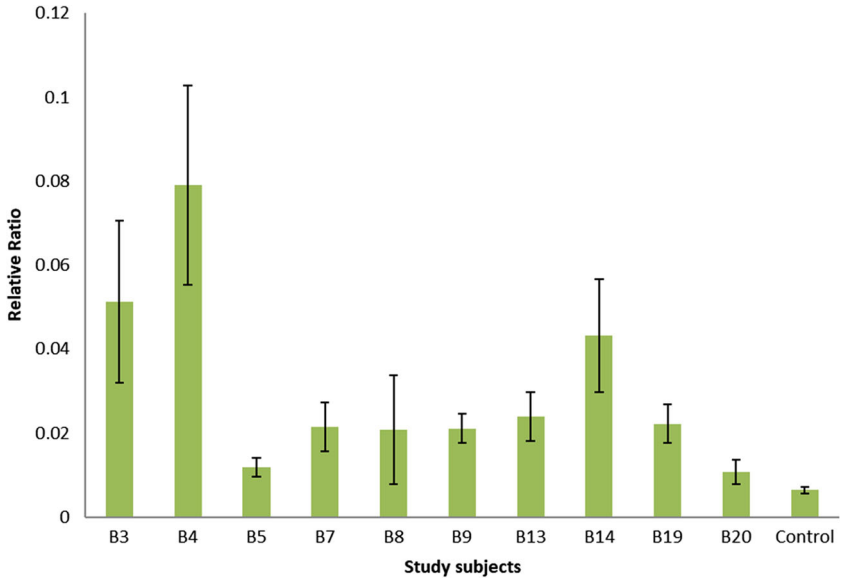

Fig. 13 Gene expression of miRNA-21 in breast cancer sample Vs control (H7) using qRT-PCR

expression is obtained for sample B4, which is reported as stage 4 at the time of diagnosis. B3 was diagnosed at stage 3 and the miRNA level of this sample was detected almost same level as B4 using fluorescence detector. Correlation analysis was performed for the results obtained by microfluidic platform with reader and qRT-PCR resulting Pearson correlation coefficient of 0.730 and p-value of 0.011.

4 Conclusion

Screening of breast cancer for a high-risk population is essential to improve the mortality rate of women and the existing accepted scheme is a mammogram. This tool is not affordable for much of the population of developing countries. Mammogram has side effects if there is the need for regular monitoring in high-risk population. The scheme proposed here where screening is done by an inexpensive blood test and moreover can reach even the population who are reluctant to come to a hospital. The method is useful even for young women with dense breasts where mammogram sometimes suggests further tests and adds to the financial burden to the individual.

The method is cost effective for mass population due to the use-and-throw microfluidic device, does not require a scientist or skilled technician, low power consumption, battery backup, portable and the short time for getting result. The platform is versatile and is useful for any biomarker-based screening. The method proposed here uses a device optimized to use the minimum quantity of probe, and the time required for the result is only 30 min. This test can be done any number of times for high-risk populations since there is no side effect like radiation hazard as in the case of mammogram and other imaging schemes. This cost-effective screening tool will have a tremendous impact on cancer diagnosis and treatment in developing countries.

Screening tools must have high specificity so as to rule out people for a disease when they do not have any symptom, whereas for a diagnostic test the tool must have high sensitivity to rule in people who has a symptom (Kumar and Indrayan 2011). The gold standard for breast cancer screening is a mammogram and therefore the adaptability of the test proposed here is compared with the mammogram and the benefits are clearly seen. Since the designed method comes under molecular diagnosis category, comparison for validation is performed using the standard test which is Real-Time PCR. From this study, a voltage level for miRNA 21 expression less than 2 Volts measured by the device could be confidently declared as a true negative case for breast cancer. In addition, molecular beacon probes can be designed to include multiple miRNA so as to detect multiple miRNA levels in the sample by a single test to enhance true positive and true negative while eliminating possibility of other diseases.

INTRODUCTION:

Steroids are a class of chemicals that includes the hormones. There are two types of steroids namely, glucocorticoids & mineralocorticoids. Glucocorticoids such as cortisol, control carbohydrate, fat & protein metabolism and other mechanism. While the mineralocorticoids such as aldosterone control electrolyte and water levels. Most of the uses of corticosteroids in day to day practice have been in the field of Rheumatology, Orthopaedics, dermatology, oncology, respiratory medicine, otorhinolaryngology & ophthalmology.(1) Endocrinology utilizes corticosteroids for hypoadrenalism and tapering regimens in hypothalamic-pituitary-adrenal axis suppression. Glucocorticoids causes the following adverse effects such as osteoporosis, hyperglycemia, cushing syndrome, CVS disease, glaucoma, cataracts, infections. While, mineralocorticoids causes hypernatremia, hypokalemia, arterial hypertension, hyperglycemia, edema as the side effects.(2,3)

The main purpose of this review is to analyse the serious side effects caused by corticosteroids while administering in different routes of administration like topical steroids, intranasal steroids, steroid ear & eye drops, intra-articular steroid injections, oral steroids. Being very powerful anti-inflammatory agents, they were described as impressive drugs as they not only improved certain clinical conditions, but also confered a subjective sense of well-being. So, double headed action of steroids are widely discussed in this paper.

SYSTEM WISE USES AND SIDE EFFECTS OF CORTICOSTEROIDS

Corticosteroids and cardiovascular system:

Studies states that prescribed 7.5mg of prednisolone or more/ day compared to non-steroid prescription in cardio patients causes increased risk of CHF, MI, stroke, transient ischemic attack(Relative risk : 3.72, 3.26,1.73,7.41 respectively)(4).

There was an increased risk of arteriosclerosis in patients with Rheumatoid arthritis receiving long term corticosteroids therapy, shown by 3 fold increase in the incidence of lower limb calcifications.

Corticosteroids and endocrine system:

There is 1.8 fold risk of developing diabetes even at doses lower than 10mg prednisolone per day blood sugar should be monitored before and after commencement of corticosteroids as there is an increased risk of developing hyperglycemia when steroids exceed the dose equivalent to 10mg prednisolone per day.(5-7)

Corticosteroids and bone mineral density:

If steroids are required for prolonged periods, the dose should be limited to 15-20mg prednisolone per day to avert osteonecrosis. Fractures may occur in 30-50 % of patients on chronic corticosteroid therapy. Fracture risk may decrease rapidly after cessation of steroids.(8-10)

Corticosteroids and central nervous system:

At a daily dose prednisolone of 15mg per day, mood disorders have been observed in rheumatoid arthritis patients.High dose of corticosteroids taken for ocular symptoms produced hypomanic symptoms in 30% and depressive symptoms in 10% of patients within 1 week period[36] Partial memory loss was observed in patients receiving steroid doses between 5-40 mg prednisolone per day for one year or more.(11-13)

Corticosteroids and Gastro intestinal system:

Used in inflammatory bowel disease, auto immune hepatitis, severe alcoholic hepatitis.

Oral budesonide is less effective than intravenous because it is an oral non-systemic corticosteroid with only 10% systemic bioavailability.[14]

Corticosteroids and liver disease:

Steroids are used in the treatment of alcoholic hepatitis patient. they are used to suppress the activated immune response but in conditions like renal failure,active infections,gastric bleeding risk may occur.

Steroids when given in combination with NSAID increase the risk of peptic ulcer but when prescribed alone it will not cause any risk.[15-18]

Corticosteroids and hepatitis:

Initial studies had demonstrated the effectiveness of steroids for treating chronic active hepatitis in non hepatitis-B patients. Subsequent studies on patients who are hepatitis –B virus carriers have either shown no added effects or worse outcome in those treated with long term steroids.

There is an increase in hepatitis-B virus DNA levels with the use of steroids and its subsequent cessation can lead to a flare of the condition so it is therefore not advisable to start patients with hepatitis-B virus on long term systemic steroids.

The usage of corticosteroids has neither beneficial nor deleterious effects in patients with Hepatitis – C.[19-22]

Routes of corticosteroids and side effects:

Steroids administered in different routes may cause varied side effects which are discussed below:

TOPICAL ROUTE:

DRUGS	REPORTED ADVERSE EFFECTS	PERCENTAGE
Budesonide	Intra ocular pressure changes	30%
	Irritation,Itching,Bruising	1%
	Contact dermatitis	In 100 out 7238 patients
Hydrocortisone	Pseudotumour , Benign intra cranial hypertension, Cataract glaucoma, Contact dermatitis .	74 out of 7238 patients
Triamcinolone acetonide	Cushing syndrome	

A study report says that misuse of topical steroids out of 6723 patients 379 patients (5.63%) were reported ADR .Out of which 78.89% were females and the remaining were males Most common ADR: acne (37.99%), Telangiectasia(18.99%).[23]

CONDITION	NUMBER	PERCENTAGE
Facial acne	144	37.99%
Plethoric face and telangiectasia	72	18.99%
Facial hypertrichosis	70	18.46%
Hyper hypo pigmentation	60	15.83%
Cutaneous atrophy	38	10.02%
Perioral dermatitis	30	7.91%
Pyoderma	21	5.54%
Tineaincognito	17	4.48%

Side effects topical use of steroids in different age groups :

PATIENTS	**DOSE**	**SIDE EFFECTS**
Infants(210)	89.5g	Telangiectasia is prolonged effect Other effects: Atrophy of the anticubital and popliteal fossae
Children(546)	135g	
Adolescent(515)	304g	
Adult(515)	304g	

INTRANASAL ROUTE:

Used in nasal obstruction, nasal discharge, nasal itching, post nasal drip. It is better than oral histamine.Eg: Budesonide nasal spray administered for 6 weeks which does not cause HPA suppression in children (2-5 years).

Fluticasone propionate administered for one year which does not cause any effect on growth velocity in children(3.5-9 years)

Memetasone furoate administered for one year in children (3-9 years)which does not cause any growth velocity and HPA suppression.

Intranasal corticosteroids causes Osteopenia in male(18%), in female(42%)and it also causes cushing's syndrome[24-26]

INHALATION ROUTE:

The following local adverse effects are caused due to inhalation route of corticosteroids:

- Pharyngitis
- Dysphonia
- Reflex cough
- Bronchospasm
- Oropharyngeal candidiasis
- Reduction in bone markers in adults
- Acute adrenal insufficiency in >500µg / day of fluticasone propionate
- Moderate dose: Aggressiveness,Hyper anxiety, Mood changes and Excitability.
- Skin thining.

In low doses it do not cause neuropsychological and behaviourial changes.[27]

SYSTEMIC SIDE EFFECTS:

It causes the following side effects which includes:

- Suppressed HPA axis function
- Adrenal crisis
- Suppresses growth velocity in children
- Reduced bone mineral density
- Bone fractures
- Osteoporosis
- Skin thining
- Cataract
- Glaucoma

INTRAOCULAR ROUTE:

Steroid induced ocular hypertension (>21mm hg) was reported in some patients. : Total number of patients (156)

NO. OF PATIENTS	CONDITION	PERCENTAGE
36	Steroid induced ocular hypertension	24%
22	Bilateral steroid hypertension	44(eyes)
15	Vernal conjunctivitis	41.6%
16	Withdrawal effects	22(eyes)
7	Needed surgery	10(eyes)

But,It was reported that 80.5% had normal intra ocular pressure even after withdrawing steroids.[28]

ORAL ROUTE:

- It causes HPA axis suppression.
- Oral prednisolone 2 mg /kg / day for 5 days causes behavourial changes(aggression and anxiety)
- It is effective in acute asthma, Polyarticular gout,Ulcerative colitis.[29-31]

PARENTRAL ROUTE:

It is used in early treatment of lateral epicondylitis and medial epicondylitis,De quervian's tenosynovitis, polyarticular gout,adhesive capsulitis,osteoarthritis, ulcerative colitis.

ADR: Subcutaneous necrosis with local skin atophy, post injection pain,local discomfort, flare, bruising, superifical radial nerve neuropraxia and local subcutaneous fat atrophy[32-34]

CONCLUSION:

Steroids are available in different dosage form to explore its potency differently and always there is questions to answer all steroid preparations are same to produce its action and side effects. This review will help us to understand the safety and toxicity profiles of steroids in different route of administration. Selection and use of steroids is like handling double edged sword in a single hand ie., the indication will become a side effect when it is used for a long duration or with wrong therapeutic justification. The practitioner should have a thorough knowledge about the uses and toxicity profile of different steroids in different route before initiating or terminating it.

Abstract

Purpose: Drug use prescribing indicators advocated by the World Health Organization (WHO) are important tools for assessing the degree of polypharmacy, use of generic medicines, and to evaluate if there is inappropriate use of antibiotics or parenteral medications besides estimating the adherence to the essential drugs list. This study aimed to assess the WHO prescribing indicators in prescriptions given at the medical outpatient department (OPD) in a private medical college hospital in South India.

Materials and Methods: The study was done prospectively from patients when they presented for consultation at the medical OPD at our tertiary care center. Prescriptions were randomly chosen to be analyzed for the WHO prescribing indicators from September 2016 to April 2017.

Results: A total of 700 prescriptions were analyzed and the average number of drugs per prescription was 2.955 ± 1.32. 32.57% of prescriptions had fixed drug combinations and a similar value of 36% was obtained for prescriptions containing more than one drug for the same indication. Amongst the prescribing indicators, generic prescribing was appallingly low (6.42%). In contrast, antibiotic prescribing and prescription of injections showed an appreciably rational trend with 15.42% and 8.14%, respectively. Furthermore, the prescription of the drugs enlisted in the essential drugs list was determined to be 90.67%.

Discussion: The need for increase in generic prescribing and augmenting the adherence of prescriptions to the essential drugs list has been identified. This can be accomplished by multimodal approach that includes regulatory changes, conducting educational programs directed at attitudinal change among current doctors and imparting modifications in medical curriculum so as to inculcate the culture of abiding by the best prescription practices among budding doctors.

Conclusion: This study has delineated the requisite for pertinent changes in current prescribing trends in a tertiary care teaching private colleges.

Keywords: Generic drugs, polypharmacy, prescribing indicators, rational prescribing

INTRODUCTION

Evaluation of drug prescription pattern is an important aspect of patient care, which also serves as a measure of the quality of care provided. A recent systematic analysis has ascertained that prescribing quality is a dimension requiring constant evaluation.[1] The rational use of drugs is imperative for an effective and efficient health-care system. However, irrational drug use, considered as a global menace

is especially prevalent in the developing countries due to irrational prescribing, dispensing, and administration of medications.[2] Such irrational prescribing is unethical and greatly decrease the standard of drug therapy in addition to resulting in widespread health hazards such as increased incidence of adverse effects, drug interactions, and emergence of drug resistance, especially with antimicrobial therapy.[3] The World Health Organization (WHO) has reported that more than half of all medicines are prescribed, dispensed, or sold inappropriately.[4]

Prescription pattern monitoring studies are tools for assessing the prescribing, dispensing, and distribution of medicines prevailing in a particular locale. The main aim of such studies is to facilitate rational use of medicines.[5] The drug use indicators have been developed by the WHO in coordination with international network for rational use of drugs as an endeavor to measure the extent of rational prescribing.[5,6] According to the WHO, core drug use indicators are divided into three categories, namely, the prescribing indicators, patient care indicators, and the quality of care indicators. These are highly standardized indicators which do not need national adaptation. Although they do not measure all aspects of drug utilization which require intensive methodologies, extensive and varied sources of data, the core drug use indicators provide a simple tool for quickly and reliably assessing a few critical aspects of pharmaceuticals use in health care.

The drug use indicators collected in a cross-sectional survey or measured at different points in time to assess the change in performance are typically measured within a defined geographic or administrative area, either to describe drug use at a given point in time or to monitor changes over time. This study was designed to assess the drug prescribing practices at the medical outpatient department at our tertiary care center which is a teaching medical college hospital, using the five WHO prescribing indicators which include the average number of drugs per patient encounter, percentage of drugs prescribed by generic name, percentage of encounters with an antibiotic prescribed, percentage of encounters with an injection prescribed, and percentage of drugs prescribed from essential drugs list or formulary.[6] These WHO indicators would be instrumental in identifying the degree of polypharmacy, extent of generic prescribing, whether usage of antibiotics and parenteral medications are appropriate besides estimating the adherence to the essential drugs list.[6,7]

Treatment of diseases by the use of essential drugs, prescribed by their generic names, has been emphasized by the WHO and the National Health Policy of India. It has been highlighted that the prescription monitoring studies are imperative to bridge the areas such as rational use of drugs, pharmacovigilance, pharmacoeconomics, pharmacogenetics, and evidence-based medicine.[5] In India, it is currently essential to conduct studies on prescribing patterns in every state and utilize the data generated by such studies to improve the quality of patient care with the primary aim of promoting rational use of drugs.

Appraisal of the WHO prescribing indicators in a private health facility is less common compared to public sector hospitals. Moreover, the level of health care, wherein this study is undertaken adds to its significance. Unlike most Indian studies, the current study is aimed to analyze the entire list of prescribing indicators advocated by the WHO in a teaching medical college hospital. In such a scenario, not only are the prescribers and patients but also the medical students from one of the stakeholders who imbibe the culture of rational prescribing. Thus, this study would throw light on deficiencies which require appropriate and sustained interventions to avoid being carried onto the next generation.

Noteworthy, most studies encompass prescription monitoring of a particular group of drugs such as antiepileptics, antimicrobials, antiasthmatics, and antihypertensive drugs[5] rather than evaluating all the prescribing indicators irrespective of the diagnosis like our study, which would enable capturing a wider picture of the current trends. Medicine is an ever-evolving science and it is important to understand that conducting such prescription monitoring studies periodically as a measure to ensure rational drug use is imperative.

MATERIALS AND METHODS

The study protocol was approved by the Institutional Ethics Committee (Approval number: 16/261), The research was conducted as a cross-sectional study in the outpatient medical department (OPD) of our tertiary care teaching hospital in South India. Based on the WHO guideline of including at least 600 patient encounters, we chose a sample size of 700. This study was done prospectively from the patients when they presented for consultation at the OPD after obtaining a written informed consent. Prescriptions were randomly chosen to be analyzed for the WHO prescribing indicators over 8 months from September 2016 to April 2017. Two well-trained clinical pharmacists were involved in collecting data on prescribing indicators. Each prescription was regarded as single-patient encounter for calculation of the required parameters. Prescriptions of patients attending medical OPD and treated on outpatient

basis for their ailments were included irrespective of the comorbidities. Data were collected on the demographic details of age, gender, diagnosis, and the treatment prescribed which were mentioned in the prescription. The prescribing indicators were studied in accordance to the standard guideline advocated by the WHO.[6]

1. Average number of drugs per encounter: Average was calculated by dividing the total number of different drug products prescribed, by the number of encounters surveyed. Whether the patient actually received the drugs was not considered relevant in calculating this indicator
2. Percentage of drugs prescribed by generic name: percentage was calculated by dividing the number of drugs prescribed by generic name, by the total number of drugs prescribed and expressed as a percentage
3. Percentage of encounters with an antibiotic prescribed: Percentage was calculated by dividing the number of patient encounters during which an antibiotic was prescribed, by the total number of encounters surveyed and expressed as a percentage
4. Percentage of encounters with an injection prescribed: percentage was calculated by dividing the number of patient encounters during which an injection was prescribed, by the total number of encounters surveyed, multiplied by 100
5. Percentage of drugs prescribed from essential drugs list or formulary: percentage was calculated by dividing the number of products prescribed which were on the essential drugs list or local formulary, by the total number of products prescribed and multiplied by 100.

RESULTS

The data were entered in Microsoft Excel 2007 and analyzed as frequency distributions and percentages to assess the prescribing indicators. A total of 700 prescriptions were analyzed over 8 months from September 2016 to April 2017. The demographic distribution of patients mirrored a rising trend with increasing age as a higher proportion of patients (295) were 60 years and above (42.1%). Among the rest, those aged 40 years and above were 36.7% (257) and 21.2% (148) were <40 years. Both males and females were almost equal in proportion with 357 males and 343 females. Diagnosis were multiple and diverse. Hence, categorization into communicable and non-communicable diseases showed that majority (68.6%) had non-communicable diseases contrary to those with communicable diseases (31.4%). It was found that a total number of 2069 drug products had been prescribed in the 700 patient encounters, and thus, the average number of drugs per prescription was 2.955 and the standard deviation was 1.32. Moreover, the median number of drugs per prescription was 3, which unlike the mean, would not be unduly influenced by the outliers. Overall, the study revealed a higher value for this indicator than the reference standard [Table 1]. Analyzing the patient encounters lacking the data for specified variables, it was found, 647 (92.42%) prescriptions did not have any generic names, whereas only 17 patient encounters lacked at least one drug from essential drugs list. It was evident that 84.57% prescriptions did not have any antibiotics and likewise, a high percentage of 91.85% did not have any injections prescribed.

It was interesting to find that among the 2069 drug products prescribed, the highest percentage (10.95%) of prescribed drugs were supplements which ranked first followed by the antidiabetic, antiplatelet, hypolipidemic, and anti-hypertensive drugs, whereas the overall percentage of antibiotics prescribed was only 15.42%, and hence lower in comparison to the former groups of drugs [Table 2].

The number of prescriptions with fixed drug combinations was 228 accounting for 32.57% [Figure 1]. The most common one being prescribed was analgesic combination (paracetamol with ibuprofen followed by tramadol with paracetamol) for pain relief. A similar value of 36% (252 out of 700) was obtained for prescriptions containing more than one drug for the same indication. Interestingly, prescriptions analyzed showed that patient encounters with two drugs (27.73%) were equal in proportion to those that included three drugs (27.28%) accounting for a total of 55% prescriptions falling under either of these two categories. An analogous high percentage (23.98%) was also recorded for prescriptions with four drugs in the treatment regimen [Figure 2].

With respect to generic prescribing, this study recorded a very low percentage of 6.42% indicating that current prescribing pattern of clinicians favored prescribing by

Table 1: Comparison of the World Health Organization prescribing indicators observed with standard reference range

Indicator	*n*	Average/percentage (SD)	Standard reference range/optimal value
Average number of drugs per patient encounter	2069	2.955 (1.32)	1.6-1.8
Percentage drugs prescribed by generic names	133	6.42% (0.34)	100%
Percentage patient encounters with an antibiotic	108	15.42% (0.38)	20.0%-26.8%
Percentage patient encounters with an injection	57	8.14% (0.27)	13.4%-24.1%
Percentage drugs from essential drugs list	1876	90.67% (1.31)	100%

SD=Standard deviation

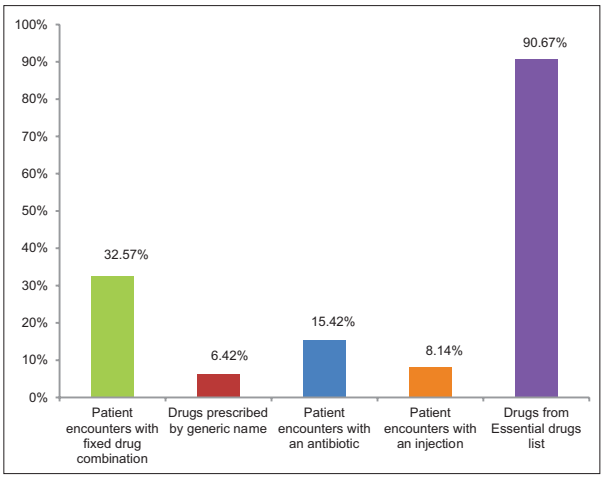

Figure 1: Measured percentages of prescribed fixed-drug combinations and the World Health Organization prescribing indicators

Table 2: Frequency distributions of commonly prescribed drugs

Name of the drug groups commonly prescribed	Name of drugs commonly prescribed	Sum (%)
Antidiabetic drugs	Metformin	161 (7.78)
Antiplatelet drugs	Aspirin	52 (2.51)
NSAIDS	Paracetamol	86 (4.15)
Supplements	Calcium and Vitamin D3	60 (2.89)
	Iron and folic acid	112 (5.41)
	Multivitamins and folic acid	55 (2.65)
Antiulcer drugs	Pantoprazole	99 (4.78)
	Ranitidine	73 (3.52)
Antihypertensive drugs	Amlodipine	36 (1.73)
	Telmisartan	21 (1.01)
Antibiotics	Levofloxacin	10 (0.48)
	Trimethoprim + sulfamethoxazole	8 (0.38)
	Azithromycin	7 (0.33)
	Amoxicillin + clavulanate	7 (0.33)
	Cefpodoxime proxetil	6 (0.28)

NSAIDS=Nonsteroidal anti-inflammatory drugs

brand names rather than using the generic ones. The percentage of patient encounters in which an antibiotic was prescribed was only 108 (15.42%) [Figure 1]. The highest prescribed antibiotic was levofloxacin followed by co-trimoxazole with azithromycin, amoxicillin-clavulanate, and cefpodoxime proxetil being next to the quinolone and the sulfomethoxazole-trimethoprim combination which were widely prescribed at our center during the study period [Table 2]. The most common indication for the antibiotic use was found to be a variety of respiratory infections ranging from pharyngitis, sinusitis to pneumonia.

About 8.14% of patient encounters had an injection being prescribed, and an overall 90.67% of adherence to essential drugs list was evident [Figure 1].

DISCUSSION

It is well known that the indicators of prescribing practices measure the performance of health-care providers in several key dimensions related to rational use of drugs. The indicators were assessed in our study based on a sample of 700 patient encounters that took place at the OPD in our hospital. The data that were collected prospectively by analyzing the prescriptions demonstrated that in our teaching hospital, the average number of drugs prescribed per encounter was 2.955. Comparison to the standard range advocated by the WHO for this indicator which estimates the degree of polypharmacy revealed that the measured average was much higher than the reference range of 1.6–1.8 considered as ideal.[6] This is also reflected in the high percentage of fixed drug combinations prescribed in addition to the use of combination of different drugs for a single indication in one patient encounter. In a similar study done in Goa,[8] the average number of drugs prescribed was 1.8 which was found to be lower than our finding and that obtained in other Indian studies on prescribing indicators by Upadhyay *et al.* (3.76) and Raj *et al.* (4.98).[9,10] In contrast, similar studies of drug use pattern in other countries such as Sudan (1.4), Zimbabwe (1.3), and Ethiopia (1.9)[11] have shown that the average number of drugs per encounter estimated in our study was higher.

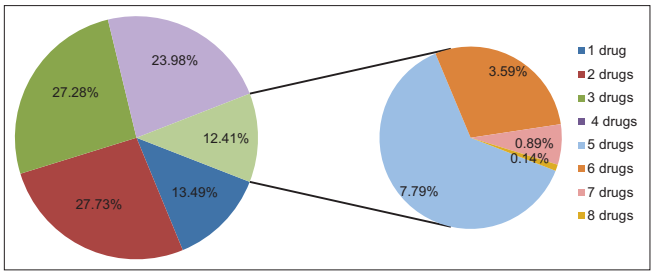

Figure 2: Percentage distribution of number of drugs in the prescriptions

The high average number of drug products per prescription exceeding the WHO reference range is demonstrative of a high degree of polypharmacy prevalent in our study locale. The reasons that could be attributed to this is the change in the epidemiological trend of rampantly increased prevalence of non-communicable diseases such as diabetes, hypertension, dyslipidemia, and coronary artery disease which are often coexistent contributing to the need for treating multiple disease entities in the same patient simultaneously.[12] Concomitance of such cardiometabolic conditions in a single patient further entails the requisite for prescribing more than a single drug for a given clinical indication which is often resistant to treatment in the face of multiple diseases presenting concurrently. Our study also stands testimony to this fact since a high proportion of participants (68.6%) had the diagnosis of non-communicable disease with diabetes ranking highest with 34.4%

Another rationalization for the high percentage of polypharmacy lies in the fact that currently there is a demographic shift with an increase in the aging population in our country.[13] This epidemiological transition is further responsible for perpetuating the current scenario prevailing. About 42.1% of the study population also was aged >60 years signifying that the greater proportion of aged population contributed to the high polypharmacy.

However, the high prescription rates for supplements recorded in our study remain unjustified and arise from two important factors potentially contributing to the irrational prescribing practice. First, the influence of pharmaceutical industries which vigorously promote supplementary products among doctors by providing biased information supporting the need for prescribing such products. Second, patients misconceptions on the health-promoting effects of supplements resulting in their persuasion and demand for such products in their prescriptions. However, the best approach toward such patients is to educate them rather than giving in to their false ideations.[3]

The percentage of drugs prescribed by generic name in our study was 6.42% which is too low compared with the standard derived to serve as ideal, which is 100%.[6] Wang *et al*. found that higher the doctor's education and training experience, the proportion of drugs that they prescribed by generic names showed a decrease.[14] Moreover, attitudinal differences have also been shown to exist among consultants in low- and middle-income countries compared to those in high-income countries.[15]

The likely explanation for the low percentage of generic prescribing could be due to repeated and persuasive promotion of the propriety products by pharmaceutical companies and in certain instances, clinicians are compelled to concede to the insistence of affluent patients demanding innovator drugs for treatment.[16] Another plausible cause for this stems from the presumed belief among a subset of prescribing physicians that the bioavailability differences between generic and brand drugs could adversely affect the therapeutic outcomes.[17] Such prejudices could unfavorably affect the tendency of prescribing generic drugs. Finally, the role played by industries in hindering generic prescribing by offering financial perks to prescribers cannot be underestimated.[18] Literature evidence states that generic prescribing is better in public centers in comparison to that in private sector hospitals.[16]

It is important to increase awareness on generic prescribing considering the high treatment costs incurred by the practice of prescribing by brand names. Nicolosi and Gray investigated the cost impact of generic and proprietary prescribing among chronic disease patients in South Africa and their findings indicated that "all generics were more than 40% cheaper, per defined daily dose per month, than the brand version."[19] An analysis of facility-based medicines price data from 17 countries by Cameron and Laing,[20] found that an average of 9%–89% could be saved by switching from brand to generic equivalents. Shift in the trend favoring generic prescribing is warranted and this can be implemented by an integrated approach of training the medical students who are future prescribers on the pharmacoeconomic significance of this practice in addition to conducting continuing medical education programs for clinicians with the focus of alleviation of their apprehension on bioequivalence regarding the use of generic drugs. Moreover, a variety of strategies have been recommended by experts to overcome the barriers to genetic prescribing and the most vital of these include enforcing statutory obligations, setting clear guidelines for generic prescribing, and legally de-incentivizing prescribing by propriety name.[21]

Interestingly, we found that the number of antibiotics prescribed (15.42%) as well as the number of encounters with an injection (8.14%) was low, indicating a positive trend toward reduction in indiscriminate use of antibiotics and unnecessary injections. An obviously rational prescribing pattern is noted for both these indicators in our tertiary care center. Noteworthy, our study duration was 8 months, and hence, the study would not have comprehensively captured the seasonal variation in antibiotic prescription pattern due to differential incidence rates of infections at different times of the year.

About 90.67% of drugs prescribed conform to the WHO essential drugs list which is lower than that obtained in other studies in India (99.6%), Tanzania (96%), and South Ethiopia (96.6%), whereas higher in comparison to that in countries like Nepal (88%). This could be attributable to the lack of sensitization of the prescribers and lack of rules enforced to mandate prescribing from the essential drugs list. Akin to generic prescribing, this indicator also has been demonstrated to vary between the private and public sectors[22] indicating the need for the practice of prescribing from essential drugs list to be more widely adopted especially in private sector hospitals.

One of the strengths of the study is that it was done prospectively using the patient prescriptions attending the OPD rather than the data being collected retrospectively from case records which is often the design adopted in prescription pattern studies as it is much easier to

collect information from patient records. In addition, the prospective design of this study positively ensures eliminating duplication of data, while retrospective analyses cannot be claimed to be completely devoid of bias such as exclusion of incomplete data from poor record keeping unlike prospective evaluation.

A major limitation of our study is that it was done in a single center which is a private medical college hospital with limited sample size, and hence, the data cannot be extrapolated to other centers lacking similar characteristics like public or government hospitals and health-care centers.

This study implies the need for implementing interventions such as programs, workshops, and symposia to impart awareness on rational prescribing among the medical fraternity. Thus this research has not only identified the pitfalls in current prescription practices, but in addition, has recommended the potential solutions to weed out irrational prescribing trends encountered.

CONCLUSION

Our study on prescribing indicators has clearly delineated that the prescribing practices for antibiotics and injections are appropriate and rational; conformity to essential drugs list is considerably good, though scope for improvising is certainly evident. However, the degree of polypharmacy is higher than the standard. Generic prescribing is also an element that needs to be vastly improved on. Therefore, appropriate measures to reduce polypharmacy and increase generic prescribing by clinicians have to be implemented by the administrative team and policymakers to ensure rational and safe prescribing.

ABSTRACT

Background: Clinical audit is based on the concept of quality assurance in health care. It is important for all health care providers especially specialists and consultants to be aware of the principles governing clinical audit in addition to the methods in conducting such an audit.
Objectives:
- To assess the knowledge and attitude of medical postgraduate students on clinical audit.
- To evaluate the effectiveness of an interventional program conducted to educate the principles and methods of conducting clinical audit to medical postgraduates.

Methods: The study was done in 92 postgraduate medical students in our institute using a pre-test and post-test questionnaire, evaluating their knowledge on different perspectives of medical audit and also assessing the change in their attitude towards audit after an educative interventional program. The questionnaire consisted of 13 knowledge questions and 3 attitude questions. Each question was scored and the overall maximum score was 35.
Results: The mean post-test score (24.45 ± 3.21) was significantly higher than the mean pre-test score (16.18 ± 3.41) using paired *t*-test ($p < 0.001$) indicating that the educational intervention was effective in improving the understanding of the candidates on clinical audit.
Conclusion: It is imperative for all medical postgraduates to realize the importance of clinical audit in addition to acquiring the skill of conducting a meaningful and successful clinical audit. Attainment of such a competency can be achieved through planned repeated interventions and help usher in an era of best quality of patient care.

1. Introduction

It is important for all clinicians to realize the growing importance of the clinical audits. A clinical audit is considered as an integral part of the clinical practice. It is a quality improvement process that seeks to improve patient care and outcomes.[1,2] Evaluation of patient outcomes in the field of medicine have been conducted since as early as 1853.[3] The aim of the clinical audit process is to ensure adequate quality of care in the management of patients. With the current day and age of advanced medical care, it is crucial to review and constantly improve the standard of care provided. This requires sustained efforts in the unrelenting strive towards providing the best possible quality of care to patients.

The "Quality Initiative" considered forerunner of clinical audit, was launched by the Royal College of General Practitioners in 1983 to define specific objectives for patient care and monitor the extent to which those objectives were met.[4] Later, the National Institute for health and Clinical Excellence (NICE) published the paper "Principles for Best Practice in Clinical Audit", which defined clinical audit as "a quality improvement process that seeks to improve patient care and outcomes through systematic review of care against explicit criteria and the implementation of change".[2]

Hence it is necessary to understand and be familiar with the underlying principles and methods in conducting a clinical audit. This is especially important from the perspective of the medical

post-graduate who is not only the future specialist and consultant but an important stakeholder in ascertaining whether quality care is offered to all patients in a particular health care unit. It is therefore essential for all medical postgraduates in various disciplines to have first-hand knowledge of clinical audit. It is also being increasingly recognized by the academic sectors that postgraduates should be trained to conduct clinical audit conceptualizing it as an essential component of evidence based medicine.[5,6]

Accordingly, our study was designed to assess the knowledge of postgraduate students on the principles and methods of clinical audit in our tertiary care teaching hospital and also to evaluate the effectiveness of an interventional training program in medical audit which was conducted specifically with the objective of sensitizing and imparting knowledge on how to conduct a clinical audit.

2. Materials and methods

The study protocol was approved by the institutional human ethics committee before the start of the study (Approval Number: 13/289). The study was done prospectively in a tertiary care teaching medical college hospital using a pre-test and post-test questionnaire that was validated by a team of three experts from the hospital clinical audit committee and institutional quality control committee. After obtaining a written informed consent, the questionnaire was administered to the postgraduate students at the beginning and at the end of an educational program on how to conduct clinical audit by audit experts. The questions framed evaluated the knowledge and attitude of medical postgraduates about clinical audit before and after the program. The data was collected from the participants of two consecutive programs conducted in two successive years. Each participant attended only one of the two consecutive sessions. The questionnaire consisted of 16 questions out of which 13 were knowledge and three were attitude questions.

2.1. Statistical analysis

The questions were scored and statistical difference in the mean pre-test and post-test score was analyzed using paired *t*-test. The results of the survey was also analyzed qualitatively and expressed as frequency distribution of percentages.

3. Results

A total of 92 postgraduates participated in the study. The study which was done at a single centre in two consecutive years involving two different batches of 2nd year postgraduates from various specialties, 39 students participated in the first year and the remaining 43 in the next successive session in the following year.

The first question on the need for an audit evoked diverse array of responses both in pre and post-test. The four options which were included were (1) audit has to be an integral part of clinical practice, (2) done to evaluate adverse patient outcomes, (3) as academic program in medical education and (4) administrative evaluation of patient care. Though all the four choices may be apparently appropriate, doing an audit as a mere administrative evaluation is unjustified as the objective of any clinical audit is betterment of patient care, based on which, the first three options are considered the correct responses. At the end of the session, it was observed that about 60% had clearly excluded administrative evaluation though only 20% of them had acquired complete knowledge on the need for clinical audits in contrast to only 8% who were aware of this before the program as made obvious by pre-test analysis. It was apparent that the term 'audit' had been deeply entrenched with the belief of being a tool for administrative evaluation, as made evident from a statistical comparison of pre-test and post-test scores ($p = 0.904$) (Table 1).

Answering the question on types of clinical audit which can be standard based, adverse occurrence screening or critical incident monitoring and peer reviewed, only 50% in the pre-test agreed that all three were indeed the audit types while the post-test revealed that 82.6% accepted "all the above" as the appropriate response.

In assessing the understanding of the students on the types of evaluation, design of the audit and the stages in the audit cycle, it could be demonstrated that there was definitive acquisition of knowledge on these aspects of audit based upon the increase in percentage of the responders opting for the correct answer in the post-test when compared to the pre-test (Figs. 1 and 2).

On the ethics approval perspective, a shift in the responses favoring the need for ethics committee approval before publication of the results (54.3%) rather that at the beginning of the audit (9.8%) was evident in the post-test, contrary to the impression of most students in the pre-test that ethics committee's approval had to be obtained before the start of an audit (59.8%). A considerable increase in the proportion of participants who indicated that there

Table 1
Comparison of pre-test and post-test scores on knowledge questions in clinical audit.

Knowledge/Attitude on clinical audit	Pre-test score Mean ± SD	Post-test score Mean ± SD	Mean difference of the paired sample ± SD	P value
Need for audit	0.47 ± 0.68	0.49 ± 0.68	−0.02 ± 0.85	0.904
Types of audit	2.78 ± 1.48	3.51 ± 1.11	−0.72 ± 1.85	<0.001

Design	1.52 ± 0.85	1.96 ± 0.29	−0.43 ± 0.82	<0.001
Steps in audit cycle	0.44 ± 0.83	1.82 ± 0.56	−1.38 ± 1.01	<0.001
Ethical approval process	0.53 ± 0.79	1.42 ± 0.69	−0.89 ± 1.02	<0.001
Who can conduct audit	3.64 ± 0.97	3.87 ± 0.61	−0.22 ± 1.01	0.034
Who can make recommendations	1.28 ± 1.05	1.63 ± 1.06	−0.34 ± 1.50	0.029
Tool for prioritizing topic	0.61 ± 0.92	1.24 ± 0.97	−0.63 ± 1.14	<0.001
Defining aims	0.93 ± 1.00	1.52 ± 0.85	−0.58 ± 1.09	<0.001
Criteria selection	0.54 ± 0.89	1.35 ± 0.94	−0.80 ± 1.15	<0.001
Standard definition	0.76 ± 0.97	1.50 ± 0.87	−0.73 ± 1.35	<0.001
Commonest method involving service users	0.58 ± 0.49	0.78 ± 0.41	−0.20 ± 0.56	0.01
Audit is not research	0.51 ± 0.50	0.91 ± 0.28	−0.40 ± 0.51	<0.001
Professional responsibility	0.71 ± 0.45	0.82 ± 0.38	−0.11 ± 0.50	0.041
Achievement of same performance level as in research indicates lag in quality	0.20 ± 0.39	0.26 ± 0.44	−0.06 ± 0.48	0.203
Overall score	16.18 ± 3.41	24.45 ± 3.21	−8.28 ± 4.02	<0.001

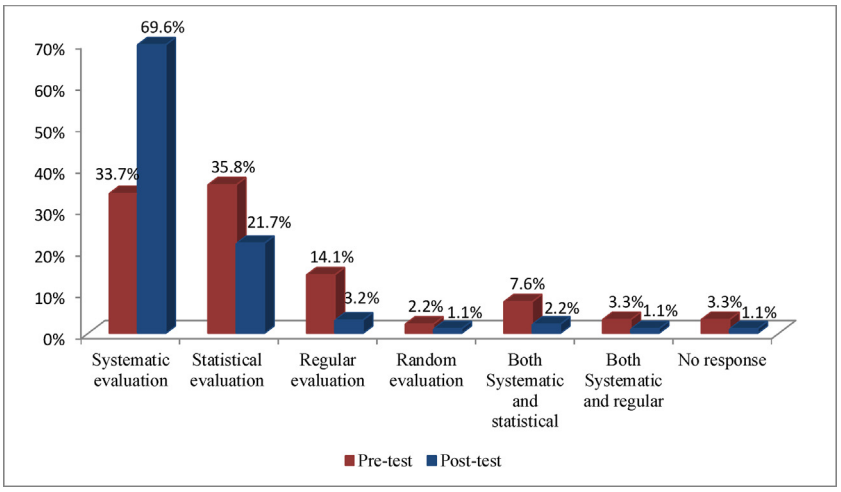

Fig. 1. Percentge of responses to types of evaluation for structure, processes and outcomes of care in clinical audit.

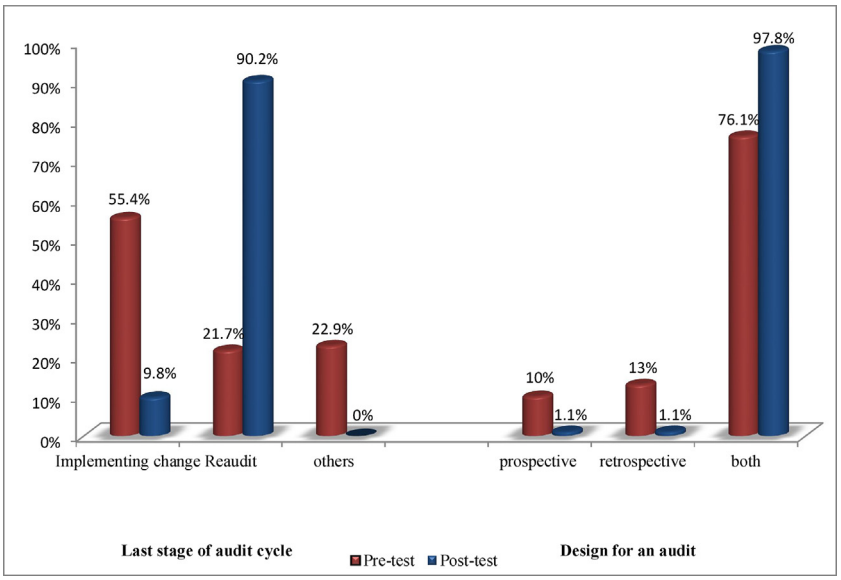

Fig. 2. Percentage of responses to steps in an audit cycle and the design for an audit.

was no need for ethics approval for the conduct of a clinical or therapeutic audit was also noted in the post-test (33.7%).

Appraisal of the postgraduate students' knowledge on who can conduct an audit and who can make recommendations based on an audit result, drafted as two separate questions made it evident that the session had enlightened 97.8% on the fact that any medical professional including an administrator can conduct an audit whilst the question on recommendation which was structured as dual correct response one, namely the PI (principal investigator) and the hospital audit team, only 5.5% responded with completely correct answer in contrast to 72.8% who had chosen only one of the correct responses at the end of the session though it was obvious that there was an increase in the percent of single correct response compared to the pre-test results (59.8%).

Knowledge on the tool for prioritizing the audit topic showed an increase, demonstrated by the rise in percentage of students opting the right response in the post-test (69.6%) compared to the pre-test (30.4%) (Fig. 3). Likewise their understanding on defining the aims, criteria selection and comprehending the standard revealed augmentation, manifested by selection of the correct choice indicating an improved knowledge on these concepts by large majority of participants (Fig. 4).

Attitude questions patterned on yes/no response ascertained that the students considering audit as yet another research was high before the program (40.2%) but they were able to discern the difference between an audit and research subsequent to the intervention (91.30%). In addition, a high proportion of participants were able to appreciate that auditing forms part of their professional accountability at the end of the program (82.6%). However, it was clear that the study subjects had not undoubtedly understood that failure to achieve the same performance level as that in research was often not possible in unselected patient populations in a practical clinical scenario; only 60.9% had chosen the right response in the post-test (Fig. 5).

Evaluating the candidates' knowledge on the commonest method of audit involving patients, 85.9% rightly agreed that it was satisfaction survey in the post-test contrary to only 57.6% who were in favor of it in the pre-test. Each question was scored with maximum total score being 35. A paired *t*-test was done to assess if the difference in mean score for post-test (24.45 ± 3.21) was statistically higher compared to that of the pretest (16.18 ± 3.41)

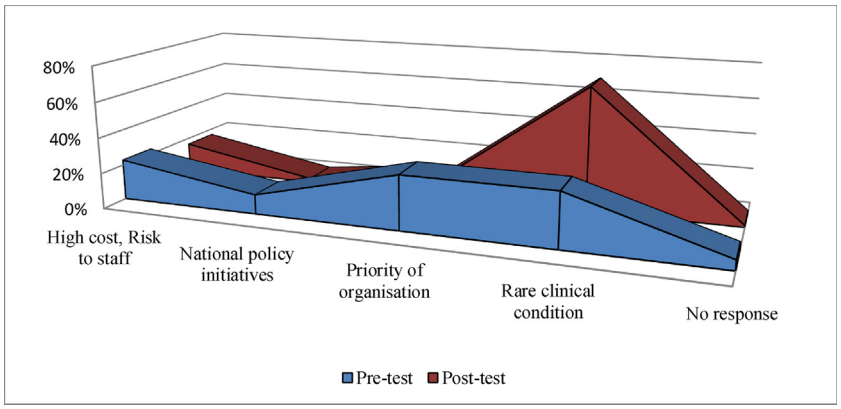

Fig. 3. Frequency distribution of responses to "the tool for prioritizing the topic for audit are all except" expressed in percentages.

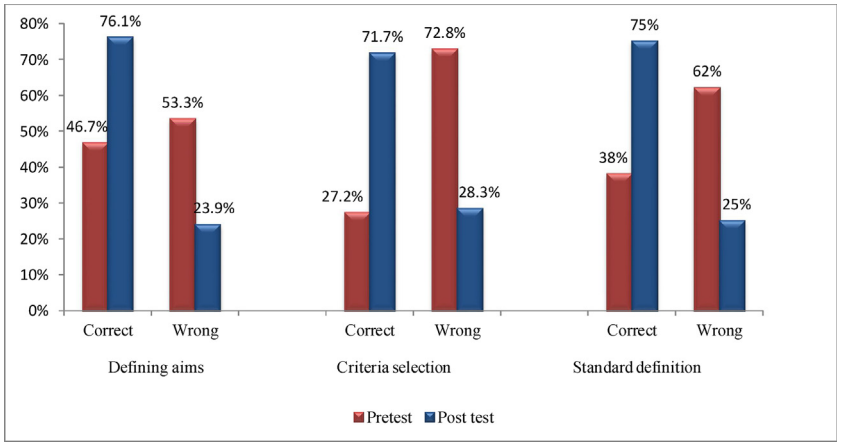

Fig. 4. Frequency distribution of the percentage of correct and wrong responses to the parameters of aims, criteria and standard in an audit.

and it was found that a statistically higher ($p < 0.001$) mean post-test score was achieved (Table 1).

4. Discussion

This study involving 92 postgraduate students in a tertiary care teaching hospital revealed that the knowledge and understanding on the principles and concepts were quite limited as was evident from the pretest analysis. However the planned intervention in the form of an educational session was effective in conveying the basic fundamentals regarding clinical audit to the participants. This was discernible from the statistically greater mean score attained in the post-test compared to the pre-test (Table 1).

In analyzing the individual components, it was demonstrable that elements such as types of audit, types of evaluation, design and stages, ethics committee approval for an audit were well comprehended by the participating candidates following the intervention. Likewise their understanding on the prioritizing tool,

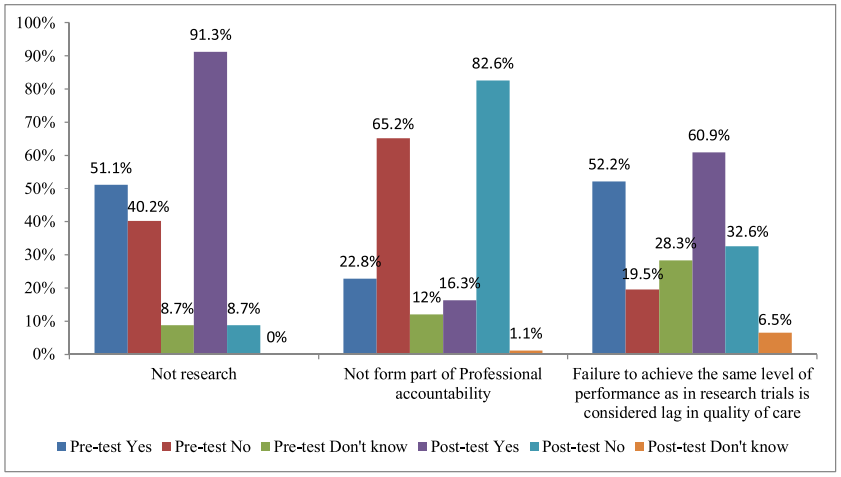

Fig. 5. Percentage distribution of responses to the attitudinal aspects of an audit.

defining aims, criteria selection and the meaning of standard showed statistically significant improvement ($p < 0.001$). A fairly good knowledge was also gained on who can conduct ($p = 0.034$) and who can make recommendations following an audit ($p = 0.029$). The participants were able to appreciate the role played by the PI in making recommendations proved by the shift in the choice of responses from the hospital audit team in the pre-test to the PI in the post-test.

An equal magnitude of improvement was not seen in the understanding on the need for an audit because a considerable majority of participants, despite the program, erroneously believed that the conduct of clinical audit was purely on administrative motive; this was made obvious by the post-test score on this element (Table 1). Also, their attitude towards achieving the same performance level as in research to ensure the best quality of care was rather unaltered (Fig. 5). Such misbelieves and misconceptions seem to be deeply rooted signifying the need for repetitive and sustained measures such as continuing medical education programs, symposia and workshops in clinical audit to enable better understanding as well as need for an attitudinal change towards such clinical audit facets.

Introspecting on the need for such programs targeting the medical postgraduates reveals that this measure not only provides a good learning experience but also would ensure ready involvement of these future consultants in the quality improvement process, as rightly pointed out by Walshe that the outcomes of an audit depend on 'who did it and how it was done'.[7] In addition, enhanced understanding of the audit concepts would pave the way for weeding out the lack of commitment, poor record keeping and inadequate data entries which are the deterrents in the path of quality improvement. Assuming the role of audit lead to facilitating teamwork are the positive attributes that would stem from the in-depth knowledge thus gained. It would not be an exaggeration to say that incorporating the competency of participation in medical audit as a module in postgraduate medical curriculum would be a step forward in implementing evidence based medicine in clinical care, since it is understandable that practicing medicine does not merely stop with updating on current research evidence of best practice but being able to show that such new standards of care is achieved in one's own practice through the clinical audit findings. Thus postgraduate training should encompass clinical audit which is considered as an integral part of clinical governance, for ascertaining the best clinical care to patients.[8]

5. Conclusion

This study has highlighted that educational programs on clinical audit with the objective to impart knowledge and improve understanding of the principles, concepts and methods should be designed and conducted for the postgraduate medical students of diverse specialties for enabling them to acquire the skill of conducting clinical audit which would ensure sustained quality control in patient care.

A study comparing cognitive function assessment in type-2 diabetes mellitus using Rowland Universal Dementia Assessment Scale and Mini Mental State Examination

S Shanmugapriya, N Dhandapani[1], T Saravanan[1]

Abstract:

BACKGROUND: Diabetes mellitus is a metabolic disorder which can predispose to cognitive impairment. It is important to screen diabetic patients for cognitive dysfunction in the routine clinical management. Our study aimed at comparative evaluation of commonly used cognition assessment tools such as Mini Mental State Examination (MMSE) and Rowland Universal Dementia Assessment Scale (RUDAS) in diabetes patients.

METHODS: The study was conducted as a prospective case–control design in a tertiary care teaching hospital from March to October 2015. After obtaining written informed consent, the data on demographic details, duration of diabetes, and glycemic control marked by glycated hemoglobin were recorded. A total of 101 previously diagnosed type-2 diabetes patients and an equal number of age-, gender-, and literacy-matched controls without diabetes were administered the MMSE and RUDAS cognition scales in a one-to-one interview by a trained diabetic educator who was blinded to the groups.

RESULTS: The study revealed that there was a significant difference in cognition scores between the diabetic patients with short duration (<5 years) and those with a longer history of diabetes (≥5 years) only in the MMSE scale using independent sample *t*-test ($P = 0.018$), unlike the RUDAS in which the difference was insignificant ($P = 0.235$). Similarly, there was also a significant correlation between glycemic control and cognition scores in the MMSE ($P = 0.03$), but not in the RUDAS scale ($P = 0.083$).

CONCLUSION: MMSE scale has been proved to be advantageous over the RUDAS as a screening tool for cognition assessment in diabetes patients.

Introduction

Diabetes mellitus is a metabolic disorder due to dysregulation of glucose homeostasis. The world prevalence of diabetes in adults has been predicted to increase from 285 million in 2010 to 439 million by 2030.[1] It is well established that diabetes is associated with significant morbidity, including neurological disability. Although it is known that diabetes can lead to cognitive deficits in the long term, elucidation of the effects on the central nervous system is still incomplete, unlike other complications such as nephropathy, retinopathy, and peripheral neuropathy. It is estimated that in 2010, 35.6 million people lived with dementia worldwide, with numbers expected to almost double every

20 years, to 65.7 million by 2030 and 115.4 million by 2050.[2] In addition to this, the scenario of type-2 diabetes predisposing to and accelerating cognitive impairment would further increase the burden of disease. With increasing prevalence of type-2 diabetes in India, the magnitude of cognitive impairment that the disease contributes to and the factors affecting should be studied.

Studies from various populations have consistently shown that diabetes is associated with cognitive deficits and dementia; both in elderly and younger patients.[3] Various pathophysiological mechanisms have been proposed. A process similar to that of peripheral neuropathy such as alterations in Na^+K^+ATPase activity and the ensuing reduction in myoinositol and sorbitol metabolism has been suggested. These may trigger biochemical abnormalities at the neuronal level, resulting in structural and functional changes, primarily in the white matter.[4] Chronic hyperglycemia, atherosclerosis, and hemodynamic changes may lead to microinfarcts which in turn to cognitive impairment. Diabetes-induced microvascular changes, such as disruption of the blood–brain barrier, and the resultant derangement of neurovascular coupling could be partly related to cognitive dysfunction.[5-7] Hyperglycemia may also be directly toxic to the neuron, leading to its degeneration[8] and consequentially the hippocampal as well as global atrophy.[5] Thus, diabetes is considered as one of the important contributory factors in the development of cognitive deficits.

Undiagnosed cognitive impairment can lead to reduced health status,[9] implying that screening for cognitive deficits should be an integral part of patient management in diabetes. Among the neuropsychological tests for dementia, the Mini Mental State Examination (MMSE), devised by Folstein *et al*., is one of the most widely used tools for the assessment of cognitive impairment.[10] The Rowland Universal Dementia Assessment Scale (RUDAS) is yet another screening test, designed as a multicultural cognitive assessment scale relatively unaffected by gender, education, and first language, as it can easily be converted for implementation in the local community.[11] Although there are studies comparing the accuracy and reliability of these two scales in geriatric population with and without dementia,[12-15] a thorough literature review reveals a paucity of studies directly comparing the two in a diabetic population. Hence, our study aimed at evaluating the effectiveness of the two scales as tools in assessing the cognitive decline in type-2 diabetes patients by comparing the correlation of cognitive score with the glycemic control and duration of diabetes.

Methods

This was a single-center, hospital-based case–control study conducted by collecting data from study participants from March to October 2015. Approval from the Institutional Human Ethics Committee was obtained before the start of the study.

Inclusion criteria

All patients willing to give consent, both males and females aged between 30 and 60 years with previously diagnosed type-2 diabetes mellitus (case) and without diabetes mellitus (control), with or without hypertension were included for the study.

Exclusion criteria

Patients with type-1 diabetes, stroke, alcohol intake or smoking habits, total blindness in both eyes, or complete loss of hearing in both ears; and patients who were previously diagnosed with and were known case of mental retardation, psychiatric disorders, and psychoactive drug use in addition to pregnant and lactating women were excluded.

The sample size calculation was done using "Epi tools," with a prevalence of 7% which was based on the previous data, and desired precision of 0.05 at 95% confidence interval revealed the sample size estimate of 101.

After obtaining written informed consent, the data on age, sex, literacy, current fasting and postprandial blood glucose (done by enzymatic reference method with hexokinase), and glycated hemoglobin (HbA1c) values (done by immunoturbidimetry), along with history on duration of diabetes and duration of hypertension were collected. The study was conducted on a sample of 101 diabetic cases and 101 non-diabetic controls matched for age, sex, and literacy to ensure homogeneity of the sample and to avoid bias in the results, owing to these parameters. In this study, patients who exhibited the ability to both read and write the colloquial language and/or English were included as literates.

MMSE and RUDAS scales were administered in a one-to-one interview with the study participant by a trained diabetic educator who was blinded to the group to which the patient belonged to. MMSE tested global cognition function with items assessing orientation, word recall, registration, attention, language abilities, and visuospatial ability and was scored out of 30. As per the MMSE scale, 21–23, 11–20, and ≤10 scores were indicative of mild, moderate, and severe cognitive dysfunction, respectively, while a score of 24 or higher was considered normal.[10] According to the recommendations of Crum *et al*., the MMSE scores were corrected for the literacy status. Based on these criteria, a score <24 was considered as impaired cognition for literates and that <22 for illiterates.[16] RUDAS scale measured memory, gnosis, praxis, visuospatial skills, judgment, and language. The maximum RUDAS score

[Downloaded free from http://www.ijhas.in on Tuesday, August 14, 2018, IP: 192.168.30.162]

was 30, for which the recommended cut point ≤22 was used to indicate cognitive impairment.[11]

Statistical analyses was done using Pearson's correlation test to analyze the correlation between mean MMSE/RUDAS score with parameters such as duration of diabetes and glycemic control. Student's *t*-test was used to identify significant difference in the mean scores between cases and controls based on age, sex, literacy, and comorbidity.

Results

The data were entered into Excel and analyzed using SPSS version 19. Among 101 cases, 4% had mild and 1% had moderate cognitive dysfunction using MMSE, whereas cognition deficit was identified in 5% cases using RUDAS. 1% controls, according to RUDAS score, had cognitive impairment while MMSE scoring revealed that 3% controls had cognitive dysfunction which was mild.

The baseline characteristics of age, sex, and literacy in both groups were matched [Table 1]. There were a higher proportion of females in both the case and the control group, with a male to female ratio of 36:65. Percentage of literates was high (94%) in both groups. The cases were arbitrarily categorized based on the observed HbA1c value as those with good control and poor control. An HbA1c value of 8.5% was taken as the cutoff value; those with <8.5% were included in the good control group and those with HbA1c values ≥8.5% were grouped as poor controllers of glycemic level. 44.6% of cases had good control, while 54.4% were included in the poor control group. The mean score was found to be less in patients who had HbA1c level ≥8.5% using both the scales. An independent sample *t*-test showed that the mean difference between the scores of patients with good and poor control was statistically significant in MMSE scale ($P = 0.046$), while in RUDAS scale, the mean difference was not statistically significant ($P = 0.372$) [Figure 1].

Cases in our study population were divided into those with duration of diabetes <5 years and those with ≥5 years history of diabetes. Accordingly, it was found that 60.4% cases had <5 years of diabetes history and the rest had ≥5 years duration. The mean scores were found to be less in people who had diabetes ≥5 years using both scales and was statistically significant in MMSE scale ($P = 0.018$) but not in RUDAS scale ($P = 0.235$) [Figure 2]. Furthermore, using Pearson's correlation test, a statistically significant negative correlation between duration of diabetes and cognitive levels ($P = 0.015$) in addition to a significant positive correlation between glycemic control and cognitive score ($P = 0.03$) was detected in testing with MMSE scale in the diabetes patients. In contrast, no significant correlation between duration of diabetes or glycemic control with cognitive dysfunction was evident while using RUDAS scale [Table 2].

In both MMSE and RUDAS scales, an independent sample *t*-test revealed that there was no statistically significant difference between the cases and controls in both categories of <50 years of age and those with ≥50 years. The difference in cognition level between the cases and controls in the two gender groups was similarly tested using independent sample *t*-tests, and it was found that there was no statistically significant difference in the mean scores based on gender using either of the scales [Table 3]. Another significant observation was that the mean score of females, in both cases and controls, were lower than that of males, even though the difference was not statistically significant, except in the diabetic group assessed using RUDAS scale, wherein the mean score

of females was significantly higher than that of males [Figure 3].

It was found using Student's *t*-test that the illiterates had a mean score lower than that of the literates, though a statistically significant difference was observed only with the MMSE scale (P = 0.001) but not in the RUDAS scale (P = 0.085). Ninety-five percent of the study population were literates, and this precluded performing a between-group analysis for cases and controls [Figure 4].

An independent sample *t*-test revealed that there was no statistically significant difference between the mean scores of cases and controls with hypertension. Similarly, there was no statistically significant difference between the mean scores of those with diabetes alone and those with diabetes and hypertension in the case group using both MMSE and RUDAS [Table 4], indicating that coexisting hypertension did not significantly affect cognition score in patients with type-2 diabetes.

Table 2: Correlation of duration of diabetes and glycemic control with cognitive levels using Mini Mental State Examination and Rowland Universal Dementia Assessment Scale

Scale	Parameter	Correlation value	*P*

Discussion

The MMSE is a cognitive scale used for detecting cognitive impairment. Having developed in the West, it has serious limitations due to cultural and educational

	Diabetes only	27.91±2.152		

MMSE = Mini Mental State Examination, RUDAS = Rowland Universal Dementia Assessment Scale, SD = Standard deviation

bias.[16,17] It is one of the commonly used tools for cognitive assessment consisting of 11-item testing with sensitivity of 87% and specificity of 82%.[18] The RUDAS is a newer screening test developed in Australia. It is a brief six-item screening test which is short and easy to administer. It is claimed to be culturally and educationally unbiased and developed in view of application in multicultural setting.[11,12,19] It assesses body orientation, praxis, drawing, judgment, memory, and language. It has the additional advantage of being capable of assessing the impairment in executive function. With a cutoff score of 23/30, it has 88% sensitivity and 90% specificity.[11,18]

It has been well proven that age, in addition to ethnicity and education, is an important factor affecting the MMSE score. In our study, there was no statistically significant difference in the mean score between patients aged above and below 50 years. In a study done using MMSE scale, there was no quantitative difference in cognition scores above and below 70 years of age, but a significant difference between diabetic and non-diabetic patients was detected.[3] Their result indicated that in diabetic patients, diabetes could be a greater risk factor for cognitive impairment than age. However, our study results did not replicate such a significant difference between cases and controls in both the age groups studied [Table 3]. The reason attributable to this inference is that most of the earlier studies were done in a population with higher mean age,[5,20] but our study included a much younger population and that may also account for the lower percentage of cognitive deficits detected. A similar result has been demonstrated in a study with middle-aged diabetic population.[4]

The prevalence of diabetes is higher in men than women, but there are more women with diabetes than men.[21] In our study sample, the proportion of females was much higher than the males. Using MMSE, the males scored higher than females though not statistically significant and this was in concordance with earlier studies.[3] Assessed using RUDAS, the female cases scored significantly higher than male cases, but such an observation was not seen in the control group and the reason for the result could not be explained.

Our study demonstrated that the magnitude of the difference in the mean score between literates and illiterates was significantly higher in the MMSE score as compared to the RUDAS scale, indicating that our study has also proven that RUDAS scale is free of educational barrier as described in the previous studies.[11,12] However, former studies done in Thailand and South Indian Malayalam population showed that cultural, linguistic, and education barriers were not fully overcome with the use of RUDAS scale.[13,15]

The cutoff values for glycemic control and duration of diabetes have been chosen arbitrarily and do not depend on the conventional cutoff adopted internationally for the management of clinical condition. The reason being that the duration of diabetes and the glycemic control beyond which cognitive dysfunction occurs, in comparison to other complications of diabetes, is less defined and less well understood. Hence, using the same clinical cutoff criteria used for management would obviously result in false-negative correlation. In the diabetic population studied, the association of mean cognition score with the glycemic control marked by HbA1c level was found to be statistically significant, in addition to a significant positive correlation which was evident only in the MMSE but not the RUDAS scale. Our study thus reflected the results obtained in few previous studies which have highlighted the positive association between poor glycemic control and poor cognition using MMSE,[22,23] but no such correlation detected using RUDAS.[24] Another study done in middle-aged adults with type-2 diabetes has demonstrated that there is predominantly psychomotor slowing with poor metabolic control, even though learning, memory, and problem-solving skills appear to be largely intact in such patients.[4] On the contrary, few other studies have established that the magnitude of glycemic control does not have significant correlation with the cognitive score using MMSE scale.[3,25,26] The potential explanation for the contradictory results between correlations of cognitive dysfunction with glycemic control is that only the recent HbA1c values representing short-term control were included in most analyses and not the time trend in HbA1c, indicative of long-term control as the measure to categorize patients with good and bad glycemic control.

Evaluating the association between the duration of diabetes and cognitive scores revealed a significant negative correlation. Those with a longer duration (≥5 years) of diabetes exhibited a lower mean score than those with shorter duration of diabetes (<5 years)

[Downloaded free from http://www.ijhas.in on Tuesday, August 14, 2018, IP: 192.168.30.162]

using the MMSE, but not with the RUDAS. Our results were consonant with results obtained in few similar studies.[3,22,25,27] Thus, most studies have proven a definitive correlation between cognitive decline and duration of diabetes than with glycemic control.

In addition, our study has shown that there was a statistically significant difference neither between the mean score of cases with and without hypertension nor between the scores of hypertensive cases and controls using both scales. Literature evidence states that although hypertension alone may not be associated with significant cognitive decline, along with diabetes, it increases the risk of cognitive impairment.[28]

With enormously increasing prevalence of diabetes and diabetes being an important risk factor for cognitive impairment, it is the need of the hour to incorporate cognitive assessment in the routine management of diabetes patients. Ours is the first study that compared MMSE with RUDAS head-to-head in a diabetic population, and the study has proved that MMSE has a definitive advantage over RUDAS for screening diabetes-induced cognitive deficit. In patients with type-2 diabetes, increase in memory deficits with reduction in psychomotor speed and reduced executive function are strongly supported by the findings of earlier studies though there are also other cognitive domains such as verbal fluency, complex motor function, attention, and recall which are shown to be negatively affected. Hence, it is clear that diabetes indeed has composite neurocognitive effects, rather than a single one and difficulty in diagnosis of such multiple neurocognitive function deficits is well recognized.[29] RUDAS tests the executive function unlike MMSE, yet RUDAS failed to demonstrate statistical significance which could be potentially attributed to the relatively high rate of intrasubject variability which is inherent to cognitive testing, thus impairing its ability to identify executive function deficits, especially those which are mild.[29]

In our study, the actual differences in the mean scores between those with good and poor glycemic control (0.91) and those with shorter and longer duration of diabetes (1.11) in the MMSE were small despite achieving statistical significance. Since score differences in the range of 2–4 or greater in MMSE are necessary to conclude a clinically relevant difference, the clinical significance of our interpretation has to be guarded and requires further investigation involving a larger sample size.

Another limitation of the study is that a large proportion of participants were literates and this could be a potential source of bias in interpreting the results. Hence, we recommend that the effectiveness of MMSE scale between literates and illiterates should be compared in a diabetic population before it can be emphasized that the MMSE scale is best suited for screening cognitive deficit in routine clinical examination of diabetic patients for early identification of cognitive impairment.

Conclusion

Our study has truly delineated that cognition deficits based on MMSE scoring correlates with the magnitude of glycemic control as well as the duration of diabetes. The results signify that in the general population, screening for dementia may preferably be done with RUDAS scale, given the higher sensitivity, specificity and particularly as it is efficient to overcome the literacy barrier in a multicultural multi-linguistic population like the one in India. However, in type-2 diabetes patients, it is the MMSE scale that has been proved to be useful in detecting early cognitive impairment, especially in patients with poor glycemic control and longer history of diabetes.

ABSTRACT

Background: Dengue infection is a major public health threat; early recognition is crucial to improve the survival in severe dengue. Although there are various biomarkers to predict the severity of dengue, they are not routinely used in clinical practice for prognostication. We analyzed whether serum ferritin can be used to predict the severity at an earlier stage.
Methods: A hospital based prospective observational study was done involving 119 dengue cases diagnosed by positive NS1 antigen or dengue specific serology (capture ELISA). Serum ferritin was measured in all at the time of diagnosis. Clinical and platelet count monitoring was done daily; classified as severe and non-severe according to 2009 WHO criteria.
Results: Out of 119, 5 developed severe dengue; patients with severe dengue had significantly lower median platelet count ($p<0.0001$); higher ferritin levels ($p=0.03$) and hospital stay ($p<0.0001$) than non-severe group. Age had a significant negative co-relation with platelet count ($r= -0.427$; $p<0.0001$); positive correlation with ferritin levels ($r=0.16$; $p=0.08$) and hospital stay ($r= 0.26$; $p=0.004$) indicating that elderly subjects are at risk of severe disease. Serum ferritin levels negatively correlated with the platelet count ($r= -0.51$ $p<0.001$). High ferritin levels in severe cases are noted from day 4 of clinical illness.
Conclusions: Elevated serum ferritin levels can be used as a potential early prognostic marker to predict the severity of dengue infection in clinical practice.

Keywords: Predictor of severity, Serum ferritin, Early, Severe dengue

INTRODUCTION

Dengue infection poses a major health problem in tropical and subtropical countries.[1] According to World Health Organization, around 50 to 100 million new infections are estimated to occur every year in more than 100 endemic countries across the world; of which around 500000 people with severe dengue require hospitalization each year and about 2.5% of those affected die.[2] The burden of the disease is so much that in the year 2012 World Health Organization classified the disease as "the most important viral disease that is transmitted by mosquitoes".[3] Dengue is caused by dengue virus serotypes I-IV and transmitted to human beings by the bite of Aedes mosquitoes.[4]

The clinical spectrum of dengue infection is variable from mild fever to severe forms of dengue such as dengue hemorrhagic fever and dengue shock syndrome. Severe dengue is characterized by severe thrombocytopenia with major bleeding, plasma leakage resulting in fluid accumulation, respiratory distress and

multi-organ dysfunction.[5] The presence of certain clinical warning symptoms which help to predict the severity are bleeding, skin rash, nausea, vomiting, abdominal pain and hepatosplenomegaly.[6]

Clinically severe dengue results from interplay between virus related virulence factors and host factors which include inflammatory response of the host to infection with exuberant T and B cell activation, release of cytokines (cytokine storm), altered endothelial function with increased vascular permeability and nutritional status of the host. [7]

In clinical practice, patients with dengue infection are grouped as 1) those with warning signs that need intensive monitoring and aggressive management 2) those without warning signs. Non-severe cases without warning signs can develop into severe dengue later during the course of illness. They are at risk of developing complications related to plasma leakage and thrombocytopenia often at the end of febrile stage of illness (third to fifth day of illness) which if unrecognized can be fatal.

Studies had identified various biomarkers for immune and endothelial cell activation, biochemical and genetic markers to predict the severe dengue.[8] The clinical utility of these markers is limited since measurement of these markers like soluble receptors, cytokines, growth factors, vWF; genetic profiling etc. is technically difficult and not widely available. Acute phase reactants like alpha1 anti-trypsin, ceruloplasmin and ferritin levels are elevated during dengue infection; they have a longer half-life unlike the cytokines, and it is feasible to measure their levels.[9]

Increased serum ferritin has been associated with severe dengue in children.[10] Hyperferritinemia in dengue infected subjects is associated with intense immune activation and coagulation disturbances as noted in Aruba Dengue outbreak.[11] An Indian study had shown that serum ferritin levels are significantly elevated in dengue infected cases compared to the controls; On group analysis, cases with severe dengue had higher ferritin levels than milder forms which was noted both during the febrile and defervescence stages of the illness.[9]

Results from the previous studies had shown that hyperferritinemia is associated with severe disease which is noted throughout the disease course. In a Malaysian study, a large proportion of patients developed severe dengue early during febrile stage. [12] It is very crucial to predict the risk of progression to severe dengue at the earliest, by simple measurable tests to initiate appropriate intensive, supportive therapy.

In the present study, we analysed whether serum ferritin measured during early disease course can be used as a marker to indicate the severity which helps to triage and manage them appropriately.

METHODS

This is a hospital based prospective observational study conducted from April 2015 to June 2016 in a tertiary care centre, PSG Institute of Medical Sciences and Research Centre (PSGIMS and R), Coimbatore, South India. The study was conducted in accordance with the Declaration of Helsinki, and the study protocol was approved by the Institutional Human Ethics Committee, PSGIMS and R. All adult patients who were hospitalized and diagnosed with dengue infection either by dengue NS1 antigen or positive dengue specific serology were included in the study after obtaining their informed consent for participation in the study. Patients with chronic inflammatory conditions or diseases; iron overload status; sideroblastic anemia; thalasemia; malignancy; liver disease were excluded from the study.

Study methodology

The study was based on prospective collection of data in dengue infected patients who fulfill the criteria as mentioned above. Diagnosis was based on NS1 antigen test (done with J. Mitra dengue NS1 Ag Microlisa kit) when the presentation was less than 5 days of illness or positive dengue specific serology (dengue IgM and dengue IgG done by Panbio dengue IgM; dengue IgG capture ELISA) if presented after 5 days of illness. Serum ferritin levels were measured if the presentation was less than 7 days from the onset of fever. After informed consent, 2ml of blood was collected from the study subjects; ferritin assay was done (by electrochemiluminescence immunoassay -COBAS e411) at the time of diagnosis if the diagnosis was made in the study center; or at the time of admission if referred from an outside hospital with positive test results (NS1 or dengue serology positive).

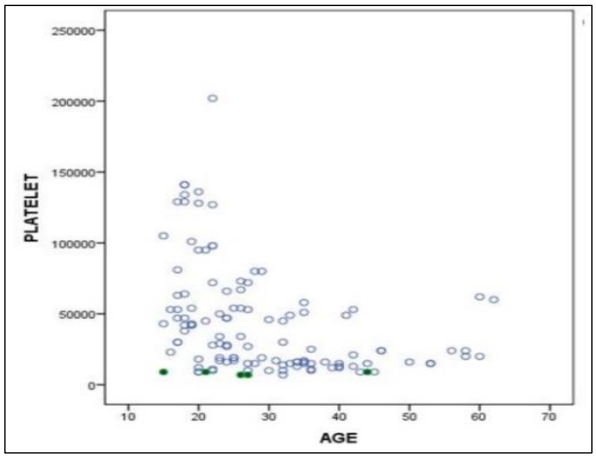
The clinical course of the disease and platelet count were monitored carefully on a daily basis and patients were classified as having severe and non-severe infection as per WHO 2009 criteria; classified as severe dengue when shock, respiratory distress, severe bleeding; organ impairment occur.[5] Mean lowest platelet count was calculated in both the subgroups from all the platelet count values obtained on a daily basis during the hospital stay. Mean ferritin levels were calculated and compared in both the subgroups.

Statistical analysis

Descriptive statistics were reported as mean±Standard deviation (SD), median with 25^{th} and 75^{th} percentiles. Mann Whitney U test was used to compare platelet count and serum ferritin between severe and non-severe dengue groups. Spearman's Rank correlation was used to assess the correlation between age with platelet count, serum ferritin and hospital stay. All analyses were done using SPSS version 21.0. P value less than 5% was considered statistically significant.

RESULTS

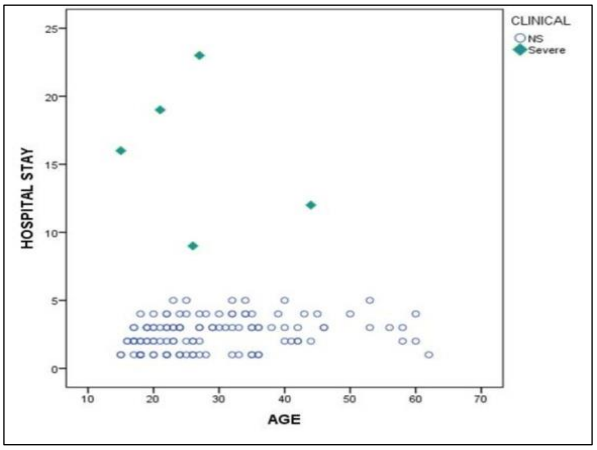
A total of 119 subjects were analyzed, of which there were 68 males (57.14%) and 51 (42.85%) females. The mean age of the study population was 29.1±11.4 years. About 50% of the study population was less than 25 years. There was no significant difference in the mean age between male and female. Diagnosis of dengue infection was established by positive NS1 antigen in 61 subjects while in the remaining 58, it was diagnosed by positive dengue serology.



Among the total 119, only 5 (4.2%) subjects had clinical severe dengue, of which 4 were males and one female. The mean lowest platelet count was 40426.47×10^9/L in males, 45000×10^9/L in females. Around 75% of the study population stayed in the hospital for ≤ 3 days; 16% stayed for 4 days; 5% stayed for 5 days. Around 5% had a hospital stay for ≥9 days. Serum ferritin levels were measured in 14 subjects on day 3; 19 on day 4; 36 on day 5; 29 on day 6 and for the remainder 21 subjects it was measured on day 7. The mean ferritin levels measured was 1399.53±690.68ng/ml; (median-1856). The mean hospital stay was 3.11 days.

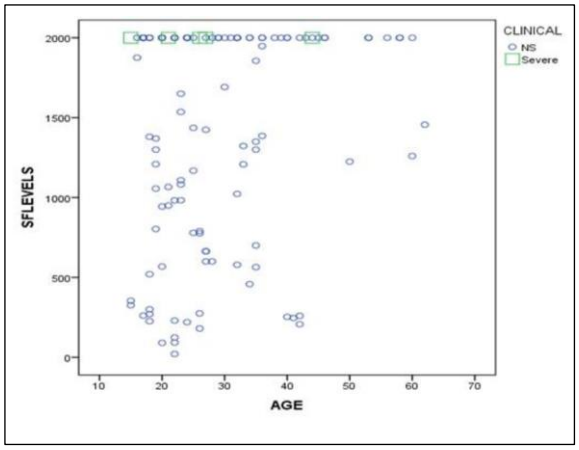
Table 1: Comparison of serum ferritin, platelet count and hospital stay in severe and non-severe dengue.

	Severe dengue	Non-severe dengue	P value
Serum ferritin ng/ml	2000 (2000, 2000)	1593 (757, 2000)	0.03*
Platelet count ×109/l	9000 (7000, 9000)	29500 (15750, 55000)	<0.0001*
Hospital stay days	16 (11, 21)	3 (2, 3)	<0.0001*



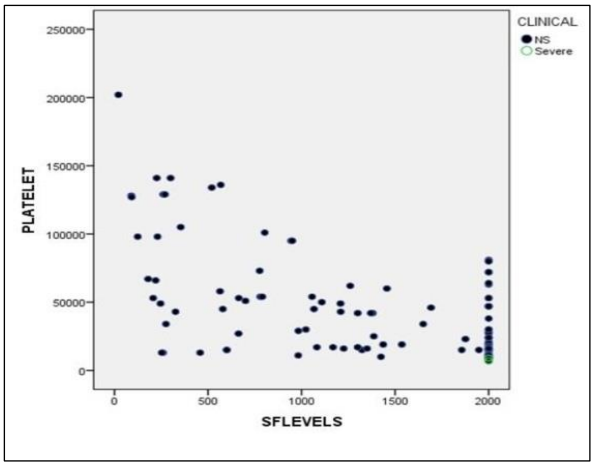
Median platelet count was significantly lower among patients who had severe dengue as compared to non-severe dengue group (Table 1). The median platelet count recorded during daily monitoring of platelets throughout the hospital stay were 9000 ×10^9/L (7000, 9000) in severe and 29500×10^9/L (15750, 55000) in non-severe dengue respectively. The median hospital stays, and serum ferritin levels were significantly higher among severe dengue subjects as compared to non-severe group (Table 1). The median serum ferritin levels and hospital stay among severe and non-severe dengue patients were 2000ng/ml (2000, 2000) vs. 1593ng/ml (757, 2000) and 16 (11, 21) vs. 3 days (2, 3) respectively.

In the present study, higher age showed a significant negative correlation with platelet count (Pearson co-efficient r= -0.427; p<0.0001). Also, higher age positively correlated with hospital stay (r= 0.26; p=0.004) and ferritin levels (r=0.16; p=0.08). The correlation with hospital stay is significant. Serum ferritin levels showed a significant negative correlation with the platelet count (Pearson co-efficient r= -o.51; p<0.001). The results are depicted in Figures 1-4.



Age negatively correlated with platelet count which is significant (r= -0.427; p<0.0001*)

Figure 1: The co-relation co-efficient between age (years) and platelet count(x109/L).



Age positively correlated with hospital stay which is significant (Pearson co-efficient r= 0.26; p=0.004*)

Figure 2: The co-relation co-efficient between age (years) and hospital stay (days).

Age positively correlated with serum ferritin levels (non significant r=0.16; p=0.08)

Figure 3: The co-relation co-efficient between age (years) and SF levels (serum ferritin in ng/ml).

Serum ferritin levels showed a significant negative correlation with the platelet count (Pearson co-efficient r= –o.51 p<0.001*)

Figure 4: The co-relation co-efficient between SF levels (serum ferritin in ng/ml) and platelet count.

Serum ferritin measured from day 3 to day 7 of illness was compared in both the severe and non-severe groups and reported in Table 2. It was observed that non-significantly, patients who had severe dengue had higher median serum ferritin levels from day 4 onwards as compared to non-severe dengue cases.

Table 2: Comparison of serum ferritin levels in severe and non-severe dengue measured from the day 3 to day 7 of illness.

Serum ferritin measurement	Ferritin level in ng/ml		P value
	Severe dengue	Non-severe dengue	
3 day	-	n=14 1486 (1013, 2000)	-
4 day	n=1 2000±0 2000 (2000, 2000)	n=18 1001±811 859 (242, 2000)	0.421
5 day	n=2 2000±0 2000 (2000, 2000)	n=34 1549±587 2000 (1183, 2000)	0.349
6 day	n=1 2000±0 2000 (2000, 2000)	n=28 1222±727 1315 (565, 2000)	0.414
7 day	n=1 2000±0 2000 (2000, 2000)	n=20 1512±722 1974 (1103, 2000)	0.571

Serum ferritin measured from day 4 to7 of illness was high in severe dengue compared to non-severe cases, although not statistically significant

DISCUSSION

Currently there is no specific drug or preventive vaccine available for dengue infection. The mainstay of management of dengue infected subjects is supportive care and close monitoring for complications.[13] Most of these patients recover within 5 to 7 days from onset of the febrile illness while only a small percentage progress to severe dengue, with a study quoting 5%.[14] Severe dengue often occurs at the end of febrile or during convalescent stage and carries a very high mortality. It is very crucial to predict the severe form well in advance even prior to the appearance of warning signs by a simple diagnostic marker so that early identification and appropriate management would improve the outcome in these patients.

Increased expression of acute phase reactants is observed in patients with severe dengue infection when compared to non-severe cases.[9] This serves to prognosticate the dengue infected patients well ahead of the appearance of clinical warning signs. One such acute phase reactant is ferritin which is produced by reticuloendothelial cells in response to infection and inflammation. Ferritin is highly elevated in dengue infected patients than in patients with other febrile illnesses.[11] Hyperferritinemia seen in these patients exhibit two opposite functions; Early in the phase of clinical illness, increased serum ferritin levels exert a protective effect by chelating the toxic free iron radicals at the site of inflammation.[15] while in severe cases, raised ferritin may assume a pathogenic role by activating immune cells resulting in cytokine storm.[9]

Males constitute 57.14% of the study population in the present study which was in accordance with other studies. The mean hospital stay was comparable with other studies. The mean duration of hospital stay was 2.73±1.41 days as observed by Ahmed at al, and 3.7±1.02 days in a study conducted in Rawalpindi.[16,17]

Results from the present study showed that hyperferritinemia is associated with severe dengue which is noted in other studies as well.[9-11, 17] To analyze whether serum ferritin can predict the severity earlier in the course of illness, day wise serum ferritin levels was compared in both the sub-groups; the serum ferritin levels were higher in severe dengue cases when compared to non-severe group and this increase is noted from day 4 of illness onwards which clearly indicates that serum ferritin can predict the severity of dengue at an earlier stage.

A study conducted during a dengue outbreak on the Caribbean island Aruba which compared the ferritin levels in dengue infected patients with those having other viral illnesses concluded that ferritin is a useful clinical marker to differentiate dengue from other febrile illnesses; serum ferritin levels >1500ng/ml is associated with severe disease ; serum ferritin levels measured on day 4-5 better predicts the outcome of dengue infection and it concluded that these patients with hyperferritinemia should be monitored carefully for complications.[11] Results from the present study also had shown that hyperferritinemia (2000ng/ml) is seen in all cases with severe dengue and this increase in serum

ferritin levels is noted from day 4 of clinical illness in severe cases when compared to non-severe cases.

Another study conducted in one hundred seventy-seven Thai children which measured serum ferritin levels during the entire clinical course (febrile, toxic and convalescent stages) showed similar results.[10] Increased serum ferritin was associated with severe dengue; patients with non-severe dengue had serum ferritin levels less than 1,200ng/ml during the entire course of illness, while severe forms recorded higher levels of serum ferritin during the febrile stage and the defevervescence stage. Patients with dengue hemorrhagic fever (DHF) grade III and IV had significantly higher median ferritin levels measured on day 5,6 and 7 of illness than those with grade I, II DHF and dengue fever. In that study it was concluded that serum ferritin level ≥1,200ng/ml from day 4 of the illness predicts the occurrence of dengue hemorrhagic fever.

In a study conducted in South India by Soundravally R et al, which included 48 dengue infected cases and 48 cases with other febrile illness as controls, serum ferritin levels were measured on the day of admission (which is a median of 4 days after the onset of fever) and day of defervescence (which is a median of 4 days after the day of admission).[9] Compared to other febrile illnesses, dengue cases demonstrated significant increase in serum ferritin levels ;also within clinical groups, severe disease exhibited higher ferritin levels compared to non-severe group throughout the febrile and defervescence stages of illness (940.09±568.31 in non-severe cases vs. 1264.71±492.59 in severe dengue on day of admission ; 418.19±404.59 vs. 1490.74±359.40 on day of defervescence) The study concluded that raised serum ferritin levels could predict the severity of dengue with a sensitivity and specificity of 76.9% and 83.3% respectively. The present study also showed similar results; hyperferritinemia was noted in severe cases compared to non-severe group from day 4 to day 7 of illness.

One another study showed significant association between raised serum ferritin levels on the day of admission and the development of severe dengue.[16] Serum ferritin was measured on the day of admission in a total of 104 dengue positive cases and they were grouped into a) Group A with normal ferritin levels (up to 100µg/dl) and b) Group B with high serum ferritin levels ; both the groups were followed up for the occurrence of severe dengue. Severe dengue was noted only in 2 out of 31 patients with normal serum ferritin levels while more than half of the patients with severe dengue (35 out of 73) had raised serum ferritin levels. The study concluded that serum ferritin can be used as an early marker to predict the severity of the disease.

Another significant observation made out in the present study was that age had a positive co-relation with the serum ferritin levels and the duration of hospital stay while it negatively co-related with the platelet count. This implies that age is an important predictor of severity of dengue infection. As age advances, there is increased risk of developing severe disease with low platelet count, high ferritin levels and prolonged hospital stay. Studies had shown that elderly individuals are at risk of developing severe disease. In a study conducted in Southern Taiwan during a dengue outbreak with 5336 dengue cases, the incidence of dengue hemorrhagic fever and dengue shock syndrome is significantly higher in persons aged 60 years and above when compared with younger age groups.[18] Similar observation was made in a Singapore study; persons aged more than 60 years had more occurrence of severe dengue (20.3% vs. 14.6%, P = 0.006) as compared to younger adults.[19]

Our study is unique in that serum ferritin was measured once at the time diagnosis whereas in most of the earlier studies serum ferritin levels were done at multiple times during various stages of clinical illness.[9-11] The results of the present study in which serum ferritin was measured either at the time of diagnosis (or at the time of admission if referred from outside) within 7 days from onset of fever, correlated with the findings of the previous studies . It would be simpler, easier and convenient to measure serum ferritin on a single day, which is practically feasible in clinical setting catering to a large population.

The present study has few limitations as well. First, is the small number of severe dengue observed in the present study; hence we were unable to derive the cut-off value of day wise ferritin levels which can predict the risk of development of severe dengue. A larger sample size with more number of severe cases would be appropriate before arriving at a definite conclusion. Second, the upper limit of serum ferritin measured in the present study was 2000ng/ml due to laboratory limitations; so higher values could not be observed which if available can enable us to better understand about its correlation with both the severity of thrombocytopenia and clinical severity with more accuracy.

Also, the nature of infection (primary or secondary); dengue serotypes were not taken into consideration. To address the limitations in the present study, future studies are needed to find out the cut off level of serum ferritin which can predict severe dengue at the earliest for effective disease management.

CONCLUSION

The present study had shown that elevated serum ferritin levels done early during the febrile stage of the illness (3rd to 7th day of illness) predict the severity of dengue.

ABSTRACT

Rat killer, in the form of a paste, is a commonly used rodenticide in India. It contains 3% yellow phosphorus, which is a local and a systemic toxin that damages all tissues it contacts. The lethal dose of yellow phosphorus is about 1 mg/kg of body weight. We present a case report of a 30-year-old female patient with an alleged history of intake of 30 g rat killer paste mixed with one glass juice with suicidal intent. She presented with clinical features of acute liver failure (ALF) and was treated with N-acetylcysteine (NAC) infusion with other supportive therapy and recovered completely within 13 days. Poisoning with yellow phosphorus needs to be studied in the aspect of treatment, due to the lack of any specific antidote. The patient factors that help in the recovery also need to be investigated. Although highly lethal, the recovery of ALF due to yellow phosphorus-containing rodenticide is possible. Early intravenous administration of NAC, which acts as glutathione substitute, anti-inflammatory agent, and anti-oxidant could contribute to complete resolution of ALF in yellow phosphorus poisoning.

INTRODUCTION

Poisoning is a major problem worldwide. Intentional and accidental ingestions of toxins in humans lead to high mortality and morbidity rates. Yellow phosphorus is a well-known hepatotoxic agent commonly found in fireworks, ammunition, agricultural dung and it is ubiquitously present in rodenticides. It is available as both paste and powder form in the open market in India, with concentrations varying from 2% to 5%. The lethal dose of yellow phosphorus is 1 mg/kg of body weight, and ingestion of amounts >780 mg is almost invariably followed by death [1,2]. It is a protoplasmic poison, which spontaneously combusts in air and causes multi-organ failure when ingested. The quantity of yellow phosphorus consumed, lack of specific antidote, and time lapse in treatment affects the outcome of poisoning. Very few case reports of yellow phosphorus poisoning have been reported worldwide. Here is one such rare case report of successful management of a 30-year-old female patient who consumed a substantial amount of yellow phosphorus in the form of rodenticide paste which is 18 times of the lethal dose.

CASE REPORT

A 30-year-old female patient, a housewife of weight 50 kg, with no medical or medication history was brought to the emergency department with complaints of loose stools (2 episodes), vomiting (7 episodes), and mild giddiness. The initial presentation of the patient depicted gastroenteritis. On personal interview of the patient, it was revealed that she consumed two packets of 15 g rodenticide paste-containing yellow phosphorus (3%), 11 hours before admission with suicidal intent.

On initial examination, she was conscious, oriented, had paled, and was psychologically depressed. There were no bleeding manifestations, jaundice, or other signs of liver failure. Laboratory investigations showed normal biochemical parameters. Electrocardiogram was within the normal limits. Ultrasonography of the abdomen showed fatty liver. She was treated with supportive measures such as intravenous pantoprazole 40 mg and intravenous ondansetron 4 mg. N-acetylcysteine (NAC) infusion was started within 1 hour of admission, and the patient was shifted to the intermediate care unit (Tables 1 and 2).

From day 2, the patient experienced a clinical deterioration with mild abdominal pain and vomiting. It was followed by two episodes of vomiting, fatigue, abdominal pain, and nausea on day 3. On day 4, she had generalized body tiredness, myalgia, and disturbed sleep due to nausea. On day 5, she experienced mild nausea. On day 6, she had 1 episode of vomiting and was shifted to the ward. On these days, her laboratory investigations showed deranged liver enzymes (Table 3).

From day 7 to day 13, the patient was asymptomatic and improved clinically. She was discharged from hospital on day 14 after 1 day of observation. The discharge medications consisted of tablet pantoprazole 40 mg O.D, tablet ursodeoxycholic acid 300 mg B.D, tablet rifaximin 550 mg B.D, tablet L-adenosyl L-methionine 200 mg BD, and syrup lactulose 20 ml TID, which was continued till review.

The patient was reviewed on the 7th day from hospital discharge, her laboratory investigations showed improvement in the liver enzymes. On the second review, the laboratory investigations were normal and the patient had completely recovered (Table 4).

DISCUSSION

Sporadic cases of ingestion of toxins on a suicidal intent are common in developing countries [3]. Our patient allegedly ingested 900 mg of yellow phosphorus in the form of a paste which is highly lethal. Orally ingested yellow phosphorus is rapidly absorbed through the gastrointestinal tract. About 69%–73% of the total ingested dose concentrates in the liver after remaining in the gut for a few hours [4].

The features of yellow phosphorus poisoning are classically divided into three stages. The first stage involves gastrointestinal irritation and shock. Features begin within minutes of ingestion, but may be delayed in some cases. Symptoms involve nausea, vomiting, diarrhea, and abdominal pain [5-7]. Our patient developed several episodes of vomiting, diarrhea, and giddiness within 11 h of ingestion.

The second stage is quiescent or asymptomatic period, which lasts for 24–74 h [8]. The patient is mistaken to be improving and is most likely to get discharged prematurely. The patient was asymptomatic and was clinically stable for 24 h after initial supportive therapy.

The third stage involves a clinical deterioration with fulminant hepatic failure, which may progress to multi-organ failure. This stage involves high rates of mortality, and death usually occurs in 4–8 days [9]. From day 2, our patient's biochemical and clinical parameters deteriorated. She was at increased risk of fulminant hepatic failure but recovered by day 13 due to prompt treatment with NAC.

The current report is in line with other reports that it is difficult to manage yellow phosphorus poisoning due to multiple factors. First due to the property of yellow phosphorus itself, that it gets rapidly absorbed and remains stable for long periods in the gut because of higher water content and low oxygen tension [10]. Second, because there are no diagnostic tests to detect or antidote available to treat yellow phosphorus poisoning. Finally, treatment of yellow phosphorus is complicated due to symptomatic improvement in stage 2.

Mechanism of toxicity of yellow phosphorus is by the production of phosphoric acid, which produces an exothermic reaction and causes direct tissue damage due to the production of free radicals. NAC, which is an antioxidant and hepatoprotectant, acts as a glutathione precursor by donating sulfhydryl groups [11]. It also improves mitochondrial energy metabolism [12]. It acts as a scavenger of oxygen free radicals and it replenishes the glutathione stores. It is found to have a good prognosis in patients with yellow phosphorus poisoning when administered early [13,14]. The patient's liver enzymes were highly elevated. The outcome of the patient after 10 days of NAC administration was excellent; highlighting the importance NAC in nonacetaminophen-related liver failure.

Table 1: Core therapy of NAC

Day	NAC dose
Day 1	NAC 10.5 g in 200 ml 5% dextrose over 1 h NAC 3.5 g in 500 ml 5% dextrose over 4 h NAC 7 g in 1000 ml 5% dextrose over 16 h
Day 2 to Day 10	NAC 3 g in 500 ml 5% dextrose over 4 h (2 doses per day)

NAC: N-acetylcysteine

CONCLUSION

Our case report highlights the importance of history taking of patients brought to emergency care. Yellow phosphorus poisoning requires more than just primary care. Early improvement in symptoms should not be mistaken as a resolution to the clinical problem. Instead, the patient has to be periodically monitored for clinical and biochemical parameters for at least 5 days before premature discharge from the hospital. Prompt use of NAC within the first 12 h of poisoning has been

Looking Beyond Lupus in Lupus

BHARGAVI KUMAR[1], SARAVANAN THANGAVELU[2]

ABSTRACT

Haematological abnormalities are a common finding in Systemic Lupus Erythematosus (SLE) patients. The wide spectrum includes anaemia, cytopenias, thrombosis as well as bleeding. Among the bleeding disorders, qualitative coagulation defects can be rarely encountered because of clotting factor inhibitors. More uncommon is the occurrence of quantitative clotting factor deficiencies. Here, we describe a rare cause of abdominal pain in a patient with SLE who developed perinephric and colonic sub mucosal haematomas owing to a rare association with acquired factor XIII deficiency which was diagnosed on quantitative assays and effectively treated with cryoprecipitate and fresh frozen plasma.

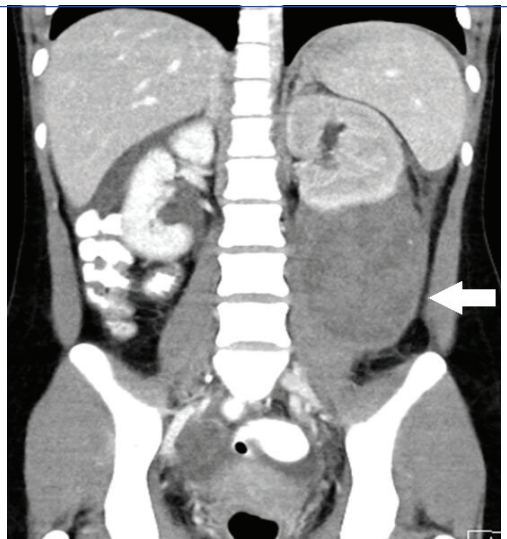
Keywords: Abdominal haematomas, Factor XIII deficiency, Systemic lupus erythematosus

CASE REPORT

A 21-year-old young lady presented to the Emergency Department with left loin pain, vomiting and loose stools for the last one day. She did not report any fever, radiation of pain, urinary symptoms, pain aggravation on food intake or any prior strenuous activity.

The patient was diagnosed with SLE 2 years ago and was on treatment with steroids, Mycophenolate Mofetil (MMF) and Hydroxychloroquine. She reported history of intermittent episodes of pain in her calf muscles in the last one year. Magnetic resonance imaging (MRI) had revealed the presence of organised haematomas in calf muscles, but the patient did not follow-up due to spontaneous resolution of symptoms.

On examination, the patient was pale, tachycardic and hypotensive. No rashes were noted. Respiratory system examination fairly ruled out pleurisy and musculoskeletal examination was normal. A non-tender firm ballotable mass was palpable in the Left lumbar region.



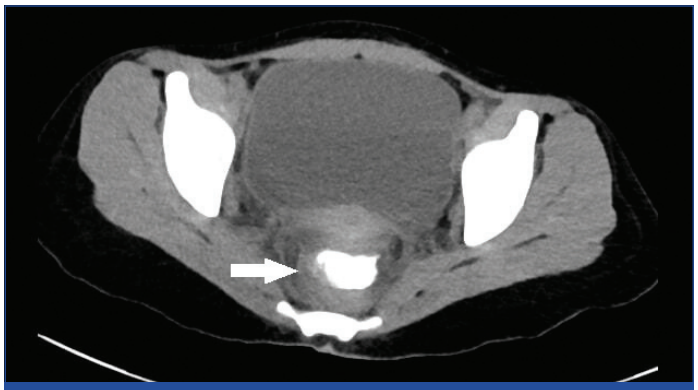
Preliminary investigations showed microcytic anaemia, (haemoglobin 6.2 g/dL), severe thrombocytopenia (22×10^9/L) and mild neutrophilic leucocytosis as shown in [Table/Fig-1]. Her renal function and complements were normal with slightly elevated Erythrocytic sedimentation rate (35 mm first hour). Ultrasonogram of the abdomen showed 9.4×7.4 cm heterogeneous lesion adjacent to the lower pole of the left kidney. A computed tomography revealed the presence of left perinephric haematoma with left hydroureteronephrosis [Table/Fig-2]. Initial coagulation profile revealed normal Prothrombin Time (PT), Activated Partial Thromboplastin Time (APTT) and slightly low fibrinogen levels (1.4 g/L). Direct Coombs test turned out to be positive. Von Willebrand Factor assay was normal. Antiphospholipid Antibody (APLA) work up was done in which anti beta2 glycoprotein turned out to be negative, with Lupus anticoagulant ratio of 1.6.

The differential diagnoses considered were acute SLE flare/bleeding due to thrombocytopenia/coagulation defects and MMF induced haematological crisis. However, complement activity, disease markers were normal and the patient was on irregular treatment with MMF. Since initial PT, APTT levels were normal, possible factor XIII deficiency was considered and she was evaluated accordingly.

The patient was stabilised with intravenous fluids namely Normal Saline, low dose methyl prednisolone 250 mg over 3 days and 2 units packed red blood cells transfusion. There was recurrence of vomiting and loose stools during initiation of enteral feeds and a repeat CT abdomen revealed new onset transmural haematomas in small bowel loops, distal ascending colon, transverse colon,

	Day 1	Day 5	Day 7	Day 11	Standard value
Haemoglobin g/dL	6.2	8.4	9.9	11.9	12-15
Mean corpuscular volume fL	73.2				80-100
White blood counts ×10^3/uL	15	10.6		9.2	4-10
Platelets x10^3/uL	22000	42000	83000	110	150-400
Prothrombin time (seconds)/INR	13.3/1.2	13.9/1.33		13.1/1.25	9-12
APTT (seconds)	29.1	22.8		28.2	25-34
Serum fibrinogen levels mg/dL	76	140		342	200-400
C3 c level/C4 mg/dL	83/21				90-180 10-40
ESR mm 1st hour	35	30		17	4-12 mm
HsCRP mg/dL	0.30				<0.5 mg/dL
Procalcitonin ng/mL	0.2				<0.5

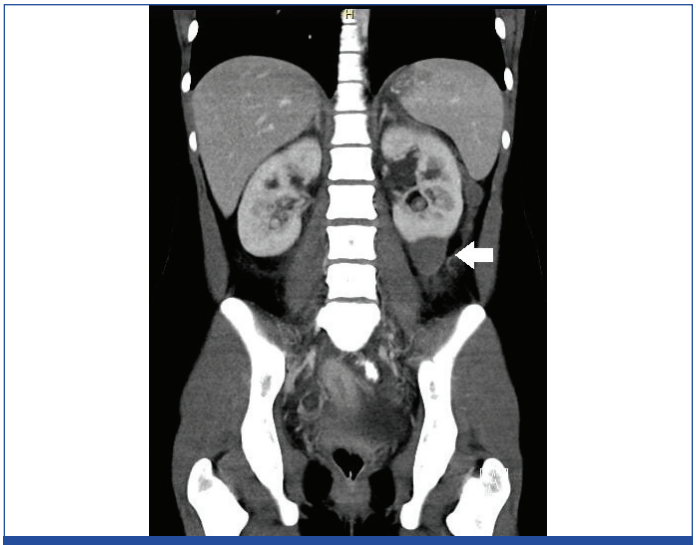
[Table/Fig-1]: Preliminary investigations showing microcytic anaemia, severe thrombocytopenia and mild neutrophilic leucocytosis.



[Table/Fig-2]: CT abdomen showing perinephric haematoma over lower pole of left kidney with ureteric compression.

descending colon and rectum [Table/Fig-3,4]. The coagulation profile results reaffirmed normal APTT levels; repeat fibrinogen levels were normal (3.4 g/L) and platelet counts were improving (120×10^9/L). On performing a clot solubility test, the clot completely dissolved in 5M urea solution and on mixing studies, the clot dissolved partially. Since the results were equivocal, it was not possible to differentiate a hereditary factor XIII deficiency from a factor XIII inhibitor in this case. Subsequently, a factor XIII assay was done which turned out to be <1% thus confirming severe deficiency. Patient was transfused with a total of 18 unit's cryoprecipitate (270 mL) and 10 units of fresh frozen plasma (2400 mL total) during her entire hospital stay following which she showed steady improvement.

[Table/Fig-3]: CT abdomen depicting transmural haematoma of distal ascending, transverse and descending colon.



[Table/Fig-4]: CT abdomen showing transmural haematoma involving rectum.

A follow-up CT abdomen a month later showed resolving left perinephric haematomas with resolution of colonic and rectal haematomas. The patient is currently doing well on 5 mg once daily prednisolone and azathioprine [Table/Fig-5].

DISCUSSION

SLE is a challenging disease to treat. In the current era, diagnosing SLE has become common due to increasing awareness, knowledge of its varied presentations and available investigations. However, the course of the disease poses a constant challenge to the treating physician owing to the myriad of systemic manifestations and complications.

Acute abdomen in SLE patients is a challenging diagnostic and therapeutic problem. Most patients are on steroids and/or immunosuppressive agents which mask the physical findings, thus leading to a delayed definitive diagnosis. The reported incidence of abdominal pain in SLE varies from 8 to 40% [1,2]. Assuming that all are due to vasculitis may lead to diagnostic errors. In an observation of 36 active SLE patients presenting with acute abdomen by Medina F et al., 19 had vasculitis, 3 had Anti Phospho Lipid Antibody (APLA) related intra-abdominal thrombosis and the rest were non-SLE related [3]. Therefore, it is imperative to carefully evaluate such a patient based on their clinical, imaging and immunological profile.

[Table/Fig-5]: CT abdomen revealing resolving haematoma over the lower pole of left kidney.

Haematological abnormalities are common findings in patients with SLE. The prevalence is described as 47% in most studies [4]. In a study by Sasidharan PK et al., haematological manifestations were found to be the most common initial presentation of SLE and it was the presenting manifestation in 82% of the patients. The haematological spectrum encompasses anaemia, leucopenia, thrombocytopenia, autoimmune haemolytic anaemia, thrombotic thrombocytopenic purpura, myelofibrosis-hypoplastic anaemia and thrombotic manifestations if associated with APLA [5]. The index patient too had leucopenias along with cutaneous manifestations in her initial presentation leading to her diagnosis.

It is imperative to distinguish haematological abnormalities arising due to disease activity from those due to drug effects. The index patient had normal complement activity and disease markers making acute SLE flare unlikely. The patient was on irregular treatment with MMF, making drug related side effect a remote consideration. Bleeding despite normalisation of platelet count, fibrinogen levels and normal PT, APTT prompted us to investigate us for rare clotting factor abnormalities, such as Factor XIII defects. Coagulation defects in SLE could be due to inhibitors more commonly [6], and due to factor deficiencies rarely [7-9].

Factor XIII is needed to stabilise the fibrin clots and it's deficiency could be genetically acquired as Autosomal recessive disorder or could be due to acquired causes [7]. Hereditary deficiency is attributed to the F13A1 gene located on the short arm of chromosome 6 (6p24.2-p23). Acquired factor XIII deficiency occurs much less often, and usually affects middle-aged or elderly individuals [10]. It can be associated with conditions such as severe liver disease, chronic kidney failure, inflammatory bowel disease, Henoch-Schonlein purpura, autoimmune disorders such as SLE or scleroderma and certain cancers such as myeloid forms of leukaemia. It has also been linked to the use of certain medications including isoniazid, penicillin, and phenytoin.

Individuals with factor XIII deficiency form blood clots per se, but the clots are unstable and often break down, resulting in prolonged, uncontrolled mild to fatal bleeding episodes. The most common bleeding symptoms are subcutaneous bleeding (57%), delayed umbilical cord bleeding (56%), muscle haematoma (49%), haemorrhage after surgery (40%), haemarthrosis (36%) and intracerebral bleeding (34%) [11,12]. However, the index patient's presentation was unusual with perinephric, colonic submucosal and transmural haematomas.

Factor XIII deficiency is screened by clot solubility test and confirmed by quantitative assays [13]. It is treated by factor XIII concentrates,

fresh frozen plasma or cryoprecipitate. When inhibitors develop in individuals with factor XIII deficiency, additional therapy in the form of immunosuppressive agents would be required.

On review of literature, there is a reported Lupus patient with associated factor 13 deficiency who developed intracerebral haematoma [9]. There are case reports of subcutaneous and intramuscular haematomas due to factor XIII deficiency following an invasive procedure in a patient with SLE [14]. In another instance a 70-year-old man had developed spontaneous left gluteal haematoma owing to factor XIII deficiency [15]. Occurrence of gastrointestinal haematomas as in the index patient seems to be extremely rare.

CONCLUSION

It is fruitful to think beyond lupus while approaching the presenting complaints even in a diagnosed patient of SLE. Attributing all the features to the disease per se might be misleading. A high index of suspicion for rarer clotting factor deficiencies is required while evaluating the bleeding manifestations with a normal coagulation profile. There exists a lacuna in ascertaining the fact as to why in an autoimmune disease, there is associated clotting factor deficiency, unlike the expected scenario of clotting factor inhibitors. Only continued medical research can unravel such mysteries.

ABSTRACT

Euglycemic ketoacidosis is defined by the triad of euglycemia, metabolic acidosis and ketonemia or ketonuria. In the current era of diabetic management, it is a serious concern with the usage of sodium glucose co-transporter 2 (SGLT2) inhibitors potentiated by a number of precipitating agents. Empagliflozin though a novel oral hypoglycemic agent in this category may also lead to this potential complication. Here we report a 59 year old male, type 2 diabetic who was on empagliflozin and presented with euglycemic ketoacidosis after a binge of alcohol.

Keywords: Empagliflozin, SGLT2 inhibitor, Type 2 diabetes, Euglycemic ketoacidosis

INTRODUCTION

Hyperglycemic states in diabetes like Diabetic ketoacidosis (DKA) and hyperglycemic hyperosmolar non ketotic coma are widely encountered, well known and therefore easily diagnosed emergencies. However euglycemic ketoacidosis is an often missed relatively less known condition and under reported scenario. A high index of clinical suspicion is warranted to arrive at this diagnosis because the normoglycemia may mask our clinical judgement of DKA.

The management of diabetes mellitus is ever evolving with oral hypoglycemic agents being an area of constant research and updates. Approved by the Food and Drug administration of USA (FDA) in 2014, Sodium glucose co-transporter 2 (SGLT2) inhibitors is a new addition to the already existing broad list of oral hypoglycemic agents for type II diabetes mellitus. Apart from reducing blood sugars, its spectrum also extends to reducing blood pressure, reduction of weight and cardio protection.[1] It is now included in American Diabetes Association treatment guidelines as one of the add-on agents in dual or triple drug combinations in diabetes as it can effectively reduce HbA1c by 0.5-0.7%. However euglycemic ketoacidosis is a rare but potential complication in this class of drugs for which FDA has released a safety alert in 2015.[2] Its diagnosis may be delayed owing to the normal sugar levels and needs a strong index of suspicion whenever there is ketonemia or ketonuria in the presence of normal blood sugar levels and high anion gap metabolic acidosis.

CASE REPORT

A 59 year old male presented to the emergency department with abdominal discomfort and orthopnea following a binge alcohol intake. Patient was a chronic smoker and alcoholic for 30 years and a known case of

type 2 diabetes mellitus and systemic hypertension for 5 years. He was on irregular treatment with tablet metformin 500 mg in once daily dosage and had started taking tablet empagliflozin 10 mg once daily for the past 2 years without prescribed medical advice. His concomitant medications included tablet nebivolol 5 mg once daily for systemic hypertension. On examination, the patient was moderately dyspnoeic, tachypnoeic, drowsy, arousable and normotensive. Respiratory system examination showed basal crepitations and abdomen examination showed mild epigastric tenderness.

Preliminary investigations revealed normal sugar levels (169 mg/dl), ketonuria (3+) and elevated HbA1c (10.8%). His complete blood counts, serum procalcitonin, liver, thyroid and renal functions were normal but for low bicarbonate (4.65 mEq/l) and a pH of 7.2. The calculated anion gap was high (27.7). Cardiac functions were normal as evidenced by echocardiogram and biomarkers.

An ultrasonography of the abdomen was done in view of epigastric tenderness and showed a bulky pancreas suggestive of acute pancreatitis. His amylase (956 U/l) and lipase (3873 U/l) were also elevated and lipid profile evaluation revealed hypertrigliceridemia (242 mg/dl). His laboratory parameters are summarised in Table 1.

Noting his ketonuria and high anion gap metabolic acidosis with normal blood sugars we arrived at a diagnosis of euglycemic ketoacidosis in the background of his medication history of empagliflozin therapy which was probably precipitated by alcohol binge and acute pancreatitis. Patient was put on ventilator support and started on intravenous fluids, insulin along with 5% dextrose and bicarbonate correction. The acidosis improved gradually and blood glucose levels were controlled with rapidly acting insulin. After the patient improved symptomatically, he was weaned off and tolerated soft diet.

Table 1: Laboratory parameters of the patient across his days of admission showing his normal sugar values at admission and metabolic acidosis which resolved following treatment.

	Day 1	Day 2	Day 3	Day 5	Day 7	Day 9	Day 10
Sugars (mg/dl)	169	141	132	178	193	299	268
Urine for ketones	+++	+++	++	+	Nil	Nil	Nil
pH	7.2	6.9	7.47	7.4	7.48	7.40	7.41
HCO_3 (mEq/l)	4.65	7.0	14	11.3	18	23.8	24.1
Amylase (U/l)	956	-	-	145	242	-	-
Lipase (U/l)	3873	-	-	639	1158	887	637

On discharge, the patient was counselled regarding diet, insulin therapy, advised alcohol abstinence and was counselled to stop any self-medication of new oral hypoglycemic agents. The patient is now on regular follow up, maintaining average blood sugars of 200 mg/dl. As the patient was apprehensive about continuing insulin, he is now put on oral agents-insulin secretagogues alongside diet and lifestyle modification.

DISCUSSION

There are a multitude of causes leading to metabolic acidosis in diabetics. These include normal anion gap acidosis like renal failure as well as high anion gap states like lactic acidosis and ketoacidosis. Ketoacidosis could be due to diabetic ketoacidosis, starvation ketoacidosis or alcoholic ketoacidosis. Diabetic ketoacidosis may be either hyperglycemic or euglycemic. Thus analyzing the risk factors that contribute to the development of ketoacidosis is very crucial.

Euglycemic ketoacidosis was first observed and reported in a case series by Munro et al who observed that a subset of DKA patients had sugar levels <300 mg/dl.[3] Subsequently euglycemic ketoacidosis has been characterized by the triad of euglycemia (blood glucose <250 mg/dl), metabolic acidosis (pH <7.35, bicarbonate <18 mEq/l) and ketonemia or ketonuria.[4] To explain it succinctly, euglycemic ketoacidosis is DKA sans marked hyperglycemia. It is mainly described in type 1 diabetes but nevertheless not uncommon in type 2 diabetes. Possible contributing factors include starvation, alcoholism, pregnancy, pancreatitis and drugs. Among drugs, SGLT2 inhibitors are notorious to cause euglycemic ketoacidosis.

SGLT 2 inhibitors act primarily by inhibiting sodium glucose co-transporter 2 in proximal convoluting tubule which mediates 80-90% of glucose absorption in kidney. As a result of this facilitation of glucose excretion by kidney, blood glucose levels are lowered. When the blood glucose levels reduce, the insulin release from pancreas also reduces proportionately tilting the normal insulin: glucagon ratio, thereby favoring ketogenesis. Other proposed mechanisms include release of glucagon by direct SGLT2 inhibition in pancreas, release of kisseptin which inhibits insulin release and also decreased reabsorption of ketones leading to ketonemia.

Empagliflozin has shown meticulous benefits in reducing major cardiac events as evidenced in the 'EMPA-REG OUTCOME' trial.[5] Since empagliflozin's mechanism of action is independent of beta cell functioning, they are useful in all type 2 diabetes patients as long as estimated glomerular filtration rate is above 45-60 ml/min. Other potential benefits include weight loss (2-3 kg) and

reduction in blood pressure (3-6 mmHg systolic, 1-2 mmHg diastolic) due to natriuresis besides cardioprotection. Though beneficial in numerous aspects, empagliflozin also has adverse effects like genital fungal infections (3-5%), urinary tract infections (1-2%), volume depletion and hypotension. However of serious concern is the development of euglycemic ketoacidosis though reported in less than 0.1% patients. Canagliflozin and dapagliflozin also carry the risk of euglycemic ketoacidosis with reported incidence being 0.8% and less than 0.1% respectively.[6]

On literature review, we noted that Gammons and Counselman have presented a case report of a chronic alcoholic, type 2 diabetic patient on empagliflozin developing euglycemic ketoacidosis with acute pancreatitis similar to our index patient.[7] So also Candelario and Wykretowicz have presented a type 2 diabetic female who developed euglycemic ketoacidosis while on empagliflozin therapy precipitated by acute cholecystitis.[8]

In our index patient with euglycemic ketoacidosis, the clear culprits were empagliflozin overtly precipitated by his binge of alcohol and pancreatitis. A high index of suspicion alone prompted us to withdraw the offending drug and treat him with insulin and dextrose apart from intravenous fluids in correcting his metabolic acidosis.

CONCLUSION

DKA need not necessarily present with hyperglycemia. High anion gap ketoacidosis should be a red flag to look for euglycemic ketoacidosis which requires both insulin and dextrose in correcting the underlying metabolic derangement. Careful drug history and possible precipitators should be identified and promptly corrected. SGLT2 inhibitors though a novel agent in the treatment of diabetes also comes with its quantum of adverse effects like euglycemic ketoacidosis which is a potential life threatening complication. The key to a successful usage of newer exciting hypoglycemic agents lies in choosing our patients wisely and carefully avoiding those who have other contributing factors for acidosis.

CASE REPORT

Dengue Fever Complicated By Hemophagocytosis – A Difficult To Manage Case

Saravanan Thangavelu*, Clement Jenil Dhas and Mohammad Zeya Ansari

Department of General Medicine PSG Institute of Medical Sciences and Research, India

Abstract: Dengue fever, which is transmitted by the mosquito Aedes aegypti is a common acute viral febrile illness, affecting 390 million people worldwide every year. It is endemic in several countries. Although the usual presentation is that of a self-limiting illness, its complications are protean. Infection associated with hemophagocytic syndrome (IAHS) is a rare and fatal complication of dengue fever. It should be suspected in a patient with fever beyond seven days, associated with hepatosplenomegaly, hyperferritinemia, worsening cytopenias and development of multiorgan dysfunction(MOD). We report a 19-year-old female, who presented with an acute febrile illness and was diagnosed with primary dengue fever. Despite appropriate supportive therapy, she worsened clinically during the course of hospitalisation. A disproportionately high ferritin level and persistent bicytopenia prompted investigations for hemophagocytic lymphohistiocytosis (HLH). Further evaluation revealed features of HLH, as per the diagnostic criteria laid down by the Histiocyte Society. She was successfully treated with glucocorticoids, etoposide and intravenous immunoglobin and other supportive therapy. She had severe cytopenia and cardiac dysfunction during the course of her illness and its management. This case adds to the limited adult cases of dengue-associated hemophagocytic syndrome and shows its difficulty in management due to associated extra complications.

Article History	Received: October 09, 2018	Revised: January 06, 2019	Accepted: February 01, 2019

1. INTRODUCTION

Dengue fever which is endemic in India and several other countries can sometimes manifest with many atypical features sometimes that may be life-threatening too if not diagnosed and intervened in time **(1).** HLH is one of them, which is now being detected more readily due to increasing awareness amongst clinicians. It is a status of abnormal immune response caused by a cytokine storm induced by the uncontrolled proliferation and activation of the macrophages in the reticuloendothelial system causing a systemic inflammatory response and multi-organ dysfunction **(2)**. Reactive HLH is associated with infections, autoimmune disorders or malignancies. HLH has been reported in dengue patients **(3)**. Its incidence is estimated to be approximately 1.2 cases per 10,000,000 individuals **(4)**. Primary HLH occurs due to various genetic abnormalities and often presents during infancy and early childhood. It is associated with an autosomal recessive inheritance pattern. Secondary HLH is associated with infections, malignancy, metabolic and rheumatological conditions. Many infections are known to cause HLH and this is often mistaken for sepsis and multiorgan dysfunction syndrome(MODS). We describe the case of a 19-year-old female, who had primary dengue fever complicated by hemophagocytosis which was difficult to manage due to different drug and non-drug related complications.

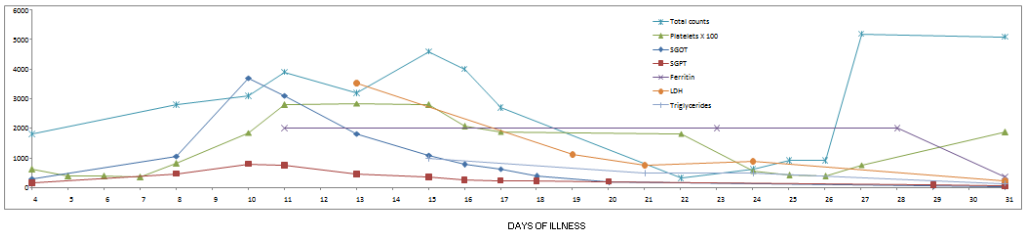
1.1. Case Report



A 19-year-old female was admitted with high-grade intermittent fever for 3 days, associated with a headache and myalgia without any symptoms suggestive of a focus of infection. On the day of admission, she had mild pallor, no icterus or edema and her vitals were stable. Systemic examination did not reveal any significant finding. Her white blood cell count was 1800cells/cu.mm, hemoglobin was 8.7g/dl and platelet count was 60,000cells/cu.mm. Liver function tests were moderately deranged with elevated transaminase, alkaline phosphatase and Gama glutaryl transferase. With clinical features and preliminary reports, she was diagnosed to have dengue fever and it was confirmed with dengue IgM positivity (by ELISA). She was treated with supportive care, intravenous fluids and antipyretics. Follow up of cultures was also negative for any organisms.

But even after 6 days of illness, she continued to have a fever and general unwellness. There was an increasing trend in serial liver enzymes, with mild prolongation of prothrombin time. However, she had no bleeding manifestation. She was suspected to have hospital acquired new infection and was evaluated for the same. She started on an empirical intravenous broad-spectrum antibiotic as per hospital antibiotic policy. Urine, blood and bone marrow culture were sterile. But she continued to have a fever and general unwellness and worsening of liver function and prothrombin time as well. Serology for human immunodeficiency virus, hepatitis-B, C,

A, E and scrub typhus infections was negative. Epstein-Bar virus serology was consistent with past infection while IgM antibody for cytomegalovirus was positive. Anti-nuclear antibody profile was also negative.

On the ninth day of illness, she was shifted to the medical intensive care unit in view of desaturation and worsened sensorium. She was intubated and mechanical ventilation was given. Since she had a worsening course of illness even after on appropriate antibiotic therapy, the possibility of HLH was considered. She underwent a panel of investigations for the same, which included serum triglycerides, ferritin, lactate dehydrogenase (LDH), peripheral smear and bone marrow smear and biopsy, repeat cultures and procalcitonin (Trend of laboratory results shown in Fig. (**1**). She had high levels of serum triglyceride, ferritin, LDH and evidence of hemophagocytosis in the bone marrow examination (as shown in Figs. (**2** and **3**). Fig. (**4**) Peripheral smear showing spherocytes, suggestive of the transfused population.

Apart from supportive care, she was also started on treatment for hemophagocytic lympho- histiocytosis as per HLH 2004 protocol. She continued to have fever and biochemical parameters showed no improvement even after two days of therapy with Dexamethasone and Etoposide. Hence she was also started on Immunoglobulin therapy. Subsequently, fever and other abnormal parameters regressed. She was extubated and shifted out of the intensive care unit. During her stay in the intensive care unit, she had worsening of neutropenia secondary to Inj. Etoposide, for which she was given Inj. Granulocyte colony-stimulating factor (G-CSF). She also developed left ventricular systolic dysfunction probably as a complication of dengue and/or secondary to immunoglobulin therapy which was managed with fluid restriction and diuretic. After stabilization, she was shifted to ward where she underwent a complete rehabilitation programme. At the time of discharge, her biochemical and hematological parameters normalized. During the three months follow up, she maintains good health and blood parameters.

2. DISCUSSION

HLH is a rare and life-threatening disorder with major therapeutic and diagnostic difficulties. It causes tissue destruction due to abnormal immune activation. Clinical features of HLH, which is secondary to unrestrained immune activation are not specific and mimic sepsis with MODS. Although primary HLH is typically seen in the paediatric age group, secondary HLH can occur in adults and children in association with certain triggers which includes solid organ malignancies, infections, rheumatological disorders and

inherited or acquired immunodeficiency. Several infections like visceral leishmaniasis**(5)**, tuberculosis, dengue and scrub typhus trigger HLH.

Dengue is an uncommon cause of HLH and has been mentioned in a few case reports **(6)**. T cells infected with dengue virus produce cytokines like tumor necrosis factor (TNF)-α and interferon (IFN) gamma which possibly contribute to the development of HLH syndrome. HLH is characterized by excessive macrophage activation and cytokine release. This results in unchecked inflammation due to immune dysregulation. Patients with HLH are acutely ill with fever, hepatosplenomegaly, effusions and lymphadenopathy. Laboratory findings include bicytopenia, coagulopathy, liver dysfunction, hyperferritinemia and elevated triglycerides. Bone marrow infiltration by activated macrophages can be demonstrated, and diagnosis is made based on the HLH-2004 protocol proposed by the Histiocyte Society. HLH can be established in the presence of (i) molecular diagnosis consistent with HLH or (ii) the presence of five out of eight criteria, namely, fever, splenomegaly, cytopenias, hypertriglyceridemia and/or hypofibrinogenemia, hemophagocytosis in tissue, hyperferritinemia, increase in CD25/IL-2 receptor and reduced or absent NK cell activity. Our patient met 6 of the 8 criteria.

Glucocorticoids are used as the first line of treatment of HLH. Other agents as per HLH-2004 protocol **(2)** are cyclosporin, etoposide and intrathecal methotrexate (for patients with central nervous system involvement). The presence of both dengue-associated HLH and multiorgan dysfunction (MOD) in majority of the patients may indicate that they are part of an inflammatory spectrum, which also includes systemic inflammatory response syndrome **(7).** Interleukin (IL)-6 and TNF are associated in the pathogenesis of MOD. Nonetheless, treatment for each syndrome is different, as HLH is treated with chemo-immunotherapy whereas supportive therapy is a keystone in MOD.

Dengue fever, caused by a mosquito-borne virus belonging to the Flaviviridae family, is a serious public health problem in the Indian subcontinent. The year 2017 has seen a gross increase in the number of dengue cases in India. The clinical manifestations range from a self-limiting febrile illness to life-threatening disease with shock and MOD. In a study focusing on 162 adult HLH patients, 58% survival was noted **(8).** The diagnosis of dengue is based on the detection of virus non-structural protein 1, which has greater sensitivity in primary infection (90%) when compared with secondary infection (60–80%). Alternatively, real-time PCR tests are available for virus detection. Serological testing for IgM and IgG antibodies helps in differentiation between primary and secondary infections.

Dengue-associated HLH has been described commonly in children, with few reports in adults **(9).** It has been more commonly noted in patients with dengue hemorrhagic fever. But our patient didn't have any bleeding manifestations. In our patient, the diagnosis was established on Day 12 of illness. During the treatment she had cardiac dysfunction probably due to the immunoglobulin administered or dengue itself, hence fluid management was prioritised. She also developed etoposide-induced severe neutropenia which was managed with G-CSF injections. She was successfully treated with etoposide, immunoglobulin and a tapering course of corticosteroids as per the HLH-2004 protocol**(10)** and showed a good response to the same. At the first month and subsequent monthly follow up, she was well with no features of reactivation. In our patient, the initial improvement was followed by clinical worsening leading to a diagnosis of dengue-associated HLH. This case highlights the need for awareness of causes of worsening dengue, its immediate confirmation and early therapeutic intervention as this may be life-saving. This case also adds to the few adults reported HLH in dengue as there have been approximately 45 cases dengue-related HLH **(11)**.

CONCLUSION

Usually, dengue fever spontaneously subsides after five days of illness with supportive care alone. If a person continues to be symptomatic even after five to seven days of illness, along with the possibility of secondary bacterial infections there should be a high index of suspicion of its atypical and rare complications. Early diagnosis and intervention may be life-saving.

DOI:
10.2174/1574886313666180731123232

Abstract: ***Background*:** Dapsone is a sulfone derived drug used in the treatment of leprosy and several chronic inflammatory dermatological diseases. Dapsone Hypersensitivity Syndrome (DHS) is characterized by fever, hepatitis, generalized exfoliative dermatitis and lymphadenopathy. It is rare and potentially fatal.

***Case Report*:** We present a case report of a 52 years old female with a recent history of antecedent dapsone exposure of 100 mg daily for 2 weeks. She developed fever 10 days after exposure to dapsone therapy and was treated in various primary and tertiary centers for features of sepsis. When she presented to us, clinical features of multi-organ dysfunction and intractable sepsis was evident. She was successfully managed with intravenous corticosteroids and other supportive therapy.This case of DHS is unique due to pulmonary, hepatic and colonic involvement in addition to secondary bacterial and fungal infection, which is associated with an increased risk of mortality. As dapsone is mainstay in the treatment several infections and inflammatory conditions,further research is needed to characterize markers to diagnose DHS and to develop screening policies prior to initiation of dapsone therapy.

Keywords: Dapsone, dapsone hypersensitivity, exfoliative dermatitis.

1. INTRODUCTION

Dapsone belongs to the sulfonamide drug class. It was initially used to treat leprosy and later found to have anti-inflammatory properties as well. At present, it is used in a wide variety of dermatological conditions, especially those with a neutrophil predominance, as dapsone inhibits neutrophil activation and recruitment through a number of pathways. The effective dose of dapsone is 100 mg daily, which can be increased upto a maximum of 300 mg daily [1]. Though dapsone is well tolerated, DHS is said to occur at an incidence of 0.2 to 0.5% in patients receiving dapsone therapy. This drug induced hypersensitivity syndrome also known as DRESS (Drug, rash, Eosinophilia and systemic symptoms) syndrome [2]. It typically occurs as a reaction to drugs like carbamazepine, phenytoin, phenobarbital, allopurinol, sulfasalazine and minocycline, mimicing a severe form of sepsis. DHS is characterized by fever, rash and multi- organ failure. It can cause irreversible organ damage and fatality. The mortality associated with DHS is 12-23%. DHS generally occurs within 1-8 weeks after starting dapsone, though in some cases, it can occur as late as six months after treatment initiation or as early as 6 hours in previously sensitized patients [3].

2. CASE REPORT

A 52 years old Indian female presented with fever of twenty days duration associated with itching all over her body. She had complaints of breathing difficulty of ten days duration, not associated with cough. She also complained of abdominal pain with loose stools for the past ten days. Her medical and medication history revealed that two months prior to current admission, she was treated with dapsone external application and oral tablet 100 mg daily by a dermatologist for suspected dermatitis. She developed fever and other constitutional symptoms 10 days after exposure to dapsone, then she was referred to a general practitioner. Basic investigations were done and medications were given for symptomatic relief, but patient did not have any relief, later admitted in a tertiary care centre. She was hospitalized for one week, where she developed hepatic dysfunction, renal azotemia, respiratory distress and new exfoliative, itchy and scaly skin leisions started to develop. Later, she was shifted to our hospital.

On physical examination, she was pale, afebrile and had icterus. She was found to have hyperpigmented exfoliative skin lesions all over her body, including the face. She also had bilateral cervical and axillary lymphadenopathy and mild nontender hepatomegaly. Laboratory investigations illustrated the presence of anemia, increasing trend of leucocytes with eosinophil counts compared to prior report elsewhere, elevated liver enzymes, hypoalbuminemia in addition to

1574-8863/18 $58.00+.00 © 2018 Bentham Science Publishers

raised lactate dehydrogenase and procalcitonin level. Blood culture was sterile but sputum culture showed moderate growth of budding yeast. Stool and urine cultures were negative. Ultra sonography of abdomen revealed mild hepatomegaly with moderate fatty infiltration, splenomegaly, and right minimal pleural effusion with consolidation. Evaluations for other infectious etiologies were negative, which consisted of hepatitis panel including hepatitis B surface antigen, human immuno-deficiency virus tests, anti-leptospira IgM antibody, weilfelix test and scrub typhus IgM antibody.

A diagnosis of DHS with co-existing secondary sepsis was made, based on the patient's treatment history, exfoliative dermatitis and multiorgan dysfunction with reasonable time relationship to dapsone exposure. As skin leisions were exfoliative and scaly, skin biopsy was not done, and due to patient's financial reasons HLA-B*13:01 analysis was not done.

Systemic hydrocortisone 50 mg every 8 hours was started by intravenous route from the second day. Bronchodilators, antihistamine, antibiotics and antifungal along with supportive therapy were also provided. Besides, she was monitored for dapsone induced secondary seizure.

The erosions on skin started healing 2 days after beginning corticosteroid therapy and no acute symptoms were noted thereafter. After 5 days of systemic corticosteroids, our patient was switched to oral prednisolone 40 mg daily. She was discharged on day 9 with oral corticosteroids, antihistamine and other supportive medications.

Prednisolone was then tapered and stopped over a period of 4 weeks. During follow-up, the patient had a relapse of itchy skin leisions and fever. Hence the oral corticosteroid was restarted at a dose of 40 mg everyday for one month and tapered the dose of 2.5 mg every week till the end of 5 months duration during which the patient had a gradual remission. Till then she was under regular periodic follow-up without any evidence of relapse of the disease.

A causality assessment of this adverse drug reaction was done, which revealed that the causality to be "probable" according to both WHO and Naranjo causality assessment scales.

3. DISCUSSION

Sulfonamides are compounds that contain sulfamoyl group ($-SO_2NH_2$). Absorption of orally administered dapsone from gastrointestinal tract occurs readily, with a bioavailability of about 86%. It is metabolized via either N-hydroxylation or N-acetylation, which leads to toxic intermediate metabolites.These metabolites form haptens resulting in the production of anti-dapsone antibodies.

DHS is thought to be an immune mediated reaction, involving T-lymphocyte activation, macrophage and cytokine release. Dapsone induced delayed hypersensitivity syndrome is directed by dapsone specific T cells. It develops typically between 2 to 8 weeks of dapsone administration and clinical features lasts even after withdrawal of the drug [4]. Our patient developed DHS after ten days from initiation of the drug and clinical features were apparent for more than a month after drug withdrawal.

The skin eruption in DHS is often initially morbilliform which later progresses into exfoliative dermatitis [5]. The skin rash severity is usually associated with fatal outcomes, especially if the damage involves more than 30 percent of the body surface [6]. Such a presentation was seen in our patient since she had lesions all over the body, including the trunk, limbs and face which is associated with an increased risk of mortality.

Hepatic involvement in DHS often demonstrates a mixed hepatocellular and cholestatic pattern. A similar pattern was evident in our patient with a high alkaline phosphatase apart from a modest increase in transaminases. Hyperbilirubinemia in DHS can be attributed to both hepatotoxicity and hemolysis, which is yet another feature of the hypersensitivity syndrome. Due to hemolysis, the lifespan of red cells is reduced and accounts for anemia that manifests in most, if not all patients [7]. Hypoalbuminemia is also reported with DHS probably due to binding of dapsone to the circulating serum albumin. Hypoalbuminemia was apparent in this patient as well [5].

Agranulocytosis caused by DHS, increases the susceptibility to infections thus, accounting for the secondary bacterial and fungal infections in DHS patients including ours [4]. Hence sepsis can be considered as an indirect consequence of the drug reaction. This element of the hypersensitivity syndrome is the one which misleads to an interpretation of infective etiology complicating the diagnosis and the subsequest management, necessitating a high index of suspicion for proper diagnosis and treatment.

Dapsone is known to produce acute eosinophilic pneumonia with hypoxia and pleural effusion [3]. This explains the presence of pleural effusion and severe hypoxemia in our patient which might as well be regarded as an interplay between drug reaction and secondary respiratory infection.

Appropriate management of DHS includes prompt discontinuation of dapsone and introduction of systemic steroids [3]. Since dapsone has a long elimination half life of 24-30 hours and it persists in organs for about 35 days, slow tapering of the corticosteroid therapy is recommended [5]. Besides, this case also bears evidence to the fact that early discontinuation may cause relapse and that adequate duration of steroid treatment is necessary to ensure prompt recovery.

The major route of elimination of dapsone is by N-acetylation which exhibits genetic polymorphism. Dapsone and sulfonamides contain an aromatic group which is readily acetylated by cytosolic hepatic acetyl transferases. Hence, fast acetylators are at a low risk of DHS as a lower proportion of the drug is available for N-hydroxylation. Thus, serious adverse drug reactions to dapsone can arise from an inter-individual pharmacogenetic variation in the drug metabolism, the sequential detoxification and elimination of metabolites [3, 7]. Recent studies show that HLA-B*13:01 allele may be used as a pharmacogenomic marker to prevent severe cutaneous adverse reactions [8]. The presence of this allele in Indians is 1-12% and its absence is associated with 7-fold risk reduction [6].

In addition, susceptibility to DHS can be increased with reduced glutathione reserve, as in conditions like AIDS (Acquired immunodeficiency syndrome). Environmental factors, such as smoking, drugs inhibiting CYP 450 and deficiency of antioxidants, such as vitamin E, vitamin C and selenium can contribute to the risk of developing DHS [9].

Evidence suggests that there is no obligatory cross-reactivity between sulfonamides and other sulfonamide non antibiotic drug, such as dapsone due to the difference in chemical structures between these compounds [10].

CONCLUSION

This case highlights that a high index of suspicion is needed to diagnose DHS. Nevertheless, physicians should be familiar with protypical features of this hypersensitivity syndrome to avoid delay in correct diagnosis. The various systemic manifestations can be easily mistaken for other disorders apart from a misinterpretation of progression of the primary skin disease. This case also delineates the significance of capturing the history of antecent drug exposure. In the current clinical scenario of dapsone being used in numerous conditions on account of its promising steroid sparing effect, it is imperative that the physicians and clinical pharmacists be aware of this potentially life threatening hypersensitivity reaction. Periodic monitoring of patients started on dapsone is necessary to detect early warning signs of DHS. It is also emphasized that early tapering of corticosteroids in DHS is not recommended as it can cause relapse of the manifestations.

ETHICS APPROVAL AND CONSENT TO PARTICIPATE

This prospective case study was approved by the Institutional Human Ethics Committee PSG IMS&R, Tamil Nadu, India..

HUMAN AND ANIMAL RIGHTS

No animals were used in this research. All human research procedures followed were in accordance with the ethical standards of the committee responsible for human experimentation (institutional and national), and with the Helsinki Declaration of 1975, as revised in 2008.

CONSENT FOR PUBLICATION

Written and informed consent was obtained from the patient for this study.

CONFLICT OF INTEREST

The authors declare no conflict of interest, financial or otherwise.

ACKNOWLEDGEMENTS

Declared none.

ABSTRACT

Medicine is a practicing art. This is because we evolve constantly with everyday learning. The core of the health care system is management of patients with pharmacological measures. However the role of the health care deliverers does not stop with prescribing drugs. It is of central importance to be aware of the potential side effects of the drug including the rarest of the complications. It is equally important to discuss with our patients the available choices, the risk - benefit ratio and counsel them accordingly regarding anticipated common and rare side effects. The patient must be repeatedly reinforced about the importance of periodic follow up with the doctor, need for regular laboratory monitoring and reporting of alarm signs without any delay. Thus patient education, awareness of drug characteristics and a detailed doctor prescription are central in avoiding as well as managing drug related adverse effects. Here we present a case series of 9 different patients presenting with varied drug related adverse effects.

Key words: Adverse drug reactions, Periodic Monitoring, Patient education, Warning signs, Physician role.

INTRODUCTION

The European Medicines Agency (EMA) defines an adverse drug reaction as "a response to a medicinal product which is noxious and unintended.[1] The US Food and Drug Administration (FDA) defines an adverse drug reaction as any untoward medical occurrence associated with the use of a drug in humans "for which there is a reasonable possibility that the drug caused the adverse event."[2] Most of the drug reactions usually go underreported. Doctor prescription, drug characteristics and patient education are the three vertices of the adverse drug management triangle.

Drug reactions could be highly characteristic or nonspecific.[3] They could be dose, frequency or time dependent, occurring either almost right away or much later. Polypharmacy is a clear culprit in the occurrence of adverse drug reactions.

Patient factors like age, gender, creatinine clearance, body weight and fat distribution, race, ethnicity, genetic susceptibility, smoking and alcoholism are well known factors contributing to adverse drug reactions.[4] Patient education of drug intake, timing with other drugs, other co-morbidities, alertness in early recognition and reporting of warning signs are also of paramount importance.

A physician should be insightful in drug prescription fully taking into consideration previous drug histories and other simultaneous drugs the patient is on. It is wise to restrain hurry while diagnosing the disease or prescription even on a crowded day practice. It is prudent to refer the patient when required or have a close follow up while in doubt.

CASE REPORT

Case 1

A 58 yr old male patient presented with history of fever, loose stools and abdominal discomfort for 1 week. Patient was diagnosed

www.ijopp.org

with Myasthenia gravis 3 months ago elsewhere and started on immunosuppressants with oral Prednisolone 5mg once daily, Azathioprine 50mg once daily and Pyridostigmine 60mg thrice daily.

His examination was normal except for right eye ptosis. His initial blood counts showed pancytopenia as shown in Table 1. Bone marrow biopsy was suggestive of myelosuppression. With the diagnosis of drug induced pancytopenia, azathioprine was withheld and he was started on broad spectrum antibiotics and antifungal agents. Patient was given an injection of Granulocyte-Colony Stimulating Factor (G-CSF), following which his counts steadily improved. 2 weeks later patient reported with normal blood counts and patient was put on Mycophenolate mofetil along with pyridostigmine and steroids. Currently the patient's myasthenic symptom has improved and is maintained on oral prednisolone 10 mg once daily.

Case 2

27 year old female was admitted with history of fever for 3 days. Patient was evaluated elsewhere for a right sided neck swelling 1 month ago. A Computed Tomography (CT) Angiogram of the chest had shown Aortoarteritis changes suggestive of vasculitis for which she was treated with oral Azathioprine 50 mg once daily and oral Methotrexate 10 mg weekly.

On admission she was pale and tachypnoeoic tachypnoeic with gingival petechial petechiae. Her blood counts showed severe pancytopenia (Table 1). With a clinical diagnosis of drug induced bone marrow suppression, patient was put on strict barrier nursing with empirical antibiotics and antifungal agents. Patient required supportive transfusion with packed red cells, platelets and G - CSF in view of profound pancytopenia. However a week later, patient developed persistent dry cough, left peri orbital hematoma, hoarse voice, hypotension and stridor. A chest imaging and tracheal aspirate were suggestive of Aspergillus. Patient was put on mechanical ventilation and high end antibiotics and antifungal agents but eventually succumbed to refractory septic shock.

Case 3

58 year old female patient was admitted with history of recurrent nasal and gum bleeding for 1 month. Patient was diagnosed with *Pemphigus vulgaris* and had been taking Methotrexate 7.5mg weekly once for 10 years.

On examination, patient was pale and had non pruritic, non-blanchable multiple hyper pigmented maculae all through the body. Initial investigations as displayed in Table 2 showed pancytopenia and subsequently a bone marrow biopsy was suggestive of myeloid suppression with no atypical cells. Patient was started on intravenous antibiotics and transfused with packed red cells and platelets. Further the skin lesions were suggestive of psoriasis and patient was managed with antihistaminic drugs and topical applications. A month later patient reported with normal counts and is doing well on topical steroids and moisturizers.

Table 1: Showing the bicytopenia pattern in case 1 and subsequent improvement; case 2 showing persistent pancytopenia.

		CASE 1				CASE 2				
Lab parameter	Reference range	Day 1	After G-CSF	2 weeks later	1 year later	Day 1	Day 3	Day 5	Day 9	Day 15
Hemoglobin	13 - 17g/dL	10.2	10.9	14.8	9.6	3.8	7.5	9.5	9	6.3
Total white blood count (WBC)	4-10x10^3/uL	0.8	6.8	6.6	8.4	0.7	1.3	1.7	2.2	0.6
Platelets	150-400x10^3/uL	261	556	247	212	22	9	3	10	11

Table 2: Showing the drug induced pancytopenia in case 3, 4 and 5 with subsequent improvement.

Lab parameter	CASE 3				CASE 4					CASE 5				
	Day 1	Day 5	A month later	A year later	Day 1	Day 3	Day 6	2 weeks later	2 months later	6 months prior to treatment	Day 1	Day 2	2 days after G-CSF	1 Month later
Hemoglobin	7.1	8.2	8.4	10.0	8.2	9	10.1	8.0	13.2	8.5	4.4	5.3	6.5	9.9
White blood count	2.1	3.9	14.7	6.8	0.3	1.9	4.3	10.5	6.2	8.5	3.1	1.8	8.0	6.7
Platelets	4	86	187	211	30	37	65	617	242	246	75	53	117	153

Case 4

68 year old male patient was admitted with complaints of fever, productive cough and breathlessness for 2 days. Patient was a known case of Rheumatoid arthritis on oral Methotrexate 5 mg weekly for 8 years.

On admission, patient was severely dyspnoeic and tachypnoeic, had bilateral lung crepitations with Varicella zoster skin lesions. His initial investigations showed pancytopenia (Table 2). Patient was treated with empirical antibiotics, antifungal and antiviral drugs. He was supported with blood products transfusion and G-CSF. His tracheal and urine cultures revealed multidrug resistant *Klebsiella pneumonia*. Patient had a tumultuous hospital stay where he required reintubation after weaning owing to excessive oropharyngeal secretions which was further complicated by an episode of atrial fibrillation reverted by cardio version. After aggressive management with sensitive antibiotics and ventilator support, patient improved symptomatically and he was able to mobilize around in wheel chair. Patient was discharged with Hydroxychloroquine tablet 200 mg once daily and reported on follow up with improved counts and no active inflammatory signs.

Case 5

51 year old female patient was admitted with history of generalized fatigability, exertional dyspnoea and swelling of legs for 10 days. She was diagnosed with Rheumatoid arthritis for the last 2 years. Initially the patient had taken native medication for her joint pain and then subsequently started elsewhere on weekly Methotrexate dose of 5 mg, Leflunomide 10 mg daily and 5 mg once daily prednisolone for the last 6 months. On examination, the patient was pale, had glossitis, bilateral pitting pedal edema and crepitations in the lungs. Initial investigations (Table 2) showed pancytopenia. On the suspicion of drug induced pancytopenia, methotrexate and leflunomide were withheld. Patient was started on broad spectrum antibiotics and antifungal agents with strict barrier nursing. Bone marrow biopsy showed hypo cellular marrow with no atypical cells. The patient was administered one dose of G-CSF and 2 units packed red cells were transfused. Her blood counts gradually started improving and patient was discharged with low dose oral prednisolone and is maintained on the same on follow up.

Case 6

59 year old female patient presented with breathlessness, decreased urine output, swelling of legs for the last 2 days. Patient had started developing facial puffiness a month ago for which she was suggested thyroid function tests elsewhere. Her Thyroid Stimulating Hormone (TSH) levels were 6 microIU/ml and patient was started directly on 100 micrograms (mcg) Levothyroxine.

On examination, the patient was tachypnoeic, had anasarca and extensive bilateral lung crepitation's. Her cardiac markers were elevated and an echocardiogram showed mild pericardial effusion with preserved ejection fraction and cardiomegaly. A diagnosis of levothyroxine induced heart failure was arrived at and patient was treated with noninvasive ventilation, diuretics and her Levothyroxine dose was brought down to 50 micrograms/day. Patient gradually improved and was discharged with 50 mcg of Levothyroxine. On follow up her dose was gradually increased by 12.5 mcg and patient is doing well on tab. Levothyroxine 75 micrograms per day.

Case 7

A 29 yr old female patient with no known previous co morbidities came with complaints of generalized swelling of body, decreased urine output and orthopnea for 1 week. Patient was apparently normal 3 months back when she started having hair fall, mild facial puffiness, dyspnea on exertion and dryness of skin but was able to attend to her household work. She had consulted elsewhere, her TSH levels were 5.3 micro IU/ml and the patient was started on tablet Levothyroxine 100 mcg following which her breathlessness exaggerated.

On examination, the patient was dyspnoeic, tachypnoeic, had anasarca and oral ulcers with lung crepitations. A clinical diagnosis of a volume overload status due to Levothyroxine induced heart failure with underlying connective tissue disease was arrived at and Levothyroxine was stopped. Initial investigations showed mild neutrophilic leukocytosis, elevated ESR with severe nephrotic range proteinuria as Table 3. Her Antinuclear Antibody (ANA) pattern was 3+ with hypocomplementemia. An echocardiogram showed grade 1 diastolic dysfunction. Patient was started on diuretics, noninvasive ventilation, intravenous Methylprednisolone 250 mg injection (3 doses) and albumin infusion. Patient subsequently improved; a week later patient developed sudden breathlessness, a CT pulmonary angiogram showed a left sub segmental pulmonary thromboembolism and antiphospholipid antibodies were also positive. Patient was administered anticoagulation and improved well. Patient was discharged a week later with oral prednisolone 40 mg once daily, oral anticoagulants and Hydroxychloroquine (HCQ). A year later patient is doing well on follow up with normalized disease markers and is on oral Prednisolone 5 mg once daily and Mycophenolate mofetil 500 mg twice daily.

Case 8

45 yr old female patient was admitted with history of fever and cough for 1 week. She was a known case of endometrial carcinoma on chemotherapy. She had undergone her 5th cycle with Paclitaxel a week ago. Patient also had underlying diabetes mellitus and chronic kidney disease, which were conservatively managed.

On examination, the patient was pale, tachypnoeic and febrile with bilateral lung crepitations. Investigations showed severe metabolic acidosis, profound pancytopenia, high procalcitonin and deranged renal functions as summarized in Table 4. Chest x-ray showed left lower lobe pneumonia. A diagnosis of febrile neutropenic sepsis was made and patient was put on aseptic precautions and barrier nursing. She required aggressive management with Granulocyte Colony Stimulating Factor, antibiotics, antifungals, antivirals, antipyretics, bicarbonate infusion and other supportive measures. Patient gradually improved and was discharged with oral antibiotics and had normalized blood counts on follow up.

Case 9

50 yr old male presented with progressive difficulty in walking over the last 8 months. He was diagnosed with retroviral disease 8 years ago and was on Tenofovir, Lamivudine and Ritonavir boosted Atazanavir for the last 4 years.

On examination, the patient was emaciated and decreased range of movements in the lower limbs due to pain. Initial investigations showed hypokalemia, hypophosphatemia with significant metabolic acidosis. Urine showed albuminuria (3+) and glycosuria (3+). His liver functions also showed deranged alkaline phosphatase levels and vitamin D levels were normal (Table 5). Subsequently an X-Ray and Computed tomography of the hips showed bilateral fracture neck of femur. Hence a diagnosis of Tenofovir induced proximal renal tubular acidosis and bone toxicity was arrived at and tenofovir was promptly withheld. Patient was managed with intravenous fluids, potassium and bicarbonate supplementation with thiazide diuretics. Bilateral open reduction with internal fixation was planned, however patient opted conservative management. His HIV viral load and CD4 counts were in the improving trend compared to previous year values. After hypersensitivity testing, patient was started on Abacavir / Lamivudine and Doultegravir regimen and was discharged with oral potassium and bicarbonate supplements. Patient reported to follow up with normal electrolytes and is attending to activities of daily living.

DISCUSSION

Drug related adverse effects are thus not an uncommon entity. Rather it is grossly underreported. This case series has observed drug reactions in 9 patients who were admitted in PSG Institute of Medical sciences and

Table 3: Showing the thyroid pattern at admission, nephrotic range proteinuria and hypocomplementemia in case 7.

Lab parameter	At admission	1 month after discharge	A year later	Reference range
T3 (Serum)	0.37	1.06		0.846 - 2.02 ng/mL
FT4 (Serum)	0.98	1.12		0.932 - 1.71 ng/dL
TSH (Serum)	0.484	1.68		0.27 - 4.2 microIU/ml
FT3 (Serum)	0.64	2.92		2-4.4 Pg/ml
Urine Protein Creatinine Ratio	27.33	10.108	0.070	
Serum Creatinine	0.83			0.66 - 1.09 mg/dL
Serum albumin	0.7 g/dl	1.5	3.4	3.4 - 4.8 g/dL
Complement 3c level	28.42mg/dl	79	102	90 - 180 mg/dl
Complement 4 level	10mg/dl	14	16	10 - 40 mg/dl

Table 4: Showing the pancytopenia and subsequent improvement with treatment in case 8.

Lab parameter	Day of admission	After 1st dose G-CSF	After 3rd dose G-CSF	Day of discharge	10 days after discharge	Reference Range
Creatinine mg/dl	3.6	3.4		2.83	2.6	0.66-1.09 mg/dl
Hemoglobin g/dL	6.7	6.4	5.5	7.6	9.0	13 - 17g/dL
Total WBC 10^3/microL	0.2	0.5	5.1	10.1	5.7	4-10x10^3/uL
Absolute Neutrophil Count 10^3/uL	0.0	0.2	4.7	9.2	4.5	2 - 7x10^3/uL
Plateletsx10^3/uL	64	63	61	82	324	150-400x10^3/uL

Table 5: Showing the hypokalemia and metabolic acidosis pattern in case 9.

Lab parameter	Day 1 of admission	Day 3	Day 5	Month after discharge	Reference range
Serum Creatinine	1.75	1.26	1.6	1.43	0.8 - 1.25 mg/dl
pH	7.230	7.342	7.334	7.33	7.35-7.45
Serum Potassium	2.45	4.6	3.0	3.66	3.5 - 5.0mEq/L
Serum bicarbonate	12.5	15.9	17	21.6	22 - 30mEq/L
Serum ionised Calcium	1.202			1.2	1.1-1.3m mol/L
Serum Phosphous		2.1			2.7-4.5 mg/dl
Serum Alkaline phosphatase	459				40 – 129 U/L

Research, a tertiary care hospital in Coimbatore, Tamil Nadu. They were either referred from their primary care physician and/or admitted in our emergency department with severe drug related adverse events. The discussed 9 patients were on different class of drugs for their respective diagnosis prescribed elsewhere and presented to us with a variety of adverse effects requiring hospitalization or developing grave complications. Fortunately 8 of them recovered with prompt diagnosis and withdrawal of the offending drug.

Azathioprine is an imidazolyl derivative of mercaptopurine which acts by blocking the pathway for purine synthesis. The 6-thioguanine nucleotide metabolites appear to mediate the majority of azathioprine's immunosuppressive and toxic effects. Azathioprine, though a well-established immunosuppressive drug for myasthenia showing improvement in 70-90% patients has its share of serious complications.

Of grave concern is haematological toxicity. Dose-related immediate or delayed severe hematologic toxicities in the form of leucopenia, thrombocytopenia or pancytopenia may occur. Panda BK *et al.* have reported a case of severe pancytopenia in a patient of myasthenia gravis following azathioprine.[5] Other side effect profile includes gastrointestinal disturbances, hepatotoxicity and carcinogenic potential. Therefore it is important to periodically monitor blood counts and educate the patient about the need for the same.

In our case 1, the patient was not aware of the potential complication of his drugs, thereby delayed presenting to the hospital until he had profound leucopenia. With a proper patient education, early diagnosis can be arrived at and prompt action can avoid grave consequences. Case 2 patient was co-prescribed with azathioprine and methotrexate - both contributing to her profound pancytopenia. Patient had a tumultuous hospital course warranting intensive care admission, developed grave fungal and bacterial infections and succumbed to the same. Therefore it is crucial to carefully evaluate and closely follow up patients while co prescribing 2 potential hematotoxic drugs.

Thiopurine methyltransferase (TPMT) genotyping or phenotyping and nudix hydrolase 15 (nucleotide diphosphate [NUDT15]) genotyping may help to identify patients who are at an increased risk for developing azathioprine related hematological toxicity.[6] Once identified, patients may require dose reduction, interruption or selection of an alternate agent altogether.

Methotrexate being a folate antimetabolite inhibits dihydrofolate reductase, thereby hampering purine and thymidylic acid synthesis. DNA synthesis, repair and cellular replication are thus hindered as methotrexate targets actively proliferative tissues more and is therefore used in a number of conditions like rheumatoid arthritis, psoriasis as well as certain malignancies.

Thrombocytopenia (3% to 10%), leukopenia (1% to 3%), pancytopenia (1% to 3%), agranulocytosis, anemia, aplastic anemia, bone marrow suppression are noted hematological adverse effects of methotrexate. That is why it is pertinent to closely monitor the complete blood counts prior to initiation, weekly in the first month of initiation, every 2 to 4 weeks in the first few months and monthly thereafter. In a study of 46 patients on methotrexate in Lucknow, India, it was noted that initial WBC count was a predictor for development of pancytopenia later.[7] Patients with renal insufficiency or older age will require frequent monitoring. Case 3 (a female patient) and case 4 (older age group) had been taking only low dose methotrexate in weekly schedule for years, yet presented with pancytopenia revealing the fact that even low dose methotrexate can cause pancytopenia as a delayed presentation and periodic monitoring is indispensable. These findings are similar to a case series report on methotrexate where pancytopenia was encountered as a later manifestation[8] and another case report which observed low dose methotrexate causing

pancytopenia.[9] Once hematotoxicity is encountered, the drug is withheld, serum methotrexate levels are monitored and leucovorin rescue dosing is done to combat methotrexate effects. Granulocyte Colony stimulating factors will also be required where the patient has persistent pancytopenia. Hepatotoxicity and lung toxicity also require close attention and a baseline work up for the above is mandatory before starting methotrexate.

Leflunomide is an immunomodulatory agent that inhibits pyrimidine synthesis, resulting in its antiproliferative and anti-inflammatory effects. It acts by inhibiting dihydroorotate dehydrogenase and is converted to the active metabolite A771726 on administration.[10] Usually used in rheumatoid arthritis and systemic lupus erythematous. In November 2003, FDA issued a drug safety alert update on leflunomide, warning of rare post marketing reports of bone marrow suppression and sepsis. Though rare (incidence of 1 in 3698 patients) the incidence of pancytopenia is potentiated by concomitant administration of other myelotoxic agents as in case 5 where the patient was on both methotrexate and leflunomide. And myelosuppression can persist even after discontinuing the drug owing to its long half-life. A number of case reports reinforce the fact that hematological toxicities of methotrexate and leflunomide combination therapy are deleteriously additive.[11]

Levothyroxine (T_4) is a synthetic form of thyroxin, which is an endocrine hormone secreted by the thyroid gland. T_4 is converted to its active metabolite, L-triiodothyronine (T_3). Thyroid hormones (T_4 and T_3) then bind to thyroid receptor proteins in the cell nucleus and exhibit their metabolic actions through control of DNA transcription and protein synthesis.

While a decision to start a patient on levothyroxine is arrived at, certain characteristics should be carefully checked. These include patient's weight, lean body mass, etiology of hypothyroidism, pregnancy, age and cardiac disease. Thyroid hormone can be started at anticipated full replacement doses in individuals, who are young and otherwise healthy in most situations, a starting levothyroxine dose of 50-75 μg/day (1.6 μg/kg/day) will suffice. In patients with coronary heart disease, initial dose should be 12.5 to 50 μg/day.[12] Aggressive replacement of thyroid hormone in initial higher doses may worsen cardiac function in patients with existing cardiac disease. That is why it is imperative to start these patients on smaller doses and then titrate in small increments after no less than 4-6 weeks. Achieving a target TSH level at times may take several months owing to delayed preadaptation of the hypothalamic-pituitary axis. Therefore in patients receiving treatment with Levothyroxine, dosing changes should be made every 6-8 weeks only in usual scenarios.

In our case 6, 59 yr old woman was forth right put on high dose levothyroxine 100 micrograms for a TSH value of 6 microIU/ml exacerbating her heart failure. In case 7, though the patient had an underlying connective tissue disease, she was able to attend to her activities of daily living. However challenging her with levothyroxine 100 micrograms for a TSH value of 5.13 microIU/ml clearly exaggerated her symptoms precipitating her cardiac failure resulting in emergency presentation and subsequent prolonged hospitalization, which could have been avoided.

Treatment with levothyroxine in patients with heart failure is associated with a higher risk for all-cause mortality, cardiovascular death and major adverse cardiac events according to findings published in The Journal of Clinical Endocrinology and Metabolism.[13] These events are attributed to the low T3 syndrome. When hypothyroidism is treated with levothyroxine, there is often a relatively high thyroxin/T3 ratio in serum with relatively low liothyronine levels in blood, which could further exacerbate the T3-deficient state in patients with chronic heart failure

Paclitaxel is a natural taxane promotes microtubule assembly by enhancing the action of tubulin dimers, stabilizing existing microtubules and inhibits their disassembly. These actions ultimately halt cell replication thereby modulating the desired immune response. Paclitaxel finds usage in a variety of conditions notably breast, ovarian malignancies, lung cancer and Kaposi sarcoma. Our index patient case 8 was on paclitaxel for endometrial carcinoma. The hematological adverse effects include neutropenia (78% to 98%), leukopenia (grade 4: 17%), anemia (47% to 90%), thrombocytopenia (4% to 20%). It is therefore crucial to regularly monitor the complete and differential blood counts of the patient while on chemotherapy.

Chemotherapeutic agents do exaggerate the immune compromised state of cancer affected patients. Usually the magnitude of the neutrophil mediated component of the inflammatory response may be muted in neutropenic patients with fever sometimes being the only sign of infection. It is critical to recognize neutropenic fever early and to initiate empiric therapy promptly in order to avoid progression to a sepsis syndrome and possibly death. Neutropenic patients have the risk of developing a neutropenic fever syndrome, risk of resultant medical complications as well as risk of non-response to empiric antibiotic treatment.[14]

Certain risk factors are predictive of the development of a neutropenic fever syndrome. Patient-related predictors include age> 65 yrs, female sex, high body surface area and poor nutritional status. Disease-related predictors include elevated lactate dehydrogenase, advanced malignancy staging and myelophthisis. Treatment-related predictors of neutropenic fever include administration of high dose chemotherapy regimens and failure to administer hematopoietic growth factor support to patients receiving high-risk regimens. High risk patients are those who have other co morbidities, significant hepatic or renal impairment or those who are expected to be severely neutropenic (absolute neutrophil count [ANC] <500 cells/microL) for >7 days. The index patient case 8 was a female patient with diabetes mellitus and chronic kidney disease enhancing her risk of pancytopenia.

A number of validated tools are used to calculate the risk index for measuring the risk for neutropenic fever–related medical complications and must be put to effective use wherever possible in tertiary centres.[15] In a research article that investigated the capability of genetic variation in drug metabolizing enzymes and transporters (DMET platform) to predict haematological toxicity, the single nucleotide polymorphism SNP rs 9285726 in MAT1A (methionine adenosyl transferees) and SNP rs 776173 in CYP39A1 were found to be associated with neutropenia. These are potential areas of research in predicting paclitaxel induced hematologoxical toxicity and in picking up individual patients who are at more risk.[16]

Tenofovir disoproxil fumarate (TDF) is a nucleotide reverse transcriptase inhibitor. It interferes with the HIV viral RNA dependent DNA polymerase resulting in inhibition of viral replication exhibiting its action via active tenofovir diphosphate. Nephrotoxicity is a known and established side effect of tenofovir. One study reported that the incidence rate of moderate or severe renal insufficiency caused by tenofovir was 29.2 and 2.2 cases per 1000 person-year respectively. Apart from this tenofovir can also cause interstitial nephritis, lactic acidosis, nephrogenic diabetes insipidus and rhabdomyolysis and decreased bone mineral density.[17]

Tenofovir can rarely cause Fanconi syndrome.[18] It is a proximal tubulopathy causing impaired reabsorption of glucose, aminoacids, bicarbonate and phosphate resulting in their excretion. The presentation of fanconi syndrome can be quite delayed also in a patient on tenofovir.[19] Therefore drug related adverse effect should be considered in any patient presenting with renal tubular acidosis type 2 while on tenofovir regardless of the duration of drug exposure.

Our case 9 patient also developed toxicities 4 years after tenofovir exposure and developed Fanconi's syndrome as well as bone toxicity which is quite rare.[20] The index patient however improved remarkably after stopping Tenofovir and with calcium and phosphate supplementation. This finding is similar to a study from Christian Medical College, South India where the incidence of tenofovir induced renal tubular toxicity has been observed as quite rare (3.6%) and the average latency period between tenofovir exposure and nephrotoxicity was prolonged (42 months).[21] The study suggests that patients on tenofovir should be monitored serially and periodically for proteinuria, creatinine clearance rather than creatinine values, hypophosphatemia and alkaline phosphate levels. Tenofovir alafenamide is the pro-drug of TDF which achieves higher intracellular concentrations rather than plasma concentrations at low dose, thereby resulting in lower toxicities and similar efficacy.

CONCLUSION

Thus it is important to choose and prescribe drugs and their dosage carefully. It is fundamental for the treating doctor to be aware of drug combination/interactions leading to profound side effects. Patient education and awareness of drug related side effects is core in management and helps in averting serious side effects earlier and thereby avoiding unnecessary/prolonged hospitalization and related complications. As a physician it is pertinent to constantly update and learn from errors whether of one's self or others. After all learning and unlearning is part of the continuing medical education process.

Tenofovir induced delayed nephro-osteo toxicity – a case report

Bhargavi Kumar[1], Rajgokul Prabhakar[2], Saravanan Thangavelu[3]

Abstract

Tenofovir disoproxil fumarate (TDF) is the foundation nucleotide reverse-transcriptase inhibitor and the recommended first-line regimen for all naive Human Immunodeficiency Virus-1 (HIV-1) patients whose age is more than 10 years and body weight is more than 30 kg. Although it has a good safety profile overall, nephrotoxicity is a concern and its overall incidence is 1–6% with a long period of clinical latency. Nephrotoxicity may manifest as either proximal renal tubule dysfunction in the form of a partial or complete Fanconi syndrome or as decreased renal function leading to acute or chronic kidney injury. Osteomalacia can also develop secondary to complicating hypophosphataemia and low calcitriol levels. Here we report a 50-year-old HIV-positive male on tenofovir who presented with proximal renal tubular acidosis and fracture of left neck of femur four years after initiation of the drug.

Introduction

Tenofovir disoproxil fumarate (TDF) is an oral acyclic nucleotide analogue reverse transcriptase inhibitor used in the treatment of HIV-1 infection approved by the Food and Drug Administration (FDA) in 2001.[1] Tenofovir has found a major role in the fixed-dose combination along with lamivudine and efavirenz or doultegravir.[2] It has an added advantage in HIV-hepatitis B co-infection. It has an overall good safety profile, a relatively long half-life and allows once-daily dosing ensuring good patient compliance with relatively rare side effects.

Tenofoviris is actively transported into the mitochondria of proximal tubule cells of the kidney and thereby can lead to proximal tubular dysfunction in long-term use.[1] Proximal renal tubular acidosis is characterised by defective proximal tubular reabsorption associated with phosphaturia, glycosuria, aminoaciduria, bicarbonaturia, resulting in hypophosphataemia, hypokalaemia and metabolic acidosis. Overt Fanconi syndrome is rare, but can occur as a delayed presentation, with incidence being 1.09 per 1000 patient years.[3]

Osteotoxicity can occur either due to direct effect of the drug itself or secondary to hypophosphataemia as a result of renal toxicity.[4] Hence routine and careful monitoring for these toxicities is absolutely essential as they may occur even after a long asymptomatic period.

Case presentation

A 50-year-old male presented with poor appetite, significant weight loss of 6 kg in 2 months and progressively painful difficulty in walking over 8 months. He was diagnosed with HIV-1 8 years ago and was on regular treatment with tenofovir, lamivudine, atazanavir and ritonavir for 4 years elsewhere. CD4 count done 3 months previously was 118 cells/mm3. He took diclofenac 50 mg intermittently over the previous 2 months.

On examination, he was thin, pale and had a limited range of movements in both lower limbs and left shoulder due to pain. His body mass index (BMI) was 16.5k g/m2.

Preliminary investigations showed macrocytic normochromic anaemia, elevated creatinine levels, hypokalaemia, hypophosphataemia, low bicarbonate levels and elevated serum alkaline phosphatase (ALP) levels. Arterial blood gas analysis revealed metabolic acidosis. Urine examination showed mild albuminuria and glycosuria (serum glucose was normal) with no pus cells. Results are shown in Table 1. Ultrasonography of the abdomen and pelvis revealed chronic renal parenchymal changes and renal artery Doppler study was normal.

X-ray pelvis showed an undisplaced fracture in the left neck of femur and an old displaced fracture in right neck of femur

Table 1

Lab parameters	DAY 1	DAY 2	DAY 3	DAY 5	2 WEEKS AFTER DISCHARGE	1 MONTH AFTER DISCHARGE	Reference range
pH	7.23	7.259	7.266		7.34		7.35-7.45
Acid base excess mmol/L	-14.4	-12.2	-11.6	-8.8			-2 - +3
Serum Sodium (mEQ/l)	139		144	143	138	143	136-146
Serum Potassium (mEQ/l)	2.45	3.22	3.24	4.60	5.5	3.66	3.5-5.0
Serum Bicarbonate (mEQ/l)	12.5	14.7	14.2	15.9	15.7	21.6	22-30
Serum Chloride (mEQ/l)	107		105			105	102-109
Serum phosphorous (mg/dl)		1.3		2.1	4.7		2.7-4.5
Serum Creatinine (mg/dl)	1.75			1.24		1.26	0.8-1.25
Creatinine clearance (mL/min)	39.29			55		54.56	97-137
Serum ALP(U/l)	459						40-129
Serum Vitamin D (ng/ml)	31.08						Deficient <20 Insufficient 21-29 Normal 30-70
Urine pH	6.8			>9.0			4.6-8.0
Urine glucose		4+			3+	1+	negative
Urine albumin		3+				1+	negative

confirmed on computed tomographic scanning. Serum vitamin D levels were normal. HIV viral load was undetermined and CD4 counts were 327.

Tenofovir-induced proximal renal tubular acidosis and pathological fracture was suspected and tenofovir withheld. He was treated with intravenous fluids, appropriate bicarbonate correction, thiazide diuretics and potassium citrate and his acidosis gradually improved. He was discharged on a high-potassium diet with oral potassium citrate, calcium and oral sodium bicarbonate supplements. At follow-up two weeks later he had an improving appetite and decreased pain in his legs. His electrolytes were normal with decreasing trend of creatinine levels. He was started on abacavir after hypersensitivity testing with HLAB5701 along with lamivudine and doultegravir. His bicarbonate, creatinine clearance and urine albuminuria and glycosuria improved significantly and he was able to attend to his activities of daily living.

Discussion

According to the India HIV Estimation 2017 report, national adult (15–49 years) HIV prevalence in India is estimated at 0.22% (0.16%–0.30%).[2] India has the third largest HIV epidemic in the world, with 2.14 million people living with HIV as per the UNAIDS 2018 data. 56% of adults are on anti-retroviral treatment.

Kidney disease in HIV-affected individuals may be attributed to a variety of causes which include: HIV-associated nephropathy (HIVAN) presenting with focal segmental glomerulosclerosis, HIV-associated immune complex kidney disease (HIVICK), acute kidney injury or chronic kidney disease.[5] The common antiretroviral therapy (ART) causes include tenofovir (tubular toxicity), protease inhibitor indinavir (nephrolithiasis, crystal nephropathy and interstitial nephritis) and enfuviritide (glomerulopathy).[6]

Tenofovir-induced nephrotoxicity is quite rare with most studies estimating it between 1–6%.[7] Tenofovir-induced nephrotoxicity could present as proximal tubular dysfunction

with preserved renal function (14%) or proximal tubular dysfunction associated with decreased renal function – which can either be acute kidney injury (1.6 %) or chronic kidney disease (8%).[1] Our patient also presented with proteinuria, glycosuria along with elevated creatinine levels and chronic renal parenchymal changes on ultrasonography.

About 20–30% of TDF is actively transported into the renal proximal tubule cells by organic anion transporters (OAT 1 and 3) located in the basolateral membrane and then subsequently secreted to the tubular lumen by the apical membrane transporters MRP4 and MRP-2 (Multidrug Resistance Proteins).[8] Any factor which causes overexpression of OAT1 and 3 or inhibits MRP-4 will cause tenofovir to accumulate within the cells, which in turn causes mitochondrial toxicity. Rarely, distal renal tubular acidosis has also been encountered (<5%), although the exact mechanism is not known.[9]

Risk factors include old age, low BMI, prior history of renal disease, reduced baseline glomerular filtration rate (eGFR), diabetes mellitus, hypertension, hepatitis C co-infection and genetic polymorphisms (APOL1G1 gene).[8] The index patient's BMI at the time of presentation was quite low. However, his BMI at the time of initiation with tenofovir was not known. Factors which inhibit MRP-4 include anti-inflammatory drugs like diclofenac, ibuprofen as well as protease inhibitors. The index patient was on concomitant ritonavir and diclofenac, both of which might have added on to the toxicity.

Nephrotoxicity can occur after years of tenofovir therapy as a delayed presentation with the median duration of presentation ranging between 16 months to 5 years.[10] Casado et al. observed a 32% prevalence of proximal tubulopathy after a median time of 5 years on tenofovir.[11] Our patient presented with nephrotoxicty 4 years after ART initiation with tenofovir. He had asthenia, loss of appetite, significant weight loss, muscle pain, easy fatigability and poor quality of life despite improvement in CD4 count, which prompted us to probe drug-related toxicities.

Osteotoxicity in HIV may be multifactorial. HIV can cause direct bone damage due to its effects on bone remodelling. Tenofovir can cause osteotoxicity through secondary effects of proximal renal tubular acidosis and its resultant hypophosphataemia. Because renal metabolism of vitamin D to its active form dihydroxyl cholecalciferol also occurs in proximal tubular cells, serum vitamin D levels can also be low in these patients. In addition, tenofovir can influence phosphate metabolism through circulating factors like phosphatonins.[4] In our patient vitamin D levels were normal but hypophosphataemia and elevated alkaline phosphate levels were noted and were probable contributors to bone toxicity and resultant pathological fracture.

This combined presentation of renal and bone toxicity with tenofovir therapy is quite rare, with few case reports available.[12,13] Lucey et al. reported a teenage boy with HIV infection on tenofovir presenting four years later with Fanconi syndrome and stress fracture of bilateral metatarsals.[13]

The early stages of proximal tubulopathy can be diagnosed by urine analysis of beta 2 microglobulin. In a study from Christian Medical College, South India, alkaline phosphatase (ALP) levels increased by nearly 200% after treatment with tenofovir. It was statistically significant thereby rendering it an important marker for monitoring of toxicity.[7] This is similar to the observation by Woodward et al. in which 89.5% of patients on tenofovir who developed hypophosphataemia had elevated ALP levels after a median time of seven years on ART.[12] It was also observed that creatinine clearance was a more valuable indicator compared to absolute creatinine values. National AIDS Control Organisation guidelines 2018 suggest measuring creatinine clearance and assessing risk factors for renal toxicity prior to starting tenofovir therapy. eGFR, urine protein/creatinine ratio, urine glucose and urine phosphates need to be monitored every three months for one year and then biannually.[2]

It is recommended to switch to alternative nucleoside reverse transcriptase inhibitors whenever tenofovir toxicity is encountered. However, even in those patients where tenofovir-related toxicities are encountered, it is still noted that the patients had a strong clinical and immunological response.

Ideally, if tenofovir entry to proximal tubule cells is prevented or exit is facilitated, renal toxicity may be averted. Drugs like probenecid which is an inhibitor of OAT1 and rosiglitazone, a peroxisome proliferator-activated receptor-gamma agonist that induces the expression of many proximal tubular cell transporters were studied in the past.[1] However, both had dose-limiting side effects.

Conclusion

Although antiretroviral therapy has given hope and life to HIV patients, it is important to be aware of the potential side effects and thereby monitor for the associated toxicities.

Early diagnosis of tubulopathy by urinary protein excretion, glycosuria assessment, creatinine clearance evaluation and alkaline phosphate assessment can be of central importance in identifying kidney and bone toxicities. Prompt recognition of toxicity and withdrawal of the drug can significantly improve or even reverse tubular damage in most patients, thereby avoiding chronic kidney damage.

Background: Gastroesophageal reflux disease (GERD) is commonly associated with impaired quality of life. Chronic symptoms in this highly prevalent disorder could potentially lead to psychological manifestations such as anxiety, depression, and sleep disorders. **Aim:** The purpose of the study was to evaluate the magnitude of association of GERD symptoms based on health-related quality of life (GERD-HRQL) with anxiety, depression, and sleep quality using Hospital Anxiety and Depression Scale (HADS) and Pittsburgh Sleep Quality Index (PSQI). **Methods:** This was a cross-sectional study done at a tertiary care hospital in 241 participants. Cases were patients diagnosed with GERD, and the control group was participants who did not have GERD, devoid of all gastrointestinal symptoms according to GERD-HRQL. Data on age, gender, body weight, smoking/alcohol intake, and medication history were obtained from 98 cases and 143 matched control subjects. The three questionnaires, namely, GERD-HRQL, HADS, and PSQI questionnaires were administered by a trained blinded interviewer. **Results:** There was a statistically significant difference ($P < 0.001$) in the mean score of cases in the HADS depression scale (7.35 ± 3.65); the HADS anxiety scale (9.33 ± 4.51) and the mean global PSQI sleep score (4.62 ± 1.96) compared to the controls. Using Pearson's correlation, heart burn ($P = 0.036$), and regurgitation scores ($P = 0.026$), including the global quality of life score ($P = 0.003$), correlated significantly with the anxiety score. We found a statistically significant correlation between heart burn and poor sleep ($P = 0.012$) but not for regurgitation ($P = 0.772$). **Conclusions:** This study highlights the increased risk of anxiety, depression, sleep disorder in GERD, and the significant correlation between HRQL, especially heartburn with anxiety and poor sleep quality. This enlightens that specific screening and treatment strategies targeting such psychological manifestations are imperative for overall improved quality of life in GERD patients.

Key words: Mood disorders, sleep quality, Hospital Anxiety and Depression Scale, Pittsburgh Sleep Quality Index, gastroesophageal reflux disease-health related quality of life

INTRODUCTION

Gastroesophageal reflux disease (GERD) is a chronic disorder characterized by reflux of the stomach contents, which can give rise to symptoms and complications. Typical GERD symptoms affect patients' quality of life and overall work productivity.[1] In addition, it also contributes to enormous health-care costs. It is a highly prevalent disorder, and a recent systematic review showed that the prevalence of GERD is 18.1%–27.8% in North America, 8.8%–25.9% in Europe, 2.5%–7.8% in East Asia, 8.7%–33.1% in the Middle East, 11.6% in Australia, and 23.0% in South America.[2] Although conventionally considered as a disease affecting middle age and the older population, recent studies have shown that there is a significant increase in the proportion of the disease in the younger age group.[3]

Patient's quality of life is increasingly being considered as a medical outcome index in the evaluation of the impact of GERD symptoms on patients' health status. The impact of

[Downloaded free from http://www.jmedscindmc.com on Friday, December 17, 2021, IP: 103.224.34.2]

GERD on quality of life can be evaluated by a detailed symptom analysis which typically includes heartburn, acid regurgitation and epigastric pain in the majority of the patients using GERD health-related quality of life (HRQL) questionnaire.[4]

Studies have shown that chronic conditions like GERD could secondarily result in psychological manifestations of anxiety, depression, and insomnia. Few studies have also demonstrated that anxiety and depression could decrease the threshold for perception of visceral stimuli, thereby exacerbating the risk of developing functional gastrointestinal (GI) disorders, thus elucidating a bidirectional cause and effect relationship.[5-7] The current research focuses on the interplay between the psychological manifestations of anxiety, depression, altered sleep, and the symptomatology of GERD with the objective to evaluate the magnitude of the correlation between the quality of life and the psychological status of patients.

Literature evidence reveals that there is a paucity of studies evaluating psychosocial impairment due to GERD symptoms in the Indian population. Hence, this study was aimed to evaluate the magnitude of association of GERD symptoms with anxiety, depression and sleep quality by assessing the correlation of the GERD-HRQL scores with that of anxiety, depression and sleep quality using the respective Hospital Anxiety and Depression scale (HADS) and Pittsburgh Sleep Quality Index (PSQI) scale in Indian patients with GERD. In addition, the study was also designed to analyze whether anxiety, depression, and sleep scores were affected by comorbidities in GERD patients.

METHODS

This was a hospital-based cross-sectional questionnaire study done at tertiary care teaching hospital after the approval by PSG Institute of Medical Sciences and Research-Institutional Human Ethics Committee (Approval no: 16/435 dated January 10, 2017). Patients attending Gastroenterology and Medicine outpatient department and diagnosed with GERD were included for the study after obtaining written informed consent. GERD was diagnosed based on the presence of the typical clinical presentation along with the endoscopic features of GERD. The control group were subjects who did not have GERD and were devoid of all GI symptoms, according to GERD-HRQL. GERD-HRQL questionnaire, a disease-specific tool, was used to measure the symptomatic outcomes and therapeutic effects in patients with GERD. The scale had 16 items that focused on heartburn symptoms, dysphagia, medication effects, and the patient's present health condition. Each item was scored from 0 to 5, with a higher score indicating a better quality of life. Two scores, namely heartburn score and regurgitation score, were obtained by the summation of the scores for questions 1–6 and 10–15 respectively in addition to the total score derived by summing all the 15 score values. The 16th question was a patient's satisfaction question based on a 3 point scale.

Velanovich *et al*. had examined the psychometric properties of the GERD-HRQL in GERD patients and reported that the Cronbach's α coefficient for each subscale ranged from 0.89 to 0.94 demonstrating a high test– retest reliability and internal consistency.[4]

The presence of anxiety and depression levels was assessed using the Anxiety and Depression Scale. The HADS, a widely used scale that had been designed for detecting depression and anxiety in out-patient clinic setting, was used to measure symptoms of anxiety and depression and consisted of 14 items, seven items for the anxiety subscale, and seven for the depression subscale. HADS Anxiety (HADS A) focused on the symptoms of generalized anxiety disorder, and HADS depression (HADS D) was focused on anhedonia, the main symptom of depression. Each item was scored on a response-scale with four alternatives ranging between 0 and 3. The overall score value 8 or higher was considered the cutoff value for the existence of anxiety and depression.[8]

The PSQI, an effective instrument was used for measuring the quality and patterns of sleep based on examination of seven domains: subjective sleep quality, sleep latency, sleep duration, habitual sleep efficiency, sleep disturbances, use of sleep medication, and daytime dysfunction over the past month. Scoring of responses ranged from 0 to 3, and all the seven components were summed together with scores of 5 or greater indicating poor sleep quality.[9]

The subjects included in this study were >20 years of age, either newly diagnosed or on proton-pump inhibitor (PPI) therapy. Patients who had concomitant diabetes, hypertension, liver, pancreatic, or chronic renal disease were also included in the study. The participants included were either non-smokers or those who were current or ex-smokers with a smoking index <100 and also non-alcoholic. However, patients who had serious comorbidities such as liver failure, renal failure, morbid obesity, patients with heart disease on antiplatelet therapy, osteoporosis patients and those on long-term nonsteroidal anti-inflammatory drugs (NSAIDs) or other chronic medications which cause gastric reflux and those with documented history of psychiatric illnesses including anxiety disorders, depression or bipolar illness and sleep disorders were excluded. Subjects aged <20 years, pregnant and lactating women were also excluded from the study.

A total of 98 cases by consecutive sampling were recruited from January 2018 to May 2018. Data on age, gender, body weight, alcohol intake, smoking, NSAID intake, concomitant GI medications other than PPI, including their daily dose were obtained. Similarly, data were also obtained from 143

[Downloaded free from http://www.jmedscindmc.com on Friday, December 17, 2021, IP: 103.224.34.2]

control subjects who were matched so that they represented the same proportion of subjects with age, sex, and smoking status as in the case group. The three questionnaires, namely, GERD-HRQL, HADS, PSQI questionnaires, were administered by a trained interviewer blinded to the group to which the participant belongs.

Statistical analysis

All data were entered in excel, and the statistical analyses were performed using SPSS version 24 (IBM Corporation, United states). The mean HADS and PSQI scores of patients and controls were compared using an independent sample *t*-test to detect statistical significance. Similarly, Student's *t*-test was also used to analyze if the mean difference in the scores of the patients with and without comorbidities were significant. In addition, the correlation of the GERD-HRQL scores with anxiety, depression, and sleep quality scores in patients with GERD was performed using Pearson's correlation.

RESULTS

We recruited a total of 241 participants after obtaining written informed consent, among which 98 subjects were GERD patients and recruited to the case group, while the remaining 143 participants were the non-GERD control population. A total of 84 cases were on proton-pump inhibitor therapy, accounting for a percentage of 85.71%. The mean age of the cases was 46 years, whereas the mean age in the control group was 50 years. Among the cases, 55.10% were <50 years of age and 44.90% were in the age group of 50 years and above. Also, 67.35% cases were males and the rest were females with male: female ratio approximating 2:1. The analysis revealed that there was no difference in the mean scores between the cases in the age group <50 years and those who were aged 50 years and above. Among the cases, an independent sample *t*-test demonstrated that the mean score for anxiety was significantly higher in the female population compared to the males among the cases, but no such significant difference was evident for the depression or the sleep score [Table 1].

The mean score of the cases in the HADS D scale (7.35 ± 3.65) was significantly higher ($P < 0.001$) compared to the mean score of the control population (4.60 ± 3.34) using independent sample *t*-test. Likewise, the mean anxiety score of the cases (9.33 ± 4.51) was greater in comparison to the mean score of the controls (6.35 ± 3.74) using HADS A, and this difference was also statistically significant ($P < 0.001$). A similar significance in the PSQI sleep score between cases and controls was also obtained using Student's *t*-test [Table 2 and Figure 1]. A Chi-square test revealed that the proportion of cases found to have depression (50%); anxiety (66.32%), and sleep disorder (45.91%) were significantly higher compared to the control population [Table 3].

Analysis of the GERD-HRQL scores revealed that among the 98 cases in the study population, 35 patients (35.7%) had symptomatic heartburn, whereas 45 patients (45.9%) were symptomatic for regurgitation. On the satisfaction scale, 66.35% were satisfied with their present condition and 26.50% recorded a neutral response, while 7.15% were found to be dissatisfied with their current clinical status [Figure 2]. A comparative analysis of whether the mean scores vary

*P**	<0.001		<0.001		<0.001	

*Statistically significant

significantly among the patients with asymptomatic (scores of ≤12 with each individual question not exceeding 2 for questions 1–6 of the GERD-HRQL indicate heartburn elimination) and symptomatic heartburn with scores of >12, it was found that the though the mean depression and anxiety scores were higher in the symptomatic patients, there was no statistical significance between the mean difference in the scores detectable. However, patients with symptomatic heartburn had a statistically significant higher mean score for sleep disturbance ($P = 0.034$) compared to the asymptomatic group. However, when a similar analysis was performed for the regurgitation, there was no significant mean difference between those with scores >12 and those with lower scores in all the three scales [Table 4].

Comparison of the mean scores of the cases with and without comorbidities, there was no statistical significance in the mean scores obtained for those with and without diabetes, hypertensive and normotensive patients, those with other comorbidities such as liver disease, pancreatic, or chronic renal disease [Table 5].

Analyzing the correlation of heartburn, regurgitation and satisfaction components of the quality of life scores with the depression, anxiety and sleep quality scores, it was found that neither the heartburn nor the regurgitation score correlated

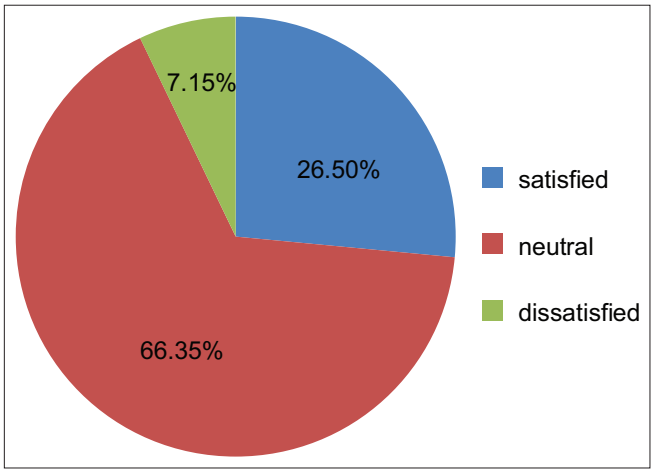

Figure 2: Chart representing satisfaction score in Gastroesophageal Reflux Disease-Health Related Quality of life Scale

with depression score whilst there was a correlation of the patient satisfaction with the depression score. However, both the heartburn and the regurgitation scores correlated with the anxiety score, including the global quality of life score. Interestingly, we found that there was a statistically significant correlation between heartburn and poor sleep, which was not detectable for regurgitation. In addition, it was found that the patients unsatisfied with their present clinical status were more likely to have depression and poor sleep quality rather than anxiety [Table 6 and Figure 3].

DISCUSSION

A statistically higher mean score for all the three clinical conditions, namely depression, anxiety, and sleep disturbance was demonstrable in the GERD cases compared to the control group indicating a high risk of these psychological manifestations in patients with reflux disease. Conceivably, impairment in quality of life was also elicited in the cases compared to the control population using GERD-HRQL.

Our study is one of the few studies evaluating the interplay between the HRQL changes in GERD with the various psychological manifestations such as anxiety, depression, and sleep manifestations in a South Indian population. Considering the cut off value of 8 for the diagnosis of anxiety and depression using the respective components of the HADS questionnaire, the study has effectively demonstrated that a high probability of anxiety disorder existed in the GERD population with a mean anxiety score of 9.33 ± 3.51 unlike with respect to depression wherein the mean score was marginally below the cut off value. A similar result was also obtained in another study done in 225 patients by Kessing *et al.*[10] However, our result was in contrast to a previous study

in which depression was found to be one of the most prevalent comorbidities in patients with GERD.[11] Our research revealed that a high proportion of cases (71.42%) had comorbidities amongst which concomitance of liver diseases recorded the highest. However, none of the comorbidities were significantly associated with the HADS or the sleep scores.

Although the literature evidence strongly supports the association of sleep disorder manifestations with GERD[7,12] the mean global PSQI score of cases in our study did not achieve the significant cut-off level of 5 indicative of poor quality sleep despite the mean score being significantly higher than the control population. This could be potentially because a large majority of patients (85.71%) were on treatment with PPI. A systematic review has delineated that a statistically significant improvement in sleep quality occurred after initiation of PPI therapy in GERD patients though it may not be completely successful in normalizing the sleep quality to achieve a global PSQI score that is not statistically different from the control population.[13] The large proportion of cases on PPI therapy precluded a between-group analysis of the depression, anxiety, and sleep scores with the patients not on PPI in our research. Symptomatic relief with PPI therapy can consequentially alleviate the psychological manifestations in GERD though evidences support that persistent symptoms despite PPI treatment is quite common which can impede the improvement in severity of the psychological parameters.

Studies have supported that chronic and mild inflammation in the GI tract due to GERD could result in up-regulation of the central nervous system (CNS) cytokine production which in turn can affect the CNS functions, ultimately resulting in psychiatric manifestations such as depressive and anxiety disorders.[14-16] Studies in animal models have also demonstrated that chronic peripheral inflammation induces central pro-inflammatory markers like interleukin IL-1β as well as tumor necrosis factor alpha-α;[17] the long term elevation of which significantly correlate with the occurrence of psychological manifestations supporting the hypothesis.[18]

In addition, the symptom complex of GERD enables envisioning the intertwined and bidirectional nature of the relationship between sleep disorders and GERD. GERD results in heartburn, acid reflux, sinusitis or sinus problems, and frequent dry cough necessitating throat-clearing that awakens the patient during sleep. Frequent arousal during sleep activates neuroendocrine systems, including the vagal nerve and triggers bronchoconstriction. Frequent bronchoconstriction narrows the diameter of the respiratory tract and arouses patients from sleep, intensifying sleep disorders.[19-21] Furthermore, GERD-related micro-aspirations inducing bronchial exudative mucosal reaction also adds to the narrowing in diameter of the respiratory tract, accelerating sleep disorder.[22] The flip side of the coin is that for several reasons, GERD symptoms aggravate during sleep. Anti-reflux mechanisms such as swallowing rate, upper and lower esophageal sphincter pressure, gastric emptying, and the awareness of heartburn have all been found to be depressed during sleep. Also, while recumbent, the force of gravity encourages the flow of gastric content towards the esophagus. Thus, current literature supports the fact that sleep disorder has a dual cause and effect relationship with GERD.[13,23]

A differential effect of the two predominant symptoms, namely heartburn and regurgitation analyzed using GERD-HRQL, illustrated that heartburn patients had a significantly lower mean PSQI score and a positive correlation with anxiety and poor sleep quality whilst regurgitation only correlated with anxiety score. A similar result has been documented by Lee *et al*. whose study disclosed that patients with heartburn had more severely impaired daily activity, including sleep interruption compared to those with a predominant regurgitation.[24] Likewise, increased anxiety level has been found to be associated with greater heartburn but not regurgitation.[10] This discrepancy perhaps stems from the

[Downloaded free from http://www.jmedscindmc.com on Friday, December 17, 2021, IP: 103.224.34.2]

differences in physico-pathological mechanism underlying the key clinical presentations of GERD. Reflux episodes inducing regurgitation has been shown to have a higher proximal extent of the liquid component, but less esophageal pH drop, than episodes inducing heartburn.[25]

In the current study, a significant positive correlation between the GERD-HRQL and anxiety was demonstrable but not for depression and sleep derangements. A similar study using a different scale for evaluating depression, anxiety and HRQL was able to prove that there existed a significant correlation of the quality of life with both anxiety and depression.[26] The difference in results could be attributed to the fact that our study was done in a smaller subset of patients with GERD and that most patients were on treatment which also precluded a between-group analysis of untreated patients with those on treatment. Furthermore, the categorization of cases into the erosive and nonerosive disease was not done, and these were our study limitations.

However, the study has clearly brought out the need to understand the increased risk of psychological manifestations including depression, anxiety, and sleep disorders in GERD patients including those on treatment, which necessitates addressal by periodic assessments and redressal by specific planned psychiatric interventions, both pharmacological and behavioral, as a part of the comprehensive treatment plan.

CONCLUSIONS

The study highlights that GERD patients constitute a vulnerable population for psychological disturbances such as anxiety, depression, and sleep disorder, which may not be completely eliminated by the treatment of the underlying reflux disease. Hence, periodic evaluation and specific treatment strategies for such manifestations would be beneficial in improving the quality of life in these patients.

ABSTRACT

There were about 65 million diabetic population in 2016 in India. There were studies which concluded that the Dipeptidyl Peptidase-4 Inhibitors and Sodium Glucose Co-Transportor 2 Inhibitor were providing non-glycaemic control and cardiovascular benefits. Hence, it is important to find out the effect of those drugs on various parameters among the Indian Type 2 Diabetes Mellitus population. The aim is to evaluate and compare the effects of SGLT-2 inhibitors and DPP-4 inhibitors in Type 2 DM patients. The objective is to find out &compare the effects of both class of drugs on the physical profile [Body Weight (BW), Body Mass Index (BMI), Hip-Waist ratio), Diabetic Profile [Fasting Blood Sugar] (FBS), Glycated Haemoglobin (HbA1C)] & Side Effect Profile. The patients were categorized into two Group 1 & 2. Both groups were containing 50 patients, each based on the inclusion &exclusion criteria. The collection of demographics and history were done. Group 1 patients were initiated with DPP-4 Inhibitor, Group 2 patients with SGLT-2 Inhibitors, respectively. At baseline and during follow-up, the parameters like the physical profile, Diabetic Profile were noted. In Body Weight, the mean difference between the groups was found to be 2.9 $\pm$0.79 ($p<0.05$). Similarly, for BMI, it was 2.9$\pm$1.36 ($p<0.04$). For the Hip-Waist ratio, it was 0.07 ($p<0.05$). For FBS, it was 22.08 mg/dl (0.0001), for HbA1c it was 1.09 ($p<0.0043$). On the Side effect profile, SGLT-2 Inhibitors were showing higher incidence for the occurrence of Urinary Tract Infection (UTI) while comparing with DPP-4 Inhibitors. This can be overcome by proper patient counseling. This study concluded that SGLT-2 inhibitors may serves as the best medication choice for add on therapy in Type 2 DM patients.

INTRODUCTION

Diabetes mellitus is one of the most common chronic diseases which is present in almost all nations. It is the most common non-communicable disease (Shaw *et al.*, 2010). About 65 million diabetic population in 2016 in India, whereas it was 26 million in 1990. In India, the prevalence of Diabetes Mellitus among adults aged 20 years or older was increased from 5.5% to 7.7% between the years of 1990 to 2016, respectively. In 2016, the highest prevalence is seen in the states of Tamil Nadu

& Kerala, which were stated as High Epidemiological Transition Level (High ETL) & Delhi as Higher-Middle ETL, which is followed by Goa, Punjab & Karnataka (Tandon *et al.*, 2018). The micro and macro vascular complications will be reduced by obtaining fair glycaemia control (Alfeena Mary PS *et al.*, 2018). Early initiation of pharmacologic therapy is associated with improved glycaemic control and reduced long-term complications in type 2 DM. In the case of uncontrolled type 2 DM, the drug classes like SGLT-2 inhibitors and DPP-4 inhibitors are used as add on therapy, sometimes as monotherapy also.

DPP-4 inhibitors (Sitagliptin, Teneligliptin, Evo gliptin) produce its effect by activating incretin, which is released by the intestinal cells after food intake. It is usually given as a once-daily dose. DPP-4 is an enzyme that degrades various biologically active peptides, including the GLP-1 and GIP. GLP-1 is playing a major part in releasing insulin (Aschner *et al.*, 2010). Along with glucose control, these drugs were found to have cardiovascular benefits due to its pharmacological augmentation of GLP-1R (Dicker, 2011).

SGLT-2 inhibitors (Dapagliflozin, Canagliflozin, Empagliflozin, Remogliflozin, Ertugliflozin) are a newer class of OHAs (Oral Hypoglycaemic Agents) which are approved to be used as monotherapy or in combination with metformin, sulfonylurea, or insulin. Work by preventing the reabsorption of glucose in PCT and by facilitating its excretion in urine. Hence, the glycaemic control is achieved along with the glucose excretion. The mechanism of action of these drugs is dependent on blood glucose levels and independent of the actions of insulin. So, there are minimum incidences for the occurrence of hypoglycaemia, and there is no risk of overstimulation or fatigue of the beta cells. (Alfeena Mary PS *et al.*, 2018).

Since both classes of drugs are being used either as monotherapy or as part of dual and triple therapy in type 2 diabetes patients, it is important to compare the effects of those drugs in the Indian type 2 diabetes population. This study involves the comparison of Physical (weight, BMI, Hip-waist ratio), Diabetic (FBS, HbA1C) & Side effect profiles of both classes of drugs.

MATERIALS AND METHODS

The study was conducted in the Department of General Medicine in PSG Hospital, Coimbatore. It was approved by the Institutional Human Ethics Committee, PSG Institute of Medical Sciences and Research (Proposal no: 19/072). It is an observational study which included a total of 100 subjects who were divided into two treatment groups. Both groups contain 50 patients each. Group 1 (G1) contains 28 Males & 22 Females whereas Group 2 (G2) contains 30 Males & 20 Females.

The inclusion criteria include Type 2 DM patient of age above 18 years with poor diabetic control and on regular follow up, Patients who are going to be initiated respectively with SGLT 2 Inhibitors & DPP-4 inhibitors as add on therapy for controlling DM and the patients with normal liver function, renal function. Exclusion criteria include patients with Type 1 DM, renal failure, psychiatric, paediatric, gestational diabetes mellitus, history of diabetic ketoacidosis & primary renal glucosuria, and patients who are unwilling to participate.

Group 1 patients were initiated with DPP-4 Inhibitor, Group 2 patients with SGLT-2 Inhibitors, respectively. At baseline and during follow-up after 3 months of drug initiation, the parameters like the physical profile, Diabetic Profile, and side effects were noted and statistically compared. The effect of drugs within a group was compared by using Paired *t*-Test and between groups were by using Independent *t*-Test.

RESULTS AND DISCUSSION

Effects of DPP-4 Inhibitors

The total of 50 G1 patients who were initiated with DPP-4 inhibitors, drugs given were Teneligliptin 20mg (14 patients), Evo gliptin 5mg (07 patients), DPP-4 Inhibitor +Metformin 500mg (16 patients), DPP-4 Inhibitor +Repaglinide 0.5 mg (06 patients), DPP-4 Inhibitor +Glimepiride 1mg (07 patients).

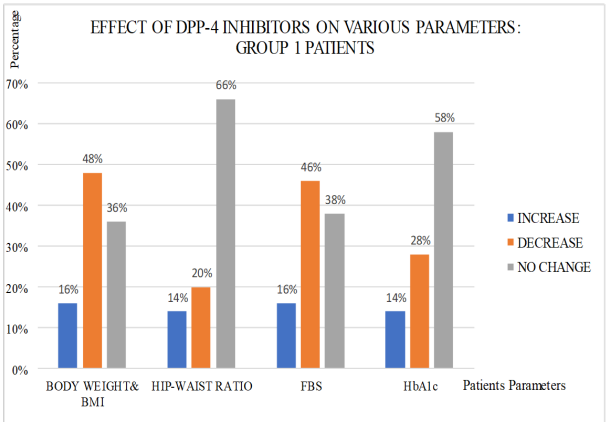

Figure 1: Cluster chart showing the effect of DPP-4 inhibitors on various parameters among Group 1 patients [BMI-Body Mass Index FBS-Fasting Blood Sugar HbA1c-Glycated Haemoglobin]

Once after the drug initiation, the patients were

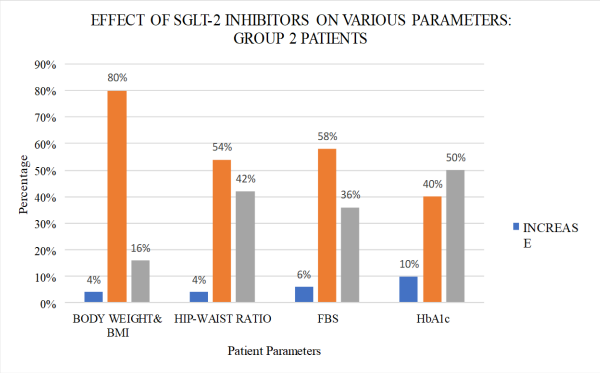

Figure 2: Cluster chart showing the effect of SGLT-2 inhibitors on various parameters among Group2 patients [BMI-Body Mass Index FBS-Fasting Blood Sugar HbA1c-Glycated Haemoglobin]

followed up for three months, and their physical and diabetic profile are monitored, and the changes were noted. According to the effect of drugs on individuals, their parameters get varied. They were depicted in Figure 1

Figure 1 showing the effect of DPP-4 Inhibitors on various parameters among G1 patients. The mean baseline weight (68.44±3.81) was reduced to 64.45±1.71) (p=0.04), the mean baseline BMI (26.73±1.31) was reduced to (25±1.38) (p=0.05), the mean difference between Hip-Waist ratio was 0.13 (p=0.05), the mean difference between FBS was 59.87 mg/dl (p=0.03), the mean difference between HbA1c was 1.2% (p=0.04).

A retrospective sub-analyzed study of sitagliptin effect on glucose and lipid metabolism, blood pressure, body weight and renal function in type 2 DM patients for a period of 6 months by dividing 173 patients of Type 2 DM into obese group (BMI $\geq$ 25) and non-obese group (BMI < 25), concluded that the body weight was significantly reduced in obese patients from the baseline values despite the ages and HbA1c also decreased in both the groups significantly (Katsuyama *et al.*, 2014)

A review of sitagliptin brought a conclusion that on the addition of sitagliptin (100mg/d) to already existing oral antidiabetic treatment produce a significant reduction of HbA1c. After 24 weeks of the addition of sitagliptin (100mg/d) to metformin produced a significant reduction of HbA1c (0.65%), FBS (25.4 mg/dl), Post Prandial Glucose (2h) (50.6 mg/dl) (Gallwitz, 2007)

GLP-1 also found have cardioprotective action in experimental models of heart failure and myocardial infarction. DPP-4 inhibitors may have cardiovascular effects either by depending or independent of GLP-1 (Jose and Inzucchi, 2012)

An Indian study reported the results of a 16-week, multicentric, double-blind, placebo-controlled, Phase 3 studies of teneligliptin 20 mg daily in drug-naive T2DM patients. This study (N = 237) reported a significant −0.55% glycated hemoglobin (HbA1c) reduction (placebo-subtracted) in teneligliptin arm (P = 0.0043) compared to control. While a significant reduction in 2 hours postprandial glucose (PPG) (−25.8 mg/dl, P = 0.0070) versus placebo was observed, an insignificant reduction in fasting plasma glucose (FPG) was seen (−8.8 mg/dl, P = 0.18) in teneligliptin 20 mg arm. Similarly, a higher percentage of patient achieved the target HbA1c of <7% in teneligliptin arm (43.4% vs. 27.3%, P = 0.026) compared to the control and "overall" the drug was well tolerated (Suryawanshi *et al.*, 2016)

Effects of SGLT-2 Inhibitors

The effects of SGLT-2 Inhibitors among various parameter of G2 patients were depicted in Figure 2

Figure 2 showing the effect of SGLT-2 Inhibitors on various parameters among G2 patients. The mean baseline weight (71.34±3.28) was reduced to 64.45±1.97) (p=0.02), the mean baseline BMI (29.93±4.32) was reduced to (27.03±2.96) (p=0.04), the mean difference between Hip-Waist ratio was 0.27 (p=0.04), the mean difference between FBS was 81.95 mg/dl (p=0.01), the mean difference between HbA1c was 2.29% (p=0.02)

A retrospective study which involves 61 patients who received 12 months of dapagliflozin concluded that After the 12 months intake of drug the body weight was -3.4±2.6 kg reduced significantly from the baseline value, the drug reduces the hyperglycemia and body weight by inhibiting the renal glucose reabsorption in a safe manner in Type 2 DM patients. (Cho *et al.*, 2017)

The study of "Efficacy and Safety of SGLT-2 Inhibitors" in Emirati patients which included 307 patients concluded that at 6 months of drug administration the baseline HbA1c was decreased from the baseline value, from 8.9±1.7% to 8±1.5% & at 1 year the mean HbA1c was 8±1.4% (p=0.0001). Likely, the bodyweight also reduced from the baseline at the sixth month, from 85.7±17.8 kg to 84±12.2 kg (p=0.0001). (Bashier *et al.*, 2017)

Comparision between the effects of DPP-4 inhibitors & SGLT-2 inhibitors

Since both categories of the drugs is used as add on therapy in the treatment of Type 2 DM, it's important to find out the effect of those drugs on various parameters among the Indian Type 2 DM population. This result may help to wisely choose the add

on therapy drugs for the treatment of Type 2 DM.

Effects of drugs on

Body weight and BMI

Table 1: DPP-4 Inhibitors Vs SGLT-2 Inhibitors on Body Weight and BMI

Body Weight& BMI	DPP-4 Inhibitors	SGLT-2 Inhibitors
Increase (%)	16	4
Decrease (%)	48	80
No Change (%)	36	16

BMI-Body Mass Index

Hip-waist ratio

Table 2: DPP-4 Inhibitors Vs SGLT-2 Inhibitors on Hip-Waist Ratio

Hip-waist ratio	DPP-4 inhibitors	SGLT-2 Inhibitors
Increase (%)	14	4
Decrease (%)	20	54
No change (%)	66	42

The comparison of the effect of both the drugs over the patient's body weight and Hip-Waist Ratio were depicted in Table 1 &Table 2 respectively. In Body Weight, the mean difference between the groups was found to be 2.9 ±0.79 ($p<0.05$). Similarly, for BMI, it was 2.9±1.36 ($p<0.04$). For the Hip-Waist ratio, it was 0.07 ($p<0.05$). SGLT-2 Inhibitors were showing significant reduction while comparing with DPP-4 Inhibitors.

In 2017, Min SH et al. conducted a meta-analysis study titled "Comparison between SGLT2 inhibitors and DPP4 inhibitors added to insulin therapy in type 2 diabetes: a systematic review with indirect comparison meta-analysis". Covariate-adjusted indirect comparison using meta-regression analyses revealed that SGLT2i/INS achieved greater reduction in HbA1c [weighted mean difference (WMD) -0.24%, 95% confidence interval (CI) -0.43 to -0.05%], fasting plasma glucose (WMD -18.0 mg/dL, 95% CI -28.5 to -7.6 mg/dL) and body weight (WMD -2.38 kg, 95% CI -3.18 to -1.58 kg) from baseline than DPP4i/INS without increasing the risk of hypoglycemia. (Min *et al.*, 2017)

FBS

HbA1c

The comparison of the effect of both the drugs over the patient's FBS & HbA1c were depicted in Table 3 &Table 4 respectively. The mean difference between the groups over FBS was 22.08 mg/dl (0.0001), for HbA1c it was 1.09 ($p<0.0043$). SGLT-2 Inhibitors were showing significant reduction while comparing with DPP-4 Inhibitors.

Table 3: DPP-4 Inhibitors Vs SGLT-2 Inhibitors on FBS

FBS	DPP-4 Inhibitors	SGLT-2 Inhibitors
Increase(%)	16	6
Decrease (%)	46	58
No Change (%)	38	36

FBS- Fasting Blood Sugar

Table 4: DPP-4 Inhibitors Vs SGLT-2 Inhibitors on HbA1c

HbA1c	DPP-4 Inhibitors	SGLT-2 Inhibitors
Increase (%)	14	10
Decrease (%)	28	40
No Change (%)	58	50

HbA1c-Glycated Haemoglobin

Table 5: Side Effect Frequency of the Drugs

Drugs Category	Side Effects (%)
DPP-4 Inhibitors	10
SGLT-2 Inhibitors	14

An observational study on "Safety and Efficacy of Sodium-glucose Cotransporter-2 Inhibitors as Adjuvant to Insulin Add-on Therapy in Uncontrolled Type 2 Diabetic Patients" concluded that the SGLT-2 Inhibitors were more effective in both glycemic control (FBS, HbA1c) and non-glycemic control (Body Weight, BMI, Blood Pressure) and acts as a well-tolerated therapy in patients. This put forth the overall reduction in cardiovascular risks (Alfeena Mary PS *et al.*, 2018)

Side effect profile of the drugs

Since 50 patients were enrolled in each group like DPP-4 Inhibitors and SGLT-2 Inhibitors, respectively, along with the effects of two categories of drugs on various patient's parameters, their Side effects are also monitored during the follow-up period of 3 months. It was given in Table 5.

Side effects of DPP-4 Inhibitors: Nausea, Diarrhoea, Stomach pain, Flu-like symptoms, Nasopharyngitis and HSR (Amori *et al.*, 2007)

Side effects of SGLT-2 Inhibitors: UTI, Hyperkalaemia, Hypotension, Hypoglycaemia and Dia-

betic Ketoacidosis (Hsia *et al.*, 2017)

On Side effect profile, SGLT-2 Inhibitors were showing higher incidence for the occurrence of UTI while comparing with DPP-4 Inhibitors

CONCLUSIONS

Both DPP-4 Inhibitors and SGLT-2 Inhibitors were producing significant impact over the Physical and Diabetic profile of Type 2 DM patients. Though while comparing with DPP-4 Inhibitors, SGLT-2 Inhibitors were producing a more prominent effect over patient's parameters, and apart from producing a significant effect on the Physical and Diabetic profile, SGLT-2 inhibitors were also found to have cardiovascular benefits. Side effects like UTI can be overcome by proper patient counseling. On an overall consideration of the effects produced by both the class of drugs, this study concluded that SGLT-2 inhibitors may serves as the best medication choice for add on therapy in Type 2 DM patients.

Looking Beyond Lupus in Lupus

BHARGAVI KUMAR[1], SARAVANAN THANGAVELU[2]

ABSTRACT

Haematological abnormalities are a common finding in Systemic Lupus Erythematosus (SLE) patients. The wide spectrum includes anaemia, cytopenias, thrombosis as well as bleeding. Among the bleeding disorders, qualitative coagulation defects can be rarely encountered because of clotting factor inhibitors. More uncommon is the occurrence of quantitative clotting factor deficiencies. Here, we describe a rare cause of abdominal pain in a patient with SLE who developed perinephric and colonic sub mucosal haematomas owing to a rare association with acquired factor XIII deficiency which was diagnosed on quantitative assays and effectively treated with cryoprecipitate and fresh frozen plasma.

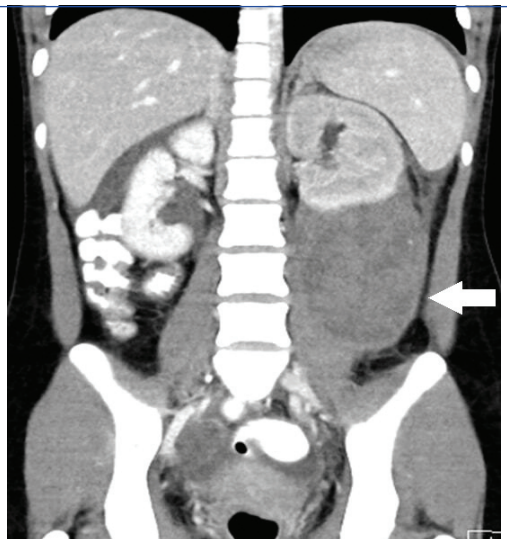
Keywords: Abdominal haematomas, Factor XIII deficiency, Systemic lupus erythematosus

CASE REPORT

A 21-year-old young lady presented to the Emergency Department with left loin pain, vomiting and loose stools for the last one day. She did not report any fever, radiation of pain, urinary symptoms, pain aggravation on food intake or any prior strenuous activity.

The patient was diagnosed with SLE 2 years ago and was on treatment with steroids, Mycophenolate Mofetil (MMF) and Hydroxychloroquine. She reported history of intermittent episodes of pain in her calf muscles in the last one year. Magnetic resonance imaging (MRI) had revealed the presence of organised haematomas in calf muscles, but the patient did not follow-up due to spontaneous resolution of symptoms.

On examination, the patient was pale, tachycardic and hypotensive. No rashes were noted. Respiratory system examination fairly ruled out pleurisy and musculoskeletal examination was normal. A non-tender firm ballotable mass was palpable in the Left lumbar region.



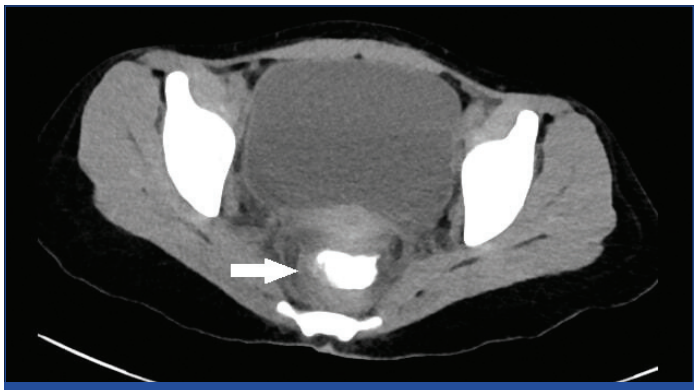
Preliminary investigations showed microcytic anaemia, (haemoglobin 6.2 g/dL), severe thrombocytopenia (22×10^9/L) and mild neutrophilic leucocytosis as shown in [Table/Fig-1]. Her renal function and complements were normal with slightly elevated Erythrocytic sedimentation rate (35 mm first hour). Ultrasonogram of the abdomen showed 9.4×7.4 cm heterogeneous lesion adjacent to the lower pole of the left kidney. A computed tomography revealed the presence of left perinephric haematoma with left hydroureteronephrosis [Table/Fig-2]. Initial coagulation profile revealed normal Prothrombin Time (PT), Activated Partial Thromboplastin Time (APTT) and slightly low fibrinogen levels (1.4 g/L). Direct Coombs test turned out to be positive. Von Willebrand Factor assay was normal. Antiphospholipid Antibody (APLA) work up was done in which anti beta2 glycoprotein turned out to be negative, with Lupus anticoagulant ratio of 1.6.

The differential diagnoses considered were acute SLE flare/bleeding due to thrombocytopenia/coagulation defects and MMF induced haematological crisis. However, complement activity, disease markers were normal and the patient was on irregular treatment with MMF. Since initial PT, APTT levels were normal, possible factor XIII deficiency was considered and she was evaluated accordingly.

The patient was stabilised with intravenous fluids namely Normal Saline, low dose methyl prednisolone 250 mg over 3 days and 2 units packed red blood cells transfusion. There was recurrence of vomiting and loose stools during initiation of enteral feeds and a repeat CT abdomen revealed new onset transmural haematomas in small bowel loops, distal ascending colon, transverse colon,

	Day 1	Day 5	Day 7	Day 11	Standard value
Haemoglobin g/dL	6.2	8.4	9.9	11.9	12-15
Mean corpuscular volume fL	73.2				80-100
White blood counts ×10^3/uL	15	10.6		9.2	4-10
Platelets x10^3/uL	22000	42000	83000	110	150-400
Prothrombin time (seconds)/INR	13.3/1.2	13.9/1.33		13.1/1.25	9-12
APTT (seconds)	29.1	22.8		28.2	25-34
Serum fibrinogen levels mg/dL	76	140		342	200-400
C3 c level/C4 mg/dL	83/21				90-180 10-40
ESR mm 1st hour	35	30		17	4-12 mm
HsCRP mg/dL	0.30				<0.5 mg/dL
Procalcitonin ng/mL	0.2				<0.5

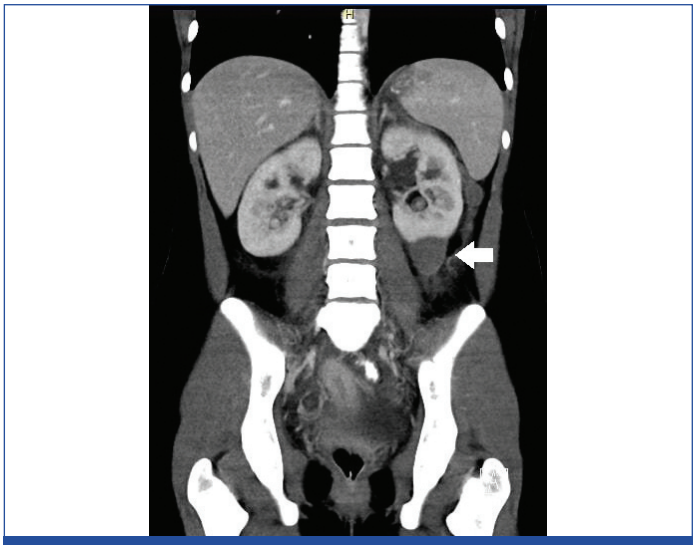
[Table/Fig-1]: Preliminary investigations showing microcytic anaemia, severe thrombocytopenia and mild neutrophilic leucocytosis.



[Table/Fig-2]: CT abdomen showing perinephric haematoma over lower pole of left kidney with ureteric compression.

descending colon and rectum [Table/Fig-3,4]. The coagulation profile results reaffirmed normal APTT levels; repeat fibrinogen levels were normal (3.4 g/L) and platelet counts were improving (120×10^9/L). On performing a clot solubility test, the clot completely dissolved in 5M urea solution and on mixing studies, the clot dissolved partially. Since the results were equivocal, it was not possible to differentiate a hereditary factor XIII deficiency from a factor XIII inhibitor in this case. Subsequently, a factor XIII assay was done which turned out to be <1% thus confirming severe deficiency. Patient was transfused with a total of 18 unit's cryoprecipitate (270 mL) and 10 units of fresh frozen plasma (2400 mL total) during her entire hospital stay following which she showed steady improvement.

[Table/Fig-3]: CT abdomen depicting transmural haematoma of distal ascending, transverse and descending colon.



[Table/Fig-4]: CT abdomen showing transmural haematoma involving rectum.

A follow-up CT abdomen a month later showed resolving left perinephric haematomas with resolution of colonic and rectal haematomas. The patient is currently doing well on 5 mg once daily prednisolone and azathioprine [Table/Fig-5].

DISCUSSION

SLE is a challenging disease to treat. In the current era, diagnosing SLE has become common due to increasing awareness, knowledge of its varied presentations and available investigations. However, the course of the disease poses a constant challenge to the treating physician owing to the myriad of systemic manifestations and complications.

Acute abdomen in SLE patients is a challenging diagnostic and therapeutic problem. Most patients are on steroids and/or immunosuppressive agents which mask the physical findings, thus leading to a delayed definitive diagnosis. The reported incidence of abdominal pain in SLE varies from 8 to 40% [1,2]. Assuming that all are due to vasculitis may lead to diagnostic errors. In an observation of 36 active SLE patients presenting with acute abdomen by Medina F et al., 19 had vasculitis, 3 had Anti Phospho Lipid Antibody (APLA) related intra-abdominal thrombosis and the rest were non-SLE related [3]. Therefore, it is imperative to carefully evaluate such a patient based on their clinical, imaging and immunological profile.

[Table/Fig-5]: CT abdomen revealing resolving haematoma over the lower pole of left kidney.

Haematological abnormalities are common findings in patients with SLE. The prevalence is described as 47% in most studies [4]. In a study by Sasidharan PK et al., haematological manifestations were found to be the most common initial presentation of SLE and it was the presenting manifestation in 82% of the patients. The haematological spectrum encompasses anaemia, leucopenia, thrombocytopenia, autoimmune haemolytic anaemia, thrombotic thrombocytopenic purpura, myelofibrosis-hypoplastic anaemia and thrombotic manifestations if associated with APLA [5]. The index patient too had leucopenias along with cutaneous manifestations in her initial presentation leading to her diagnosis.

It is imperative to distinguish haematological abnormalities arising due to disease activity from those due to drug effects. The index patient had normal complement activity and disease markers making acute SLE flare unlikely. The patient was on irregular treatment with MMF, making drug related side effect a remote consideration. Bleeding despite normalisation of platelet count, fibrinogen levels and normal PT, APTT prompted us to investigate us for rare clotting factor abnormalities, such as Factor XIII defects. Coagulation defects in SLE could be due to inhibitors more commonly [6], and due to factor deficiencies rarely [7-9].

Factor XIII is needed to stabilise the fibrin clots and it's deficiency could be genetically acquired as Autosomal recessive disorder or could be due to acquired causes [7]. Hereditary deficiency is attributed to the F13A1 gene located on the short arm of chromosome 6 (6p24.2-p23). Acquired factor XIII deficiency occurs much less often, and usually affects middle-aged or elderly individuals [10]. It can be associated with conditions such as severe liver disease, chronic kidney failure, inflammatory bowel disease, Henoch-Schonlein purpura, autoimmune disorders such as SLE or scleroderma and certain cancers such as myeloid forms of leukaemia. It has also been linked to the use of certain medications including isoniazid, penicillin, and phenytoin.

Individuals with factor XIII deficiency form blood clots per se, but the clots are unstable and often break down, resulting in prolonged, uncontrolled mild to fatal bleeding episodes. The most common bleeding symptoms are subcutaneous bleeding (57%), delayed umbilical cord bleeding (56%), muscle haematoma (49%), haemorrhage after surgery (40%), haemarthrosis (36%) and intracerebral bleeding (34%) [11,12]. However, the index patient's presentation was unusual with perinephric, colonic submucosal and transmural haematomas.

Factor XIII deficiency is screened by clot solubility test and confirmed by quantitative assays [13]. It is treated by factor XIII concentrates,

fresh frozen plasma or cryoprecipitate. When inhibitors develop in individuals with factor XIII deficiency, additional therapy in the form of immunosuppressive agents would be required.

On review of literature, there is a reported Lupus patient with associated factor 13 deficiency who developed intracerebral haematoma [9]. There are case reports of subcutaneous and intramuscular haematomas due to factor XIII deficiency following an invasive procedure in a patient with SLE [14]. In another instance a 70-year-old man had developed spontaneous left gluteal haematoma owing to factor XIII deficiency [15]. Occurrence of gastrointestinal haematomas as in the index patient seems to be extremely rare.

CONCLUSION

It is fruitful to think beyond lupus while approaching the presenting complaints even in a diagnosed patient of SLE. Attributing all the features to the disease per se might be misleading. A high index of suspicion for rarer clotting factor deficiencies is required while evaluating the bleeding manifestations with a normal coagulation profile. There exists a lacuna in ascertaining the fact as to why in an autoimmune disease, there is associated clotting factor deficiency, unlike the expected scenario of clotting factor inhibitors. Only continued medical research can unravel such mysteries.

ABSTRACT

Euglycemic ketoacidosis is defined by the triad of euglycemia, metabolic acidosis and ketonemia or ketonuria. In the current era of diabetic management, it is a serious concern with the usage of sodium glucose co-transporter 2 (SGLT2) inhibitors potentiated by a number of precipitating agents. Empagliflozin though a novel oral hypoglycemic agent in this category may also lead to this potential complication. Here we report a 59 year old male, type 2 diabetic who was on empagliflozin and presented with euglycemic ketoacidosis after a binge of alcohol.

Keywords: Empagliflozin, SGLT2 inhibitor, Type 2 diabetes, Euglycemic ketoacidosis

INTRODUCTION

Hyperglycemic states in diabetes like Diabetic ketoacidosis (DKA) and hyperglycemic hyperosmolar non ketotic coma are widely encountered, well known and therefore easily diagnosed emergencies. However euglycemic ketoacidosis is an often missed relatively less known condition and under reported scenario. A high index of clinical suspicion is warranted to arrive at this diagnosis because the normoglycemia may mask our clinical judgement of DKA.

The management of diabetes mellitus is ever evolving with oral hypoglycemic agents being an area of constant research and updates. Approved by the Food and Drug administration of USA (FDA) in 2014, Sodium glucose co-transporter 2 (SGLT2) inhibitors is a new addition to the already existing broad list of oral hypoglycemic agents for type II diabetes mellitus. Apart from reducing blood sugars, its spectrum also extends to reducing blood pressure, reduction of weight and cardio protection.[1] It is now included in American Diabetes Association treatment guidelines as one of the add-on agents in dual or triple drug combinations in diabetes as it can effectively reduce HbA1c by 0.5-0.7%. However euglycemic ketoacidosis is a rare but potential complication in this class of drugs for which FDA has released a safety alert in 2015.[2] Its diagnosis may be delayed owing to the normal sugar levels and needs a strong index of suspicion whenever there is ketonemia or ketonuria in the presence of normal blood sugar levels and high anion gap metabolic acidosis.

CASE REPORT

A 59 year old male presented to the emergency department with abdominal discomfort and orthopnea following a binge alcohol intake. Patient was a chronic smoker and alcoholic for 30 years and a known case of

type 2 diabetes mellitus and systemic hypertension for 5 years. He was on irregular treatment with tablet metformin 500 mg in once daily dosage and had started taking tablet empagliflozin 10 mg once daily for the past 2 years without prescribed medical advice. His concomitant medications included tablet nebivolol 5 mg once daily for systemic hypertension. On examination, the patient was moderately dyspnoeic, tachypnoeic, drowsy, arousable and normotensive. Respiratory system examination showed basal crepitations and abdomen examination showed mild epigastric tenderness.

Preliminary investigations revealed normal sugar levels (169 mg/dl), ketonuria (3+) and elevated HbA1c (10.8%). His complete blood counts, serum procalcitonin, liver, thyroid and renal functions were normal but for low bicarbonate (4.65 mEq/l) and a pH of 7.2. The calculated anion gap was high (27.7). Cardiac functions were normal as evidenced by echocardiogram and biomarkers.

An ultrasonography of the abdomen was done in view of epigastric tenderness and showed a bulky pancreas suggestive of acute pancreatitis. His amylase (956 U/l) and lipase (3873 U/l) were also elevated and lipid profile evaluation revealed hypertrigliceridemia (242 mg/dl). His laboratory parameters are summarised in Table 1.

Noting his ketonuria and high anion gap metabolic acidosis with normal blood sugars we arrived at a diagnosis of euglycemic ketoacidosis in the background of his medication history of empagliflozin therapy which was probably precipitated by alcohol binge and acute pancreatitis. Patient was put on ventilator support and started on intravenous fluids, insulin along with 5% dextrose and bicarbonate correction. The acidosis improved gradually and blood glucose levels were controlled with rapidly acting insulin. After the patient improved symptomatically, he was weaned off and tolerated soft diet.

Table 1: Laboratory parameters of the patient across his days of admission showing his normal sugar values at admission and metabolic acidosis which resolved following treatment.

	Day 1	Day 2	Day 3	Day 5	Day 7	Day 9	Day 10
Sugars (mg/dl)	169	141	132	178	193	299	268
Urine for ketones	+++	+++	++	+	Nil	Nil	Nil
pH	7.2	6.9	7.47	7.4	7.48	7.40	7.41
HCO_3 (mEq/l)	4.65	7.0	14	11.3	18	23.8	24.1
Amylase (U/l)	956	-	-	145	242	-	-
Lipase (U/l)	3873	-	-	639	1158	887	637

On discharge, the patient was counselled regarding diet, insulin therapy, advised alcohol abstinence and was counselled to stop any self-medication of new oral hypoglycemic agents. The patient is now on regular follow up, maintaining average blood sugars of 200 mg/dl. As the patient was apprehensive about continuing insulin, he is now put on oral agents-insulin secretagogues alongside diet and lifestyle modification.

DISCUSSION

There are a multitude of causes leading to metabolic acidosis in diabetics. These include normal anion gap acidosis like renal failure as well as high anion gap states like lactic acidosis and ketoacidosis. Ketoacidosis could be due to diabetic ketoacidosis, starvation ketoacidosis or alcoholic ketoacidosis. Diabetic ketoacidosis may be either hyperglycemic or euglycemic. Thus analyzing the risk factors that contribute to the development of ketoacidosis is very crucial.

Euglycemic ketoacidosis was first observed and reported in a case series by Munro et al who observed that a subset of DKA patients had sugar levels <300 mg/dl.[3] Subsequently euglycemic ketoacidosis has been characterized by the triad of euglycemia (blood glucose <250 mg/dl), metabolic acidosis (pH <7.35, bicarbonate <18 mEq/l) and ketonemia or ketonuria.[4] To explain it succinctly, euglycemic ketoacidosis is DKA sans marked hyperglycemia. It is mainly described in type 1 diabetes but nevertheless not uncommon in type 2 diabetes. Possible contributing factors include starvation, alcoholism, pregnancy, pancreatitis and drugs. Among drugs, SGLT2 inhibitors are notorious to cause euglycemic ketoacidosis.

SGLT 2 inhibitors act primarily by inhibiting sodium glucose co-transporter 2 in proximal convoluting tubule which mediates 80-90% of glucose absorption in kidney. As a result of this facilitation of glucose excretion by kidney, blood glucose levels are lowered. When the blood glucose levels reduce, the insulin release from pancreas also reduces proportionately tilting the normal insulin: glucagon ratio, thereby favoring ketogenesis. Other proposed mechanisms include release of glucagon by direct SGLT2 inhibition in pancreas, release of kisseptin which inhibits insulin release and also decreased reabsorption of ketones leading to ketonemia.

Empagliflozin has shown meticulous benefits in reducing major cardiac events as evidenced in the 'EMPA-REG OUTCOME' trial.[5] Since empagliflozin's mechanism of action is independent of beta cell functioning, they are useful in all type 2 diabetes patients as long as estimated glomerular filtration rate is above 45-60 ml/min. Other potential benefits include weight loss (2-3 kg) and

reduction in blood pressure (3-6 mmHg systolic, 1-2 mmHg diastolic) due to natriuresis besides cardioprotection. Though beneficial in numerous aspects, empagliflozin also has adverse effects like genital fungal infections (3-5%), urinary tract infections (1-2%), volume depletion and hypotension. However of serious concern is the development of euglycemic ketoacidosis though reported in less than 0.1% patients. Canagliflozin and dapagliflozin also carry the risk of euglycemic ketoacidosis with reported incidence being 0.8% and less than 0.1% respectively.[6]

On literature review, we noted that Gammons and Counselman have presented a case report of a chronic alcoholic, type 2 diabetic patient on empagliflozin developing euglycemic ketoacidosis with acute pancreatitis similar to our index patient.[7] So also Candelario and Wykretowicz have presented a type 2 diabetic female who developed euglycemic ketoacidosis while on empagliflozin therapy precipitated by acute cholecystitis.[8]

In our index patient with euglycemic ketoacidosis, the clear culprits were empagliflozin overtly precipitated by his binge of alcohol and pancreatitis. A high index of suspicion alone prompted us to withdraw the offending drug and treat him with insulin and dextrose apart from intravenous fluids in correcting his metabolic acidosis.

CONCLUSION

DKA need not necessarily present with hyperglycemia. High anion gap ketoacidosis should be a red flag to look for euglycemic ketoacidosis which requires both insulin and dextrose in correcting the underlying metabolic derangement. Careful drug history and possible precipitators should be identified and promptly corrected. SGLT2 inhibitors though a novel agent in the treatment of diabetes also comes with its quantum of adverse effects like euglycemic ketoacidosis which is a potential life threatening complication. The key to a successful usage of newer exciting hypoglycemic agents lies in choosing our patients wisely and carefully avoiding those who have other contributing factors for acidosis.

Tenofovir induced delayed nephro-osteo toxicity – a case report

Bhargavi Kumar[1], Rajgokul Prabhakar[2], Saravanan Thangavelu[3]

Abstract

Tenofovir disoproxil fumarate (TDF) is the foundation nucleotide reverse-transcriptase inhibitor and the recommended first-line regimen for all naive Human Immunodeficiency Virus-1 (HIV-1) patients whose age is more than 10 years and body weight is more than 30 kg. Although it has a good safety profile overall, nephrotoxicity is a concern and its overall incidence is 1–6% with a long period of clinical latency. Nephrotoxicity may manifest as either proximal renal tubule dysfunction in the form of a partial or complete Fanconi syndrome or as decreased renal function leading to acute or chronic kidney injury. Osteomalacia can also develop secondary to complicating hypophosphataemia and low calcitriol levels. Here we report a 50-year-old HIV-positive male on tenofovir who presented with proximal renal tubular acidosis and fracture of left neck of femur four years after initiation of the drug.

Introduction

Tenofovir disoproxil fumarate (TDF) is an oral acyclic nucleotide analogue reverse transcriptase inhibitor used in the treatment of HIV-1 infection approved by the Food and Drug Administration (FDA) in 2001.[1] Tenofovir has found a major role in the fixed-dose combination along with lamivudine and efavirenz or doultegravir.[2] It has an added advantage in HIV-hepatitis B co-infection. It has an overall good safety profile, a relatively long half-life and allows once-daily dosing ensuring good patient compliance with relatively rare side effects.

Tenofoviris is actively transported into the mitochondria of proximal tubule cells of the kidney and thereby can lead to proximal tubular dysfunction in long-term use.[1] Proximal renal tubular acidosis is characterised by defective proximal tubular reabsorption associated with phosphaturia, glycosuria, aminoaciduria, bicarbonaturia, resulting in hypophosphataemia, hypokalaemia and metabolic acidosis. Overt Fanconi syndrome is rare, but can occur as a delayed presentation, with incidence being 1.09 per 1000 patient years.[3]

Osteotoxicity can occur either due to direct effect of the drug itself or secondary to hypophosphataemia as a result of renal toxicity.[4] Hence routine and careful monitoring for these toxicities is absolutely essential as they may occur even after a long asymptomatic period.

Case presentation

A 50-year-old male presented with poor appetite, significant weight loss of 6 kg in 2 months and progressively painful difficulty in walking over 8 months. He was diagnosed with HIV-1 8 years ago and was on regular treatment with tenofovir, lamivudine, atazanavir and ritonavir for 4 years elsewhere. CD4 count done 3 months previously was 118 cells/mm3. He took diclofenac 50 mg intermittently over the previous 2 months.

On examination, he was thin, pale and had a limited range of movements in both lower limbs and left shoulder due to pain. His body mass index (BMI) was 16.5k g/m2.

Preliminary investigations showed macrocytic normochromic anaemia, elevated creatinine levels, hypokalaemia, hypophosphataemia, low bicarbonate levels and elevated serum alkaline phosphatase (ALP) levels. Arterial blood gas analysis revealed metabolic acidosis. Urine examination showed mild albuminuria and glycosuria (serum glucose was normal) with no pus cells. Results are shown in Table 1. Ultrasonography of the abdomen and pelvis revealed chronic renal parenchymal changes and renal artery Doppler study was normal.

X-ray pelvis showed an undisplaced fracture in the left neck of femur and an old displaced fracture in right neck of femur

Table 1

Lab parameters	DAY 1	DAY 2	DAY 3	DAY 5	2 WEEKS AFTER DISCHARGE	1 MONTH AFTER DISCHARGE	Reference range
pH	7.23	7.259	7.266		7.34		7.35-7.45
Acid base excess mmol/L	-14.4	-12.2	-11.6	-8.8			-2 - +3
Serum Sodium (mEQ/l)	139		144	143	138	143	136-146
Serum Potassium (mEQ/l)	2.45	3.22	3.24	4.60	5.5	3.66	3.5-5.0
Serum Bicarbonate (mEQ/l)	12.5	14.7	14.2	15.9	15.7	21.6	22-30
Serum Chloride (mEQ/l)	107		105			105	102-109
Serum phosphorous (mg/dl)		1.3		2.1	4.7		2.7-4.5
Serum Creatinine (mg/dl)	1.75			1.24		1.26	0.8-1.25
Creatinine clearance (mL/min)	39.29			55		54.56	97-137
Serum ALP(U/l)	459						40-129
Serum Vitamin D (ng/ml)	31.08						Deficient <20 Insufficient 21-29 Normal 30-70
Urine pH	6.8			>9.0			4.6-8.0
Urine glucose		4+			3+	1+	negative
Urine albumin		3+				1+	negative

confirmed on computed tomographic scanning. Serum vitamin D levels were normal. HIV viral load was undetermined and CD4 counts were 327.

Tenofovir-induced proximal renal tubular acidosis and pathological fracture was suspected and tenofovir withheld. He was treated with intravenous fluids, appropriate bicarbonate correction, thiazide diuretics and potassium citrate and his acidosis gradually improved. He was discharged on a high-potassium diet with oral potassium citrate, calcium and oral sodium bicarbonate supplements. At follow-up two weeks later he had an improving appetite and decreased pain in his legs. His electrolytes were normal with decreasing trend of creatinine levels. He was started on abacavir after hypersensitivity testing with HLAB5701 along with lamivudine and doultegravir. His bicarbonate, creatinine clearance and urine albuminuria and glycosuria improved significantly and he was able to attend to his activities of daily living.

Discussion

According to the India HIV Estimation 2017 report, national adult (15–49 years) HIV prevalence in India is estimated at 0.22% (0.16%–0.30%).[2] India has the third largest HIV epidemic in the world, with 2.14 million people living with HIV as per the UNAIDS 2018 data. 56% of adults are on anti-retroviral treatment.

Kidney disease in HIV-affected individuals may be attributed to a variety of causes which include: HIV-associated nephropathy (HIVAN) presenting with focal segmental glomerulosclerosis, HIV-associated immune complex kidney disease (HIVICK), acute kidney injury or chronic kidney disease.[5] The common antiretroviral therapy (ART) causes include tenofovir (tubular toxicity), protease inhibitor indinavir (nephrolithiasis, crystal nephropathy and interstitial nephritis) and enfuviritide (glomerulopathy).[6]

Tenofovir-induced nephrotoxicity is quite rare with most studies estimating it between 1–6%.[7] Tenofovir-induced nephrotoxicity could present as proximal tubular dysfunction

with preserved renal function (14%) or proximal tubular dysfunction associated with decreased renal function – which can either be acute kidney injury (1.6 %) or chronic kidney disease (8%).[1] Our patient also presented with proteinuria, glycosuria along with elevated creatinine levels and chronic renal parenchymal changes on ultrasonography.

About 20–30% of TDF is actively transported into the renal proximal tubule cells by organic anion transporters (OAT 1 and 3) located in the basolateral membrane and then subsequently secreted to the tubular lumen by the apical membrane transporters MRP4 and MRP-2 (Multidrug Resistance Proteins).[8] Any factor which causes overexpression of OAT1 and 3 or inhibits MRP-4 will cause tenofovir to accumulate within the cells, which in turn causes mitochondrial toxicity. Rarely, distal renal tubular acidosis has also been encountered (<5%), although the exact mechanism is not known.[9]

Risk factors include old age, low BMI, prior history of renal disease, reduced baseline glomerular filtration rate (eGFR), diabetes mellitus, hypertension, hepatitis C co-infection and genetic polymorphisms (APOL1G1 gene).[8] The index patient's BMI at the time of presentation was quite low. However, his BMI at the time of initiation with tenofovir was not known. Factors which inhibit MRP-4 include anti-inflammatory drugs like diclofenac, ibuprofen as well as protease inhibitors. The index patient was on concomitant ritonavir and diclofenac, both of which might have added on to the toxicity.

Nephrotoxicity can occur after years of tenofovir therapy as a delayed presentation with the median duration of presentation ranging between 16 months to 5 years.[10] Casado et al. observed a 32% prevalence of proximal tubulopathy after a median time of 5 years on tenofovir.[11] Our patient presented with nephrotoxicty 4 years after ART initiation with tenofovir. He had asthenia, loss of appetite, significant weight loss, muscle pain, easy fatigability and poor quality of life despite improvement in CD4 count, which prompted us to probe drug-related toxicities.

Osteotoxicity in HIV may be multifactorial. HIV can cause direct bone damage due to its effects on bone remodelling. Tenofovir can cause osteotoxicity through secondary effects of proximal renal tubular acidosis and its resultant hypophosphataemia. Because renal metabolism of vitamin D to its active form dihydroxyl cholecalciferol also occurs in proximal tubular cells, serum vitamin D levels can also be low in these patients. In addition, tenofovir can influence phosphate metabolism through circulating factors like phosphatonins.[4] In our patient vitamin D levels were normal but hypophosphataemia and elevated alkaline phosphate levels were noted and were probable contributors to bone toxicity and resultant pathological fracture.

This combined presentation of renal and bone toxicity with tenofovir therapy is quite rare, with few case reports available.[12,13] Lucey et al. reported a teenage boy with HIV infection on tenofovir presenting four years later with Fanconi syndrome and stress fracture of bilateral metatarsals.[13]

The early stages of proximal tubulopathy can be diagnosed by urine analysis of beta 2 microglobulin. In a study from Christian Medical College, South India, alkaline phosphatase (ALP) levels increased by nearly 200% after treatment with tenofovir. It was statistically significant thereby rendering it an important marker for monitoring of toxicity.[7] This is similar to the observation by Woodward et al. in which 89.5% of patients on tenofovir who developed hypophosphataemia had elevated ALP levels after a median time of seven years on ART.[12] It was also observed that creatinine clearance was a more valuable indicator compared to absolute creatinine values. National AIDS Control Organisation guidelines 2018 suggest measuring creatinine clearance and assessing risk factors for renal toxicity prior to starting tenofovir therapy. eGFR, urine protein/creatinine ratio, urine glucose and urine phosphates need to be monitored every three months for one year and then biannually.[2]

It is recommended to switch to alternative nucleoside reverse transcriptase inhibitors whenever tenofovir toxicity is encountered. However, even in those patients where tenofovir-related toxicities are encountered, it is still noted that the patients had a strong clinical and immunological response.

Ideally, if tenofovir entry to proximal tubule cells is prevented or exit is facilitated, renal toxicity may be averted. Drugs like probenecid which is an inhibitor of OAT1 and rosiglitazone, a peroxisome proliferator-activated receptor-gamma agonist that induces the expression of many proximal tubular cell transporters were studied in the past.[1] However, both had dose-limiting side effects.

Conclusion

Although antiretroviral therapy has given hope and life to HIV patients, it is important to be aware of the potential side effects and thereby monitor for the associated toxicities.

Early diagnosis of tubulopathy by urinary protein excretion, glycosuria assessment, creatinine clearance evaluation and alkaline phosphate assessment can be of central importance in identifying kidney and bone toxicities. Prompt recognition of toxicity and withdrawal of the drug can significantly improve or even reverse tubular damage in most patients, thereby avoiding chronic kidney damage.

ABSTRACT

Medicine is a practicing art. This is because we evolve constantly with everyday learning. The core of the health care system is management of patients with pharmacological measures. However the role of the health care deliverers does not stop with prescribing drugs. It is of central importance to be aware of the potential side effects of the drug including the rarest of the complications. It is equally important to discuss with our patients the available choices, the risk - benefit ratio and counsel them accordingly regarding anticipated common and rare side effects. The patient must be repeatedly reinforced about the importance of periodic follow up with the doctor, need for regular laboratory monitoring and reporting of alarm signs without any delay. Thus patient education, awareness of drug characteristics and a detailed doctor prescription are central in avoiding as well as managing drug related adverse effects. Here we present a case series of 9 different patients presenting with varied drug related adverse effects.

Key words: Adverse drug reactions, Periodic Monitoring, Patient education, Warning signs, Physician role.

INTRODUCTION

The European Medicines Agency (EMA) defines an adverse drug reaction as "a response to a medicinal product which is noxious and unintended.[1] The US Food and Drug Administration (FDA) defines an adverse drug reaction as any untoward medical occurrence associated with the use of a drug in humans "for which there is a reasonable possibility that the drug caused the adverse event."[2] Most of the drug reactions usually go underreported. Doctor prescription, drug characteristics and patient education are the three vertices of the adverse drug management triangle.

Drug reactions could be highly characteristic or nonspecific.[3] They could be dose, frequency or time dependent, occurring either almost right away or much later. Polypharmacy is a clear culprit in the occurrence of adverse drug reactions.

Patient factors like age, gender, creatinine clearance, body weight and fat distribution, race, ethnicity, genetic susceptibility, smoking and alcoholism are well known factors contributing to adverse drug reactions.[4] Patient education of drug intake, timing with other drugs, other co-morbidities, alertness in early recognition and reporting of warning signs are also of paramount importance.

A physician should be insightful in drug prescription fully taking into consideration previous drug histories and other simultaneous drugs the patient is on. It is wise to restrain hurry while diagnosing the disease or prescription even on a crowded day practice. It is prudent to refer the patient when required or have a close follow up while in doubt.

CASE REPORT

Case 1

A 58 yr old male patient presented with history of fever, loose stools and abdominal discomfort for 1 week. Patient was diagnosed

www.ijopp.org

with Myasthenia gravis 3 months ago elsewhere and started on immunosuppressants with oral Prednisolone 5mg once daily, Azathioprine 50mg once daily and Pyridostigmine 60mg thrice daily.

His examination was normal except for right eye ptosis. His initial blood counts showed pancytopenia as shown in Table 1. Bone marrow biopsy was suggestive of myelosuppression. With the diagnosis of drug induced pancytopenia, azathioprine was withheld and he was started on broad spectrum antibiotics and antifungal agents. Patient was given an injection of Granulocyte-Colony Stimulating Factor (G-CSF), following which his counts steadily improved. 2 weeks later patient reported with normal blood counts and patient was put on Mycophenolate mofetil along with pyridostigmine and steroids. Currently the patient's myasthenic symptom has improved and is maintained on oral prednisolone 10 mg once daily.

Case 2

27 year old female was admitted with history of fever for 3 days. Patient was evaluated elsewhere for a right sided neck swelling 1 month ago. A Computed Tomography (CT) Angiogram of the chest had shown Aortoarteritis changes suggestive of vasculitis for which she was treated with oral Azathioprine 50 mg once daily and oral Methotrexate 10 mg weekly.

On admission she was pale and tachypnoeoic tachypnoeic with gingival petechial petechiae. Her blood counts showed severe pancytopenia (Table 1). With a clinical diagnosis of drug induced bone marrow suppression, patient was put on strict barrier nursing with empirical antibiotics and antifungal agents. Patient required supportive transfusion with packed red cells, platelets and G - CSF in view of profound pancytopenia. However a week later, patient developed persistent dry cough, left peri orbital hematoma, hoarse voice, hypotension and stridor. A chest imaging and tracheal aspirate were suggestive of Aspergillus. Patient was put on mechanical ventilation and high end antibiotics and antifungal agents but eventually succumbed to refractory septic shock.

Case 3

58 year old female patient was admitted with history of recurrent nasal and gum bleeding for 1 month. Patient was diagnosed with *Pemphigus vulgaris* and had been taking Methotrexate 7.5mg weekly once for 10 years.

On examination, patient was pale and had non pruritic, non-blanchable multiple hyper pigmented maculae all through the body. Initial investigations as displayed in Table 2 showed pancytopenia and subsequently a bone marrow biopsy was suggestive of myeloid suppression with no atypical cells. Patient was started on intravenous antibiotics and transfused with packed red cells and platelets. Further the skin lesions were suggestive of psoriasis and patient was managed with antihistaminic drugs and topical applications. A month later patient reported with normal counts and is doing well on topical steroids and moisturizers.

Table 1: Showing the bicytopenia pattern in case 1 and subsequent improvement; case 2 showing persistent pancytopenia.

		CASE 1				CASE 2				
Lab parameter	Reference range	Day 1	After G-CSF	2 weeks later	1 year later	Day 1	Day 3	Day 5	Day 9	Day 15
Hemoglobin	13 - 17g/dL	10.2	10.9	14.8	9.6	3.8	7.5	9.5	9	6.3
Total white blood count (WBC)	4-10x10^3/uL	0.8	6.8	6.6	8.4	0.7	1.3	1.7	2.2	0.6
Platelets	150-400x10^3/uL	261	556	247	212	22	9	3	10	11

Table 2: Showing the drug induced pancytopenia in case 3, 4 and 5 with subsequent improvement.

Lab parameter	CASE 3				CASE 4					CASE 5				
	Day 1	Day 5	A month later	A year later	Day 1	Day 3	Day 6	2 weeks later	2 months later	6 months prior to treatment	Day 1	Day 2	2 days after G-CSF	1 Month later
Hemoglobin	7.1	8.2	8.4	10.0	8.2	9	10.1	8.0	13.2	8.5	4.4	5.3	6.5	9.9
White blood count	2.1	3.9	14.7	6.8	0.3	1.9	4.3	10.5	6.2	8.5	3.1	1.8	8.0	6.7
Platelets	4	86	187	211	30	37	65	617	242	246	75	53	117	153

Case 4

68 year old male patient was admitted with complaints of fever, productive cough and breathlessness for 2 days. Patient was a known case of Rheumatoid arthritis on oral Methotrexate 5 mg weekly for 8 years.

On admission, patient was severely dyspnoeic and tachypnoeic, had bilateral lung crepitations with Varicella zoster skin lesions. His initial investigations showed pancytopenia (Table 2). Patient was treated with empirical antibiotics, antifungal and antiviral drugs. He was supported with blood products transfusion and G-CSF. His tracheal and urine cultures revealed multidrug resistant *Klebsiella pneumonia*. Patient had a tumultuous hospital stay where he required reintubation after weaning owing to excessive oropharyngeal secretions which was further complicated by an episode of atrial fibrillation reverted by cardio version. After aggressive management with sensitive antibiotics and ventilator support, patient improved symptomatically and he was able to mobilize around in wheel chair. Patient was discharged with Hydroxychloroquine tablet 200 mg once daily and reported on follow up with improved counts and no active inflammatory signs.

Case 5

51 year old female patient was admitted with history of generalized fatigability, exertional dyspnoea and swelling of legs for 10 days. She was diagnosed with Rheumatoid arthritis for the last 2 years. Initially the patient had taken native medication for her joint pain and then subsequently started elsewhere on weekly Methotrexate dose of 5 mg, Leflunomide 10 mg daily and 5 mg once daily prednisolone for the last 6 months. On examination, the patient was pale, had glossitis, bilateral pitting pedal edema and crepitations in the lungs. Initial investigations (Table 2) showed pancytopenia. On the suspicion of drug induced pancytopenia, methotrexate and leflunomide were withheld. Patient was started on broad spectrum antibiotics and antifungal agents with strict barrier nursing. Bone marrow biopsy showed hypo cellular marrow with no atypical cells. The patient was administered one dose of G-CSF and 2 units packed red cells were transfused. Her blood counts gradually started improving and patient was discharged with low dose oral prednisolone and is maintained on the same on follow up.

Case 6

59 year old female patient presented with breathlessness, decreased urine output, swelling of legs for the last 2 days. Patient had started developing facial puffiness a month ago for which she was suggested thyroid function tests elsewhere. Her Thyroid Stimulating Hormone (TSH) levels were 6 microIU/ml and patient was started directly on 100 micrograms (mcg) Levothyroxine.

On examination, the patient was tachypnoeic, had anasarca and extensive bilateral lung crepitation's. Her cardiac markers were elevated and an echocardiogram showed mild pericardial effusion with preserved ejection fraction and cardiomegaly. A diagnosis of levothyroxine induced heart failure was arrived at and patient was treated with noninvasive ventilation, diuretics and her Levothyroxine dose was brought down to 50 micrograms/day. Patient gradually improved and was discharged with 50 mcg of Levothyroxine. On follow up her dose was gradually increased by 12.5 mcg and patient is doing well on tab. Levothyroxine 75 micrograms per day.

Case 7

A 29 yr old female patient with no known previous co morbidities came with complaints of generalized swelling of body, decreased urine output and orthopnea for 1 week. Patient was apparently normal 3 months back when she started having hair fall, mild facial puffiness, dyspnea on exertion and dryness of skin but was able to attend to her household work. She had consulted elsewhere, her TSH levels were 5.3 micro IU/ml and the patient was started on tablet Levothyroxine 100 mcg following which her breathlessness exaggerated.

On examination, the patient was dyspnoeic, tachypnoeic, had anasarca and oral ulcers with lung crepitations. A clinical diagnosis of a volume overload status due to Levothyroxine induced heart failure with underlying connective tissue disease was arrived at and Levothyroxine was stopped. Initial investigations showed mild neutrophilic leukocytosis, elevated ESR with severe nephrotic range proteinuria as Table 3. Her Antinuclear Antibody (ANA) pattern was 3+ with hypocomplementemia. An echocardiogram showed grade 1 diastolic dysfunction. Patient was started on diuretics, noninvasive ventilation, intravenous Methylprednisolone 250 mg injection (3 doses) and albumin infusion. Patient subsequently improved; a week later patient developed sudden breathlessness, a CT pulmonary angiogram showed a left sub segmental pulmonary thromboembolism and antiphospholipid antibodies were also positive. Patient was administered anticoagulation and improved well. Patient was discharged a week later with oral prednisolone 40 mg once daily, oral anticoagulants and Hydroxychloroquine (HCQ). A year later patient is doing well on follow up with normalized disease markers and is on oral Prednisolone 5 mg once daily and Mycophenolate mofetil 500 mg twice daily.

Case 8

45 yr old female patient was admitted with history of fever and cough for 1 week. She was a known case of endometrial carcinoma on chemotherapy. She had undergone her 5th cycle with Paclitaxel a week ago. Patient also had underlying diabetes mellitus and chronic kidney disease, which were conservatively managed.

On examination, the patient was pale, tachypnoeic and febrile with bilateral lung crepitations. Investigations showed severe metabolic acidosis, profound pancytopenia, high procalcitonin and deranged renal functions as summarized in Table 4. Chest x-ray showed left lower lobe pneumonia. A diagnosis of febrile neutropenic sepsis was made and patient was put on aseptic precautions and barrier nursing. She required aggressive management with Granulocyte Colony Stimulating Factor, antibiotics, antifungals, antivirals, antipyretics, bicarbonate infusion and other supportive measures. Patient gradually improved and was discharged with oral antibiotics and had normalized blood counts on follow up.

Case 9

50 yr old male presented with progressive difficulty in walking over the last 8 months. He was diagnosed with retroviral disease 8 years ago and was on Tenofovir, Lamivudine and Ritonavir boosted Atazanavir for the last 4 years.

On examination, the patient was emaciated and decreased range of movements in the lower limbs due to pain. Initial investigations showed hypokalemia, hypophosphatemia with significant metabolic acidosis. Urine showed albuminuria (3+) and glycosuria (3+). His liver functions also showed deranged alkaline phosphatase levels and vitamin D levels were normal (Table 5). Subsequently an X-Ray and Computed tomography of the hips showed bilateral fracture neck of femur. Hence a diagnosis of Tenofovir induced proximal renal tubular acidosis and bone toxicity was arrived at and tenofovir was promptly withheld. Patient was managed with intravenous fluids, potassium and bicarbonate supplementation with thiazide diuretics. Bilateral open reduction with internal fixation was planned, however patient opted conservative management. His HIV viral load and CD4 counts were in the improving trend compared to previous year values. After hypersensitivity testing, patient was started on Abacavir / Lamivudine and Doultegravir regimen and was discharged with oral potassium and bicarbonate supplements. Patient reported to follow up with normal electrolytes and is attending to activities of daily living.

DISCUSSION

Drug related adverse effects are thus not an uncommon entity. Rather it is grossly underreported. This case series has observed drug reactions in 9 patients who were admitted in PSG Institute of Medical sciences and

Table 3: Showing the thyroid pattern at admission, nephrotic range proteinuria and hypocomplementemia in case 7.

Lab parameter	At admission	1 month after discharge	A year later	Reference range
T3 (Serum)	0.37	1.06		0.846 - 2.02 ng/mL
FT4 (Serum)	0.98	1.12		0.932 - 1.71 ng/dL
TSH (Serum)	0.484	1.68		0.27 - 4.2 microIU/ml
FT3 (Serum)	0.64	2.92		2-4.4 Pg/ml
Urine Protein Creatinine Ratio	27.33	10.108	0.070	
Serum Creatinine	0.83			0.66 - 1.09 mg/dL
Serum albumin	0.7 g/dl	1.5	3.4	3.4 - 4.8 g/dL
Complement 3c level	28.42mg/dl	79	102	90 - 180 mg/dl
Complement 4 level	10mg/dl	14	16	10 - 40 mg/dl

Table 4: Showing the pancytopenia and subsequent improvement with treatment in case 8.

Lab parameter	Day of admission	After 1st dose G-CSF	After 3rd dose G-CSF	Day of discharge	10 days after discharge	Reference Range
Creatinine mg/dl	3.6	3.4		2.83	2.6	0.66-1.09 mg/dl
Hemoglobin g/dL	6.7	6.4	5.5	7.6	9.0	13 - 17g/dL
Total WBC 10^3/microL	0.2	0.5	5.1	10.1	5.7	4-10x10^3/uL
Absolute Neutrophil Count 10^3/uL	0.0	0.2	4.7	9.2	4.5	2 - 7x10^3/uL
Plateletsx10^3/uL	64	63	61	82	324	150-400x10^3/uL

Table 5: Showing the hypokalemia and metabolic acidosis pattern in case 9.

Lab parameter	Day 1 of admission	Day 3	Day 5	Month after discharge	Reference range
Serum Creatinine	1.75	1.26	1.6	1.43	0.8 - 1.25 mg/dl
pH	7.230	7.342	7.334	7.33	7.35-7.45
Serum Potassium	2.45	4.6	3.0	3.66	3.5 - 5.0mEq/L
Serum bicarbonate	12.5	15.9	17	21.6	22 - 30mEq/L
Serum ionised Calcium	1.202			1.2	1.1-1.3m mol/L
Serum Phosphous		2.1			2.7-4.5 mg/dl
Serum Alkaline phosphatase	459				40 – 129 U/L

Research, a tertiary care hospital in Coimbatore, Tamil Nadu. They were either referred from their primary care physician and/or admitted in our emergency department with severe drug related adverse events. The discussed 9 patients were on different class of drugs for their respective diagnosis prescribed elsewhere and presented to us with a variety of adverse effects requiring hospitalization or developing grave complications. Fortunately 8 of them recovered with prompt diagnosis and withdrawal of the offending drug.

Azathioprine is an imidazolyl derivative of mercaptopurine which acts by blocking the pathway for purine synthesis. The 6-thioguanine nucleotide metabolites appear to mediate the majority of azathioprine's immunosuppressive and toxic effects. Azathioprine, though a well-established immunosuppressive drug for myasthenia showing improvement in 70-90% patients has its share of serious complications.

Of grave concern is haematological toxicity. Dose-related immediate or delayed severe hematologic toxicities in the form of leucopenia, thrombocytopenia or pancytopenia may occur. Panda BK *et al.* have reported a case of severe pancytopenia in a patient of myasthenia gravis following azathioprine.[5] Other side effect profile includes gastrointestinal disturbances, hepatotoxicity and carcinogenic potential. Therefore it is important to periodically monitor blood counts and educate the patient about the need for the same.

In our case 1, the patient was not aware of the potential complication of his drugs, thereby delayed presenting to the hospital until he had profound leucopenia. With a proper patient education, early diagnosis can be arrived at and prompt action can avoid grave consequences. Case 2 patient was co-prescribed with azathioprine and methotrexate - both contributing to her profound pancytopenia. Patient had a tumultuous hospital course warranting intensive care admission, developed grave fungal and bacterial infections and succumbed to the same. Therefore it is crucial to carefully evaluate and closely follow up patients while co prescribing 2 potential hematotoxic drugs.

Thiopurine methyltransferase (TPMT) genotyping or phenotyping and nudix hydrolase 15 (nucleotide diphosphate [NUDT15]) genotyping may help to identify patients who are at an increased risk for developing azathioprine related hematological toxicity.[6] Once identified, patients may require dose reduction, interruption or selection of an alternate agent altogether.

Methotrexate being a folate antimetabolite inhibits dihydrofolate reductase, thereby hampering purine and thymidylic acid synthesis. DNA synthesis, repair and cellular replication are thus hindered as methotrexate targets actively proliferative tissues more and is therefore used in a number of conditions like rheumatoid arthritis, psoriasis as well as certain malignancies.

Thrombocytopenia (3% to 10%), leukopenia (1% to 3%), pancytopenia (1% to 3%), agranulocytosis, anemia, aplastic anemia, bone marrow suppression are noted hematological adverse effects of methotrexate. That is why it is pertinent to closely monitor the complete blood counts prior to initiation, weekly in the first month of initiation, every 2 to 4 weeks in the first few months and monthly thereafter. In a study of 46 patients on methotrexate in Lucknow, India, it was noted that initial WBC count was a predictor for development of pancytopenia later.[7] Patients with renal insufficiency or older age will require frequent monitoring. Case 3 (a female patient) and case 4 (older age group) had been taking only low dose methotrexate in weekly schedule for years, yet presented with pancytopenia revealing the fact that even low dose methotrexate can cause pancytopenia as a delayed presentation and periodic monitoring is indispensable. These findings are similar to a case series report on methotrexate where pancytopenia was encountered as a later manifestation[8] and another case report which observed low dose methotrexate causing

pancytopenia.[9] Once hematotoxicity is encountered, the drug is withheld, serum methotrexate levels are monitored and leucovorin rescue dosing is done to combat methotrexate effects. Granulocyte Colony stimulating factors will also be required where the patient has persistent pancytopenia. Hepatotoxicity and lung toxicity also require close attention and a baseline work up for the above is mandatory before starting methotrexate.

Leflunomide is an immunomodulatory agent that inhibits pyrimidine synthesis, resulting in its antiproliferative and anti-inflammatory effects. It acts by inhibiting dihydroorotate dehydrogenase and is converted to the active metabolite A771726 on administration.[10] Usually used in rheumatoid arthritis and systemic lupus erythematous. In November 2003, FDA issued a drug safety alert update on leflunomide, warning of rare post marketing reports of bone marrow suppression and sepsis. Though rare (incidence of 1 in 3698 patients) the incidence of pancytopenia is potentiated by concomitant administration of other myelotoxic agents as in case 5 where the patient was on both methotrexate and leflunomide. And myelosuppression can persist even after discontinuing the drug owing to its long half-life. A number of case reports reinforce the fact that hematological toxicities of methotrexate and leflunomide combination therapy are deleteriously additive.[11]

Levothyroxine (T_4) is a synthetic form of thyroxin, which is an endocrine hormone secreted by the thyroid gland. T_4 is converted to its active metabolite, L-triiodothyronine (T_3). Thyroid hormones (T_4 and T_3) then bind to thyroid receptor proteins in the cell nucleus and exhibit their metabolic actions through control of DNA transcription and protein synthesis.

While a decision to start a patient on levothyroxine is arrived at, certain characteristics should be carefully checked. These include patient's weight, lean body mass, etiology of hypothyroidism, pregnancy, age and cardiac disease. Thyroid hormone can be started at anticipated full replacement doses in individuals, who are young and otherwise healthy in most situations, a starting levothyroxine dose of 50-75 μg/day (1.6 μg/kg/day) will suffice. In patients with coronary heart disease, initial dose should be 12.5 to 50 μg/day.[12] Aggressive replacement of thyroid hormone in initial higher doses may worsen cardiac function in patients with existing cardiac disease. That is why it is imperative to start these patients on smaller doses and then titrate in small increments after no less than 4-6 weeks. Achieving a target TSH level at times may take several months owing to delayed preadaptation of the hypothalamic-pituitary axis. Therefore in patients receiving treatment with Levothyroxine, dosing changes should be made every 6-8 weeks only in usual scenarios.

In our case 6, 59 yr old woman was forth right put on high dose levothyroxine 100 micrograms for a TSH value of 6 microIU/ml exacerbating her heart failure. In case 7, though the patient had an underlying connective tissue disease, she was able to attend to her activities of daily living. However challenging her with levothyroxine 100 micrograms for a TSH value of 5.13 microIU/ml clearly exaggerated her symptoms precipitating her cardiac failure resulting in emergency presentation and subsequent prolonged hospitalization, which could have been avoided.

Treatment with levothyroxine in patients with heart failure is associated with a higher risk for all-cause mortality, cardiovascular death and major adverse cardiac events according to findings published in The Journal of Clinical Endocrinology and Metabolism.[13] These events are attributed to the low T3 syndrome. When hypothyroidism is treated with levothyroxine, there is often a relatively high thyroxin/T3 ratio in serum with relatively low liothyronine levels in blood, which could further exacerbate the T3-deficient state in patients with chronic heart failure

Paclitaxel is a natural taxane promotes microtubule assembly by enhancing the action of tubulin dimers, stabilizing existing microtubules and inhibits their disassembly. These actions ultimately halt cell replication thereby modulating the desired immune response. Paclitaxel finds usage in a variety of conditions notably breast, ovarian malignancies, lung cancer and Kaposi sarcoma. Our index patient case 8 was on paclitaxel for endometrial carcinoma. The hematological adverse effects include neutropenia (78% to 98%), leukopenia (grade 4: 17%), anemia (47% to 90%), thrombocytopenia (4% to 20%). It is therefore crucial to regularly monitor the complete and differential blood counts of the patient while on chemotherapy.

Chemotherapeutic agents do exaggerate the immune compromised state of cancer affected patients. Usually the magnitude of the neutrophil mediated component of the inflammatory response may be muted in neutropenic patients with fever sometimes being the only sign of infection. It is critical to recognize neutropenic fever early and to initiate empiric therapy promptly in order to avoid progression to a sepsis syndrome and possibly death. Neutropenic patients have the risk of developing a neutropenic fever syndrome, risk of resultant medical complications as well as risk of non-response to empiric antibiotic treatment.[14]

Certain risk factors are predictive of the development of a neutropenic fever syndrome. Patient-related predictors include age> 65 yrs, female sex, high body surface area and poor nutritional status. Disease-related predictors include elevated lactate dehydrogenase, advanced malignancy staging and myelophthisis. Treatment-related predictors of neutropenic fever include administration of high dose chemotherapy regimens and failure to administer hematopoietic growth factor support to patients receiving high-risk regimens. High risk patients are those who have other co morbidities, significant hepatic or renal impairment or those who are expected to be severely neutropenic (absolute neutrophil count [ANC] <500 cells/microL) for >7 days. The index patient case 8 was a female patient with diabetes mellitus and chronic kidney disease enhancing her risk of pancytopenia.

A number of validated tools are used to calculate the risk index for measuring the risk for neutropenic fever–related medical complications and must be put to effective use wherever possible in tertiary centres.[15] In a research article that investigated the capability of genetic variation in drug metabolizing enzymes and transporters (DMET platform) to predict haematological toxicity, the single nucleotide polymorphism SNP rs 9285726 in MAT1A (methionine adenosyl transferees) and SNP rs 776173 in CYP39A1 were found to be associated with neutropenia. These are potential areas of research in predicting paclitaxel induced hematologoxical toxicity and in picking up individual patients who are at more risk.[16]

Tenofovir disoproxil fumarate (TDF) is a nucleotide reverse transcriptase inhibitor. It interferes with the HIV viral RNA dependent DNA polymerase resulting in inhibition of viral replication exhibiting its action via active tenofovir diphosphate. Nephrotoxicity is a known and established side effect of tenofovir. One study reported that the incidence rate of moderate or severe renal insufficiency caused by tenofovir was 29.2 and 2.2 cases per 1000 person-year respectively. Apart from this tenofovir can also cause interstitial nephritis, lactic acidosis, nephrogenic diabetes insipidus and rhabdomyolysis and decreased bone mineral density.[17]

Tenofovir can rarely cause Fanconi syndrome.[18] It is a proximal tubulopathy causing impaired reabsorption of glucose, aminoacids, bicarbonate and phosphate resulting in their excretion. The presentation of fanconi syndrome can be quite delayed also in a patient on tenofovir.[19] Therefore drug related adverse effect should be considered in any patient presenting with renal tubular acidosis type 2 while on tenofovir regardless of the duration of drug exposure.

Our case 9 patient also developed toxicities 4 years after tenofovir exposure and developed Fanconi's syndrome as well as bone toxicity which is quite rare.[20] The index patient however improved remarkably after stopping Tenofovir and with calcium and phosphate supplementation. This finding is similar to a study from Christian Medical College, South India where the incidence of tenofovir induced renal tubular toxicity has been observed as quite rare (3.6%) and the average latency period between tenofovir exposure and nephrotoxicity was prolonged (42 months).[21] The study suggests that patients on tenofovir should be monitored serially and periodically for proteinuria, creatinine clearance rather than creatinine values, hypophosphatemia and alkaline phosphate levels. Tenofovir alafenamide is the pro-drug of TDF which achieves higher intracellular concentrations rather than plasma concentrations at low dose, thereby resulting in lower toxicities and similar efficacy.

CONCLUSION

Thus it is important to choose and prescribe drugs and their dosage carefully. It is fundamental for the treating doctor to be aware of drug combination/interactions leading to profound side effects. Patient education and awareness of drug related side effects is core in management and helps in averting serious side effects earlier and thereby avoiding unnecessary/prolonged hospitalization and related complications. As a physician it is pertinent to constantly update and learn from errors whether of one's self or others. After all learning and unlearning is part of the continuing medical education process.

Abstract

Background: Dengue infection is an exceedingly common cause of fever in the tropical countries. **Aim:**to study the demographic and clinical profile of Dengue patients**. Design:** Retrospective observational study of serologically proven dengue cases. **Methods and materials:** the study included Dengue patients admitted in PSG Hospital between January 2011 and December 2012. **Results :**Dengue infection was found to be more common in the younger age groups. It was more common in men. It was prevalent across all occupational profiles. The common clinical features included fever, myalgia, headache, abdominal pain, diarrhea and arthralgia. Bleeding manifestations included mucosal and skin bleeds and the commonest bleeding manifestation was melena. There was no major life threatening bleeds. Analysis of the hematological profile showed that nearly 91.5% of patients had thrombocytopenia with 48.9% having severe thrombocytopenia. **Conclusion** : Dengue infection is an important differential diagnosis for acute febrile illness in the tropics which can present with multiple non specific and systemic symptoms with a high incidence of thrombocytopenia.

Key-words: Dengue,Coimbatore,Demography,Tropical,Symptoms

Introduction

The word dengue is derived from Spanish in which it means “affectation”, “careful” or “fastidious” probably to describe the cautious stiff movements of patients suffering from it due to muscle, bone and joint pain. It was considered a sporadic disease in the 19th century. With the advent of globalization and increased travel, the incidence of dengue has increased 30-fold over the past century to become endemic in 112 countries in the world (1).About 50 million people develop dengue infection every year and 2.5 billion people live in endemic areas.(2).Dengue infection is a very important health problem affecting many tropical countries. Dengue is one of the important causes of undifferentiated fevers in India along with malaria, typhoid and other viral infections. Various endogenous studies are available in India, most of which have evaluated a few aspects of the disease spectrum. Some studies have documented the extent of epidemics with data collected during that period. There have been increasing reports of dengue infection with newer manifestations, mainly with hepatic and cerebral symptoms in the past (3,4). We designed a descriptive study of adult dengue infection to describe the demographic and clinical profile. The aim of the study is to provide data on dengue infection in a tertiary care location in Tamil Nadu.

Materials and methods

This study was a retrospective analysis of patients who were admitted in the medical wards of PSGIMSR with febrile illness and diagnosed to have dengue infection by serological analysis. These were mainly adult patients and were admitted between January 2011 and December 2012.All patients screened for this study had undergone dengue serology and only patients who were dengue IgM positive and greater than fifteen years of age were included in this study. Patients with other causes for fever and with coexisting infections were excluded from this study. Demographic data regarding age, gender, occupation and location were collected and tabulated. The spectrums of clinical features were noted. Complete blood count was assessed by coulter.

Results

Our present study was a retrospective analysis of patients presenting to our hospital in the years 2011-2012 who tested serologically positive for dengue infection .We performed a retrospective analysis of demographic and clinical profile of 235 patients with dengue infection who were admitted to our hospital. In our present study, the incidence of dengue infection had the highest incidence between 15-40 years. [FIG 1]. Of the 235 cases of dengue infection 60(25.5%) were primary dengue and 175(74.5%) cases were secondary dengue infection. Among 235 dengue patients, 144 were male and 91 were female. Occupational profile showed equal distribution of blue collar workers (unskilled workers) and students with lesser incidence in house wives and white collar (skilled) workers.[FIG 2]. In our study the commonest symptoms were fever [92%] followed by myalgia [40.4%], headache [42.4%], vomiting [40.4%].[FIG 3].Hepatomegaly seen in 6.80%, Splenomegaly1.30%, lymphadenopathy 0.40%,Plerual effusion 6.40% and abdominal findings 14.90% of individuals. Bleeding manifestations happened in 26.8 % of patients , the commonest of which was melena [7.20%], followed by gum bleeds, ecchymosis,, hematemesis , petechiae and purpura[FIG 4]. When the presence of thrombocytopenia was analyzed, it was found that 91.5% of the patients had low platelet counts [<150000 cells/mm3].

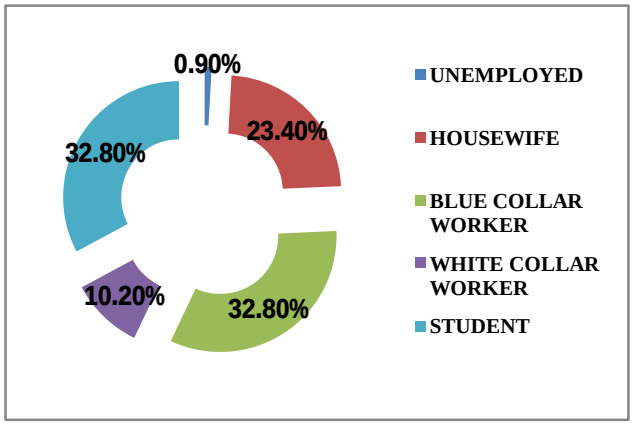

Fig 3.Symptoms of Dengue infection

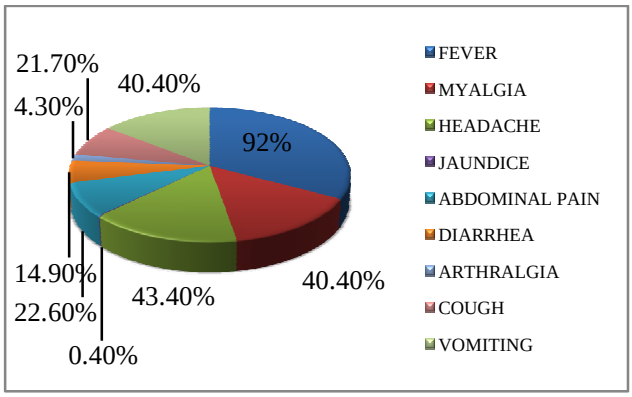

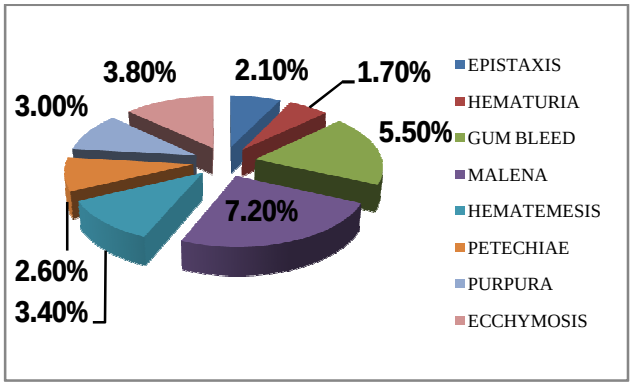

Fig 4.Bleeding Manifestation in Dengue infection

Discussion

There are 2.5 billion people living in the tropical & sub-tropical zones who are at risk of acquiring infection due to ideal environmental conditions for the transmission of dengue virus by Aedes mosquitoes. Outbreaks have occurred in five of six WHO regions over the past 50 years (1). Most of the cases of dengue infection are found in south east Asia and western pacific though it is prevalent in many countries.(2).

Our study included patients above 15 years. The incidence of dengue was least in the older age groups probably in our view because of lesser outdoor activity compared to younger people. This was similar to a study performed by Amir Khan et al (5).n a study by Khoa T.D.Thai et al (6) showed that increasing age lead to increasing risk of clinical attack in both primary and secondary dengue infection. This study was done by obtaining seroprevalence of dengue specific for age and frequency of clinical attack specific for age. This study included pediatric population and the average age of patients with primary and secondary dengue infection were 12 and 20 years respectively.

Our study showed a male preponderance in concordance with a study done by Prafulla Dutta et al (7)and Amirkhan et al(5). Another study from Prasith et al from Lao People's Democratic Republic's also showed a similar male preponderance of dengue infection (8). Majority of the patients were from Coimbatore and nearby districts.

In relation to occupational profile our study differs from the study by Prafulla Datta et al where majority of the patients were blue collar workers (7). This was because their study population was from a rural location and ours is from an urban location.

Secondary dengue infection was more common than primary dengue infection indicating that the majority of the patients had already had an attack of dengue infection.

In addition to the more common complaints such as fever, myalgia, headache, other symptoms included abdominal pain, diarrhea, arthralgia and cough .This was more or less similar to other studies from India done by Prafulla Dutta et al with slight differences (7). Their study showed a higher incidence of eye pain (68.5%) which was not present in our study. Our study showed that 20.4% of patients had cough and 40% of patients had vomiting which had not been reported in the 2003 dengue epidemic in the study by Rachel Daniel et al (10) . Our study had lesser incidence of abdominal pain when compared to the study by Ritu Karoli et al(12). Abdominal pain may be related to inflammation of serosa.This finding was also similar to another study by Muhammad H et al. (11)

There was no major intracranial bleed on our study. In the study by Rachel Daniel et al showed a lower incidence [15.2%] of bleeding manifestations but with 2 major intracranial bleeds .Their commonest bleeding manifestation was melena which was similar to our study (10). In another study by Ritu Karoli et al, hemorrhagic manifestations were higher in 40% of patients with epistaxis being the commonest symptom (12).

The incidence of thrombocytopenia in our study was 91%, which was higher compared to the study by Prafulla Dutta et al (7) where the incidence of thrombocytopenia was 71.3% and similar to the study by Rachel Daniel et al (10) where it 90%.The majority had severe thrombocytopenia [<50000 cells/mm3] (48.9%), with the rest comprising of moderate [50000-100000 cells/mm3](25.1%) and mild[100000 to 150000 cells/mm3] (17.4%) thrombocytopenia. The other 8.5% had normal platelet counts.

Conclusion: This study is a retrospective analysis capturing the demographic and clinical profile of dengue patients. Dengue infection forms an important differential diagnosis of acute febrile illness in the tropics .Since this was a retrospective analysis, not all aspects could be looked into. In future, there is a need for analysis of biochemical parameters of dengue patients.

ABSTRACT

Background: Dengue infection is an extremely common infection in tropical countries. It is considered to be prevalent all-round the year. The aim of the study was to analyse the ultrasound features of serologically proven dengue cases. To correlate the platelet count with ultrasound features of dengue.
Methods: Study included dengue patients admitted from January 2011 to December 2012. Dengue was diagnosed by IgM antibody test. All patients underwent ultrasound evaluation and platelet count testing.
Results: most common finding was ascites in 43 cases (39.8%), splenomegaly in 41 cases (37.9%), right sided pleural effusion in 25 cases (23.4%), gall bladder wall thickening was present in 30 cases (27.7%) and hepatomegaly was present in 20 cases (18.5%). Presence of most of the features of ultrasound evaluation correlated with a platelet count of less than 40000 cells/mm^3.
Conclusions: The commonest sonographic findings were ascites and splenomegaly followed by pleural effusion and gall bladder wall thickening. Thus, presence of these ultrasound features in a febrile patient may be suggestive of dengue fever and presence of all the sonographic features may suggest a low platelet count.

Keywords: Ascites, Gall bladder wall thickening, Sonography, Splenomegaly

INTRODUCTION

Dengue is an extremely common Arboviral infection seen worldwide and highly prevalent in tropical countries. There are approximately 50 million new dengue infections occurring each year. There are about 2.5 billion people living in dengue endemic areas worldwide.[1] The incidence of dengue has been steadily increasing in the last 5 decades.

The spectrum of dengue infections includes classical dengue fever, dengue hemorrhagic fever and dengue shock syndrome. Epidemic dengue is an emerging health problem in South East Asian countries where the vector of dengue infection Aedes Egypti is widely prevalent and is leading to increasing hospitalisation of both children and adults.[2] Our present study is a retrospective analysis of ultrasound findings in serologically proven dengue cases. It also correlates the ultrasound findings with platelet levels.

METHODS

This study was done at PSG Hospital, Coimbatore. The study consisted of a retrospective analysis of 108 serologically proven dengue cases (IgM ELISA positive) admitted between January 2011 and December 2012.

Inclusion criteria included patients above 15 years and other tropical infections including malaria, typhoid scrub typhus and hepatitis were excluded from this study. These patients had undergone platelet count testing by coulter. Ultrasound evaluation of abdomen and thorax was done using Siemens Accuson S3000 and Philips IU 22 machines with 3-5 MHz transducers. Dengue serology was done by Elisa method.

RESULTS

The spectrum of findings in our study included gall bladder wall thickening, pleural effusion, ascites, hepatomegaly and splenomegaly. Out of 108 patients, 30 had gall bladder wall thickening (27.7%), 13 had bilateral pleural effusion (12.03%), 25 had right sided pleural effusion (23.4%). There were no cases of isolated left pleural effusion. 43 patients had ascites (39.8%), 20 had sided hepatomegaly (18.5%), 41 had splenomegaly (37.9%). 40 patients had normal ultrasound studies (37.4%).

Correlation of platelet count with imaging findings

- Gall bladder wall thickening was seen in 19.4%of patients with platelet count less than 40000 and in 5.5% of patients with less than 1 lakh,
- Other common findings in cases with platelet less than 40000 included ascites (28.7%) and pleural effusion (25.8%),
- The commonest finding in our study was ascites followed by pleural effusion and gall bladder wall thickening,
- Out of 41 cases of splenomegaly 14.8%were seen in cases with platelet count less than 40000 cells/mm^3 and in 11.85% of cases with platelet counts between 40000 to 1 lakh cells/mm^3.

Table1: Incidence of different sonographic findings in dengue fever.

Ultrasound findings	Cases	Percentage
Gall bladder wall thickening	30	27.7
Bilateral pleural effusion	13	12.03
Right sided pleural effusion	25	25
Ascites	43	39.8
Splenomegaly	41	37.9
Hepatomegaly	20	18.5
Hepatosplenomegaly	8	7.4
Normal study	40	37.4

Table 2: Correlation of ultrasound findings with platelet count.

USG findings	<40000 cells/mm^3	40000-1 lakh Cells/mm^3	1-1.5 lakhs cells/mm^3	>1.5 lakhs cells/m^3
Gall bladder wall thickening	21 (19.4)	6 (5.5)	3 (2.7)	0
Pleural effusion	28 (25.9)	8 (7.4)	1 (.9)	1 (.9)
Ascites	31 (28.7)	10 (9.2)	1 (.9)	1 (.9)
Hepatomegaly	12 (11.1)	3 (2.7)	4 (2.8)	1 (.9)
Splenomegaly	16 (14.8)	2 (1.8)	9 (8.3)	4 (3.7)

DISCUSSION

Dengue is considered to be one of the most important tropical infections in the world. Dengue infection has increased by thirty-fold worldwide in the last five decades. It is considered to be endemic in at least 100 countries. Severe dengue is an important cause for morbidity and death in adults and children in Asian countries.

Dengue in India has been endemic in 16 states since the beginning. India contributes about 34% of the global burden of dengue infection.[3] From 2011-2012 dengue has spread to the remaining states.[4]

There has been a steady increase in dengue cases in India from 2010 onwards. The principal vector of dengue fever is the Aedes egypti mosquito. The other species which can transmit dengue is the Aedes albopictus mosquito. This virus can undergo transovarian transmission.[5]

Ultrasound findings in dengue infection include gallbladder wall thickening, ascites, pleural effusion and hepatospenomegaly. In very severe cases subcapsular collection of fluid in liver, spleen and fluid accumulation around the kidney can happen. Pericardial effusion can also occur.[6] Our study had gallbladder wall thickening in 27.7% of cases. The differential diagnosis of gallbladder wall thickening includes acute cholecystitis, pancreatitis, hepatitis and diverticular disease.[7] Hence it is considered to be a very nonspecific finding.

In a study by KS Vedaraju et al the incidence of gall bladder wall thickening was 83.3%, ascites was 53.9%.[8] These values were much higher compared to the results obtained in our study. In another study by Sunita Bajaj et al hepatomegaly was the most common finding in 74.5%. This was in contrast to our study which had an incidence of hepatomegaly of 18.5%.[9]

In a study by Dayanand et al, 17.9% of patients had isolated left sided pleural effusion which was absent in our study.[10] Majority of the ultrasound findings in our study was associated with a platelet count of less than 40000 cells/mm^3. This may suggest that patients with all the ultrasound findings may eventually go on to develop low platelet counts. This was similar to the study by Santosh VK et al.[6]

CONCLUSION

The most common ultrasound findings in dengue cases in our study were ascites followed by splenomegaly. Other findings included gall bladder wall thickening, pleural effusion and hepatomegaly. Presence of these ultrasound findings in a febrile patient supports the diagnosis of dengue infection. Also, a significant proportion of the ultrasound findings correlated with a platelet count of less than 40000cells/mm^3. Limitations of this study are that the ultrasound findings were not correlated with age.

ABSTRACT

Background: Dengue fever is an exceedingly common tropical infection in India. It can affect the liver with a wide spectrum of manifestations. The aim of the study was to analyse the liver function tests derangement in serologically proven dengue cases.
Methods: Patients who were Dengue IgM positive were included in this study. All the patients underwent liver function tests.
Results: Of 1oo patients, 33% had less than 2-fold increase in ALT levels, 18% had 2-4-fold increase, 20% had 4-10-fold increase and 11% had more than 10-fold increase. Overall 18% had normal values and 82% had values of ALT above normal. With regard to AST 8% had normal values, 26% had less than 2-fold normal, 26% had 2-4-fold increase, 25% had 4-10-fold increase and 15% had greater than 10-fold increase. 92% of patients had values above normal. Bilirubin levels were elevated in 5% of cases. Alkaline phosphatase levels were elevated in 25% of cases; serum globulins were increased in 9% of cases. Serum proteins were low in 43% of cases and serum albumin was low in 31% of cases.
Conclusions: The spectrum of hepatic involvement in dengue fever can vary from asymptomatic biochemical involvement to severe acute liver cell injury. Hyperbilirubinemia may also be observed. Low albumin levels may be present and may be a marker of the critical phase of the disease.

Keywords: ALT, AST, Dengue fever, Hyperbilirubinemia

INTRODUCTION

Dengue is one of the most important mosquito borne viral diseases which is spreading rapidly throughout the world. It has increased exponentially in the last five decades. There are about 50million new dengue infections occurring each year worldwide.[1] There are about 2.5billion people living in areas where dengue is endemic and hence potentially at risk for infection. The number of dengue cases has gone up from 15497 cases in 1960-1969 to 925896 cases in 2000-2007.[2]

Multiple outbreaks of dengue have happened in India. Reports have come from Bangalore, Punjab and Delhi.[3-5] Most of these cases have been reported in the post monsoon season from September to November. Dengue fever can affect multiple organ systems. There have been reports of dengue fever involving heart, nervous system and liver causing myocarditis, encephalitis and hepatitis. This present study is an analysis of liver function tests abnormalities in dengue fever.

METHODS

Our present study is a retrospective observational analysis of 100 serologically proven dengue patients admitted at PSG Hospital from January to September 2017. Inclusion criteria included patients more than 15

years of age, dengue IgM positive. Exclusion criteria consisted of patients with pre existing liver disease, scrub typhus, malaria and typhoid. All a patient underwent liver function testing.

Bilirubin testing was done by diazo method, alaninine aminotransferase [ALT] was tested by IFCC method, aspartate aminotransferase [AST] was tested by IFCC method. Alkaline phosphatase was tested by IFCC method. Serum proteins were tested by Biuret method, Serum albumin was tested by BCG, dyebind method and serum globulin levels were calculated. Dengue serology was done by ELISA method.

RESULTS

All patients underwent liver function tests. Of 1oo patients, 33% had less than 2 fold increase in ALT levels, 18% had 2-4 fold increase, 20% had 4-10 fold increase and 11% had more than 10 fold increase.

Overall 18% had normal values and 82% had values of ALT above normal. With regard to AST 8% had normal values, 26% had less than 2 fold normal, 26% had 2-4 fold increase, 25% had 4-10 fold increase and 15% had greater than 10 fold increase. 92% of patients had values above normal.

Bilirubin levels were elevated in 5% of cases. Alkaline phosphatase levels were elevated in 25% of cases, serum globulins were increased in 9% of cases. Serum proteins were low in 43% of cases and serum albumin was low in 31% of cases.

Table 1: Range of aminotransferase elevations in dengue fever.

	ALT number	ALT %	AST number	AST %
Normal	18	18	8	8
<Two fold rise	33	33	26	26
Two-four fold rise	18	18	26	26
Four-ten fold rise	20	20	25	25
>Ten fold rise	11	11	15	15

Table 2: Ranges of increased bilirubin, alkaline phosphatase and globulin levels.

Tests	Number	%
Bilirubin > 2mg/dl	5	5
Alkaline phosphatase increased	25	25
Serum globulins increased	9	9

Table 3: Range of protein levels in dengue fever.

Serum proteins	Number	%
Low	43	43
Normal	57	57
Increased	0	0

Table 4: Range of serum albumin levels in dengue fever.

Serum albumin	Number	%
Low	31	31
Normal	69	69
Increased	0	0

DISCUSSION

Dengue infection is known to affect the liver. The liver injury is not fully manifest in the early stages of dengue fever. The cause for the liver dysfunction is thought to be multifactorial. It is postulated that liver damage may happen secondary to hypoxia, direct effect of virus or immune mediated damage.[6] The spectrum of liver involvement in dengue fever varies from asymptomatic elevation of transaminases to severe liver involvement in the form of acute liver cell failure. Dengue virus targets the hepatocytes and the kupffer cells in the liver.[7] Virus enters the cells by binding to receptors and is taken inside the cell by endocytosis.

The final outcome of hepatic involvement is apoptosis of cells. Biopsies done on patients with dengue fever have revealed patterns such as microvascular steatosis, liver cell necrosis, councilman bodies and portal tract inflammation.[8]

Asymptomatic derangement in liver function tests are common findings. Rarely dengue fever can cause acute liver cell injury. Patients may present with pain in the right hypochondrium, hepatomegaly and jaundice.[9]

In a study by Amit Soni et al, with regards to AST levels, it was shown that 45.6% had less than 3 fold elevation, 36.7% had 3-10 fold elevation and 16.4% had greater than 10 fold elevation.[10] In the same study with regards to ALT, 27.8% had 1-3 fold elevation, 59.4% had 3-10 fold elevation and 8.9% had greater than 10 fold elevation. In this study AST elevation was more than ALT which was similar to our study. The increased AST/ALT ratios can be used to differentiate dengue infection from viral hepatitis where it is infrequently seen.[7] The incidence of AST and ALT elevations more than 10 fold were also comparable to our study.

In a study by Parkash et al, 3.1% of patients had hyperbilirubinemia which was comparable to our study which had 5 %.[11] Larreal Y et al in their study had reported hyperbilirubinemia in 2 out of 63 cases.[12]

In a study by Samatha Fernando et al, serum proteins were low in 63.6% of cases and serum albumin was low in 54.5% of cases.[6] This was in slight variance with our study where serum proteins were low in 43% and serum albumin was low in 31% of cases. In a study by Brito et al, it was shown that 71% of cases with dengue hemorrhagic fever had hypoalbuminemia concluding that serum albumin level was a marker for critical stage of the

infection where there was increased vascular permeability.[12] Our study did not differentiate between classical dengue and dengue hemorrhagic fever.

In a study by Rajoo Singh Chhina et al, alkaline phosphatase levels were elevated in 30.3% of cases with dengue fever and 40% of cases with dengue hemorrhagic fever.[13] This was comparable to our study where alkaline phosphatase was elevated in 25% of cases.

CONCLUSION

The spectrum of hepatic involvement in dengue fever can vary from asymptomatic biochemical involvement to severe acute liver cell injury. Hyperbilirubinemia may also be observed. Low albumin levels may be present and may be a marker of the critical phase of the disease. Treatment is usually supportive. Limitation of this study is that differentiation between classical dengue fever and dengue hemorrhagic fever was not done. Also, coagulation function of the liver in the form of prothrombin time was not assessed especially in patients with severe elevations of aminotransferases.

ABSTRACT

Background: Dengue is an extremely important tropical disease transmitted by the Aedes aegypti mosquito. Aim of the study: to study the white blood cell levels in serologically proven dengue cases; to study hematocrit levels in cases of dengue fever.
Methods: The present study is a retrospective observational analysis of white blood cell count (WBC count) and hematocrit in 235 serologically proven Dengue cases admitted in the years 2011-2012
Results: 107 cases (45.5%) had leukopenia, 111 cases (47.2%) had normal WBC counts and 12 cases had leukocytosis (5.1%). 23 cases had increased hematocrit (9.8%), 76 cases had a low hematocrit (32.3%) and 128 cases had a normal hematocrit (54.5%).
Conclusions: A significant proportion of patients had leukopenia which may be an early marker of dengue infection. Only a small percentage of patients had raised hematocrit. It may be that rise from baseline levels of haematocrit which may be more significant than absolute values.

Keywords: Dengue fever, Leukopenia, Raised hematocrit

INTRODUCTION

Dengue is a very important viral disease transmitted by the bite of the infected Aedes aegypti mosquito. It has been increasing year after year and has expanded into multiple countries all over the world. There are about 50 million new dengue infections each year worldwide.[1] World health organization has stated that dengue infection can be considered to be a public health emergency because of its capacity to spread exponentially beyond national borders.

Dengue infection shows great variability in its incidence with high epidemic and non-epidemic years. It can present as large outbreaks of infection and also shows seasonal variation. There are multiple serotypes of dengue virus circulating in India.[2]

Dengue infection can be classified into undifferentiated fever, dengue fever and dengue hemorrhagic fever.[3] Dengue hemorrhagic fever is further classified into 4 subtypes of which 3 and 4 are representative of dengue shock syndrome.

It can present with wide variety of symptoms. They include gastrointestinal symptoms such as anorexia, nausea, vomiting; skin manifestation such as rash, musculoskeletal features such as myalgia and arthralgia and laboratory manifestations such as leukopenia.[4]

METHODS

The present study is a retrospective observational analysis of white blood cell count (WBC count) and hematocrit in 235 serologically proven Dengue cases

admitted in the years 2011-2012. Inclusion criteria included patients above 15 years of age and were Dengue IgM positive.

Exclusion criteria excluded patients with other tropical infections such as malaria, typhoid and scrub typhus. Dengue serology was done by Elisa method.

WBC count and hematocrit were done by coulter technique. WBC count less than 5000 cells/mm^3 was taken as leukopenia and WBC count greater than 10000 cells/mm^3 was taken as leukocytosis.[5] Hematocrit of less than 40% was taken as low and greater than 45% was taken to be raised hematocrit.

RESULTS

235 patients were part of the study. All the patients included in our study were Dengue IgM positive. WBC count was available for 230 patients. Our analysis showed that 107 cases (45.5%) had leukopenia. About 111 cases (47.2%) had normal WBC counts and 12 cases had leukocytosis (5.1%).

The comparison of leukopenia in our study has been done with other studies in Table 2 with the values varying in different studies. Hematocrit values were available for 228 patients. 23 cases had increased hematocrit (9.8%), 76 cases had a low hematocrit (32.3%) and 128 cases had a normal hematocrit values (54.5%).

Table 1: Range of distribution of white blood cell count.

WBC count	Number	Percent
Normal	111	47.2
Low	107	45.5
High	12	5.1
Not done	5	2.1
Total	235	100.0

Table 2: Different studies showing incidence of leukopenia.

Study	Leukopenia (%)
Christopher et al	87
Shyamsundar khatroth	20
Rajesh Deshwal et al	20.1
Present study	47.2

Table 3: Range of distribution of hematocrit levels.

Hematocrit	Number	Percent
Normal	128	54.5
Low	76	32.3
High	23	9.8
Not done	8	3.4
Total	235	100.0

DISCUSSION

Dengue fever has three phases namely, the febrile phase, the critical phase and the stage of plasma leakage. The febrile phase is characterized by dehydration. In the critical phase there is plasma leakage with accumulation of fluid in third spaces such as pleural and peritoneal cavities and the recovery phase may lead to hypervolemia especially if large amounts of fluids are being administered.

The febrile phase is the symptomatic stage and leukopenia may be present in this stage. Also increasing leukopenia precedes the stage of plasma leakage. In a study by Christopher J Gregory et al which dealt with the utility of tourniquet test and WBC count as a marker to differentiate dengue fever from other febrile illnesses, the authors showed that 87% of dengue cases had leukopenia compared to 28% of non dengue cases.[6] The conclusion was that leukopenia could be taken up as one of the indicators to separate dengue from other febrile illnesses. The other indicator was a positive tourniquet test.

In another study by Kalyanarooj S et al, the authors concluded that early dengue infection was characterised by leukopenia.[7] In a study by Rajesh Deshwal et al, the incidence of leukopenia was 20.19%. In another study by Shyamsundar Khatroth showed that the incidence of leukopenia was 20%.[8]

In our study the incidence of leukopenia was 47.2% which was higher than the studies by Kalyoonrooj et al and Rajesh Deshwal. It is possible that a substantial subset of patients in our study could have presented in the febrile phase of the illness.

Rising hematocrit levels are a marker of the critical phase of dengue infection. After leukopenia there is the stage of plasma leakage where there are third space losses. Ultrasound and chest X-ray are useful tools to detect pleural effusion and ascites which are characteristic of this stage. The extent up to which hematocrit rises from the baseline can indicate the severity of plasma leakage. In a study by Francisca Raimunda et al, hematocrit was shown to be increased in patients with Dengue hemorrhagic fever.[9]

In another study by Kailash C Meena et al the percentage of patients with raised hematocrit was 9.8%.[10] The percentage of patients with raised hematocrit in our study was 9.8% which was similar to Kailash C Meena' s study.

CONCLUSION

Our study had an incidence of leukopenia of 47.2% which was higher than other comparable studies. Presence of leukopenia could be a marker of early dengue infection especially when combined with other indicators. The incidence of increased hematocrit was 9.8%. Rising

hematocrit may be a marker for the stage of plasma leakage necessitating increased fluid administration. Drawback of this study was that few patients did not undergo all the tests. More studies are required to look for serial WBC count and hematocrit levels during the course of dengue infection.

Abstract

Background: Coronary artery disease is a continuum of a pathological process, in which the coronary arteries gradually thicken, harden and atherosclerotic plaques develop which further occludes the blood flow. The prevalence of coronary artery disease is rapidly rising in India. There are various risk factors of CAD which have been extensively studied, out of which Type-2 diabetes is an important etiopathogenic factor of accelerated CAD. Insulin resistance plays an important role in the pathogenesis of the development of type- 2 diabetes. Despite the clear relationship between type-2 diabetes and CAD**,** the association of insulin resistance and CAD is more obscure in people without diabetes: **Aims & Objectives:** To find the association between insulin resistance and Coronary artery disease, to evaluate the role of postprandial lipid profile and its relationship with development of CHD and the evaluation of apolipoproteins (a and b) on the same group. **Subjects and Methods:** Fifty patients of coronary artery disease admitted to ICCU/CCU of psg institute of medical sciences and research were studied. The cases of this present study were 50 non diabetic CAD patients and controls were selected based on age and sex matched non diabetic 'and non CAD patients who has to undergo similar set of investigations as cases to find out association of insulin resistance by using HOMA score and to find out the significance in abnormalities of postprandial lipid profile in these patients. **Results:** 92% of the cases had insulin resistance, 52% of the controls had normal HOMA score when compared to cases. Apolipoprotein b was significantly elevated in cases (84%) than controls**.** All patients were normoglycemic. Serum triglycerides were significantly high in cases than controls in both fasting and postprandial states. **Conclusion:** Improving insulin sensitivity would offer substantial benefits by decreasing the morbidity, mortality, and economic burden associated with CAD especially in the country like India

Key words: Insulin Resistance, Coronary Artery Disease, Homa Score

Introduction

Coronary artery disease is a continuum of a pathological process, in which the coronary arteries gradually thicken, harden and atherosclerotic plaques develop which further occludes the blood flow [1]. This leads to clinical manifestations such as angina and acute coronary events resulting from disruption of plaques, such as acute coronary syndromes, myocardial infarction and death [1,2].

Manuscript received: 16th December 2016
Reviewed: 26th December 2016
Author Corrected: 04th January 2017
Accepted for Publication: 11th January 2017

The prevalence of CAD is rising rapidly in rural India. Lifestyle changes and aggressive control of risk factors are urgently needed to reverse this trend. Asian Indians have considerably higher prevalence of premature coronary artery disease and standardized mortality rates for CAD compared with Europeans.

Within the Indian subcontinent, a dramatic increase in the prevalence of CAD has been predicted in the next 20 years due to rapid changes in demography and lifestyle consequent to economic development [3, 4].

There are various risk factors of CAD which have been extensively studied, out of which Type-2 diabetes is an important etiopathogenic factor of accelerated CAD. Insulin resistance plays an important role in the pathogenesis of the development of type- 2 diabetes. Elevated insulin levels and insulin resistance may be evident several years prior to the diagnosis of type-2 diabetes. There are evidences supporting association of Insulin and CAD which indirectly reflects glucose intolerance, hypertension and dyslipidemia. However, the results from several studies are conflicting. Despite the clear relationship between type-2 diabetes and CAD**,** the association of insulin resistance and CAD is more obscure in people without diabetes [5, 6].

It is well established that dysfunctional endothelium contributes to development and progression of atherosclerosis. Consequently, early detection and treatment of endothelial dysfunction may be an attractive strategy for preventing CAD**.** Unfortunately, established validated methods for assessment of endothelial dysfunction for chronic heart disease risk prediction in the clinical setting are not currently available. Current techniques to assess endothelial function are invasive, expensive, or suffer from lack of high sensitivity, specificity, reproducibility, or clinically defined cut-off values. Therefore, at this time, targeting established and modifiable risk factors for endothelial dysfunction and insulin resistance is the best primary strategy to prevent these conditions [7, 8].

Hypercholesterolemia and hyper triglyceridemia are considered the independent risk factors but most of the earlier studies in this area have considered only the fasting lipid profiles and lipoproteins. Recently it has been proposed that postprandial lipoproteins may be better indicators of deranged lipoprotein metabolism and hence of atherosclerosis and CHD. Postprandial hypertriglyceridemia (PHTG) and delayed triglyceride (TG) rich lipoprotein clearance have been found to impair endothelial function significantly either directly or by increasing superoxide anions.

It has also been reported that magnitude and duration of postprandial lipidemia is positively related to the pathogenesis and progression of CHD [9]. There is comparatively more transfer of cholesterol and cholesterol esters from HDL to LDL in postprandial state leading to their low levels and this along with higher triglycerides and VLDL levels are better indicators of coronary heart disease [10].

Aims & Objectives

- To find the association between insulin resistance and Coronary artery disease
- To evaluate the role of postprandial lipid profile and its relationship with development of CHD
- Evaluation of apolipoproteins (a and b) on the same group

Materials and Methods

Fifty patients of coronary artery disease admitted to ICCU/CCU of PSG Institute of medical sciences and research were studied. The cases of this present study were 50 non diabetic CAD patients and controls were selected based on age and sex matched non diabetic ‘and non CAD patients who has to undergo similar set of investigations as cases to find out association of insulin resistance by using HOMA score [11] and to find out the significance in abnormalities of postprandial lipid profile in these patients. Patients with Acute coronary event and Non diabetics were selected as cases and the patients with Diabetics on insulin/ Oral hypoglycemic agents, Severe cardiac failure (classes 3–4), Renal hepatic, and other systemic diseases, Morbid obesity, History of malignancy and Previous h/o dyslipidemia were excluded. The selected patients were studied in detail with history and physical examination. Complete blood picture, Urine analysis, Renal function tests fasting Blood sugar and postprandial blood sugar, glycosylated haemoglobin, Fasting and post prandial lipid profile. Apolipoprotein a and b Fasting insulin levels, Chest x-ray, Electrocardiogram Echocardiogram and Coronary Angiography were done in patients. The estimation of Insulin resistance by HOMA score = fasting insulin (Mu/L) × fasting glucose (mmol/L)/22.5. The study Parameters entered in Microsoft Excel spread sheet and statistically analysed using Chi-square and Fisher Exact test to find the significance of proportion of incidence of insulin between various levels of study parameters namely BMI, Age, abnormal lipid profile and complications etc. and Student t test to find the significance of mean levels of lab parameters between the presence and absence of insulin resistance.

Results

Among cases 70% of patients were males and 30% were females, Among controls 66% patient were males and 34% were females .10% of the CAD patients and 9% of the controls had habit of consuming smoking and alcohol. 72% of the cases and 68% of the control are obese. 92% of the cases had insulin resistance, 52% of the controls had normal HOMA score when compared to cases. Apolipoprotein b was significantly elevated in cases (84%) than controls**.** All patients were normoglycemic. Serum triglycerides were significantly high in cases than controls in both fasting and postprandial states.HDL and Total cholesterol was unchanged both in fasting and postprandial state LDL cholesterol was found to be mildly increased in patients but not significantly as fasting level. TG/HDL RATIO was found to be >4 in cases with insulin resistance when compared to those without insulin resistance. TC/HDL RATIO was found to be > 3.5:1 in high in cases & controls with Insulin resistance (72%, 43.2% respectively) when compared to patients without insulin resistance. Post prandial triglycerides where high when compared to fasting levels among cases when compared to controls. Percentage of postprandial hypertriglyceridemia was much higher in cases when compared to controls. Significant association of Obesity & Insulin resistance in cases and controls (Table 1& 2)

Table-1: Relationship between Insulin Resistance and BMI Fishers exact test- Cases

	Normal		Obese		Total		P value
	No	%	No	%	No	%	0.041*
Normal	4	40.0	4	10.0	8	16.0	
Abnormal	6	60.0	36	90.0	42	84.0	
Total	100	100.0	40	100.0	50	100.0	

Table-2: Relationship between Insulin Resistance and BMI Fishers exact test- Controls

	Normal		Obese		Total		P value
	No	%	No	%	No	%	0.002*
Normal	22	68.8	4	22.2	26	52.0	
Abnormal	10	31.2	14	77.8	24	48.0	
Total	16	100.0	34	100.0	50	100.0	

Discussion

Coronary artery disease (CAD) is continuums of a pathological process, in which the coronary arteries gradually thicken & harden and atherosclerotic plaques develop that further occlude blood flow. This leads to clinical manifestations such as angina and acute coronary events such as acute coronary syndromes, myocardial infarction and death, due to the disruption of plaques.

Coronary artery disease is the leading cause of death in India and is also the leading cause of death worldwide. It was previously thought to affect primarily the population of developed countries. CAD now leads to more death and disability in developing countries such as India. CAD affects people at younger ages in developing countries compared to developed countries, thereby having a greater economic impact. Effective screening, evaluation and management strategies for coronary artery disease are well established in developed countries, but these strategies are not fully implemented in India. For the development & implementation of such strategies identifying the risk factors is an important initial step.

An effort has been made to recognize insulin resistance in non-diabetic CAD patients which is a simple and non-invasive practical tool. It requires only a single sample assayed for Insulin and glucose and can be calculated by HOMA score [11].

There was significant insulin resistance (IR) (92%) among cases. This is similar to a study done by Bertoluci et al [12] from Brazil which showed 82.6% of CAD patients had insulin resistance when compared to the controls/non CAD group. Another American study by David et al [13] showed that IR was responsible (96%) for 46.8%, 6.2% and 12.5 % of the annual CHD events in diabetics, non-diabetics and total US

population respectively. Yet another study by E. Devici et al [14] which compared Insulin resistance among normoglycemic patients with CAD revealed significant association of IR. Metabolic syndrome was similar in both the control and cases and thus HOMA IR values may provide more sensitive information than the Metabolic syndrome definitions about the association of IR and CAD in normoglycemic patients. Like the above study quoted, there was significant association of obesity and Insulin Resistance in our study which was 84% In the CAD group and 77.8% in the non CAD group. Approximately 50% of patients with essential hypertension, both treated and untreated, appear to be insulin resistant based on the study by Roopa et al [15].

Significance of the postprandial lipid profile in patients with CAD is a new and emerging study which has only limited references & is not practiced routinely day to day clinical setup. In this study Serum triglycerides were significantly high in cases than controls in both fasting and postprandial states. Total cholesterol was unchanged both in fasting and postprandial state. HDL cholesterol was found to be decreased significantly in fasting state, but LDL cholesterol was found to be mildly increased. A study by Vijay et al[16] done in Haryana showed significant elevation of Serum TG, total cholesterol and VLDL – cholesterol in patients than controls in both fasting and postprandial states ($p<0.001$) and HDL-cholesterol was found to be decreased significantly in fed state only ($p < 0.05$).

It concluded that there is comparatively more transfer of cholesterol and cholesterol esters from HDL to LDL in postprandial state leading to their low levels and this along with higher triglycerides and VLDL levels are better indicators of coronary heart disease. Apoprotein b was significantly higher in CAD group when compared to controls which is similar to a study by Bertsch RA et al [17] which showed that these pro-atherogenic lipoproteins were strong predictors of CAD when compared to the non HDL cholesterol. In those controls (4 patients) in whom Apo B was elevated there was also Insulin Resistant.

Among them, 2 patients were hypertensive and their ECHO and ECG showed features of left ventricular hypertrophy. Other two were obese without pre morbidities and had non specific ST-T changes in ECG with a normal ECHO study. Apo B, TG/HDLc ratio and Tc/HDL ratio were significantly higher among patients with insulin resistance

Conclusion

There is insulin resistance in patients with coronary artery disease and also among non diabetic patient who are obese. Apolipoprotein b levels where significantly raised in CAD patients. Serum triglycerides were significantly high in cases than controls in both fasting and postprandial states. Percentage of postprandial hypertriglyceridemia was much higher in cases when compared to controls. Fed state did not alter the total cholesterol/ LDL/HDL significantly. Patients with IR had high TGL/HDLc, TC/HDLc and Apo B values. Fasting Insulin and Insulin resistance (HOMA SCORE) can be included as one of the panel of investigations to assess the risk factor of CAD among nondiabetic population. Earlier identification of these patients would help to intervene and improve the quality of life. Improving insulin sensitivity would offer substantial benefits by decreasing the morbidity, mortality, and economic burden associated with CAD, especially in the country like India.

ABSTRACT

Background: Gastro esophageal reflux disease is the commonest pathologies encountered by gastroenterologist in day to day practice. Longstanding and untreated gastro esophageal reflux disease can lead to many complications including adenocarcinoma. This study was conducted to evaluate the various symptoms and to analyze the lifestyle and dietary factors influencing gastro esophageal reflux disease which can be modified.
Methods: Hundred patients with gastro-esophageal reflux disease of age more than 18 years were enrolled in the study. Various patient details including demographic details, lifestyle information and symptomatology data were analyzed and compared with complications.
Results: Mean age of gastro esophageal reflux disease patients was 56.09±15.93 years. Gastro esophageal reflux disease is more prevalent in males than females. Gastro esophageal reflux disease is more frequent in BMI <25, greater number of co morbidities and in non-vegetarians. Mean age of gastro esophageal reflux disease with complications was 67±11.53 years and without complications was 52.64±15.57 years. No strong association of smoking, alcohol, spicy foods, fried foods, citrus fruits, heavy meals, tea/coffee, aerated drinks, sleep disturbance and effect on work was identified in gastro esophageal reflux disease.
Conclusions: Classical symptoms of gastro esophageal reflux disease were not present in all the patients. Higher age of the patient infers higher risk of complications. Daily episodes of heartburn, regurgitation and retrosternal chest pain implies higher risk of complications. Presence of *Helicobacter pylori* in gastro esophageal reflux disease patients signify higher risk of complications.

Keywords: Adenocarcinoma, Gastro esophageal reflux, Heartburns, Regurgitation, Retrosternal chest pain

INTRODUCTION

Gastro esophageal reflux disease (GERD) is defined as a condition due to reflux of stomach content into the esophagus causing trouble symptoms or complications or both.[1] GERD is one amongst the common gastro-esophageal junction pathologies encountered by gastroenterologist in day to day practice. GERD occurs either due to patulous lower esophageal sphincter or increased pressure within the stomach. It has a wide variety of clinical presentations ranging from gastrointestinal (common) to extra-gastrointestinal (uncommon) symptoms. Common gastrointestinal symptoms are heartburn, regurgitation and retrosternal chest pain. Less common gastrointestinal symptoms are dysphagia and odynophagia. Extra-gastrointestinal symptoms are bronchial asthma, laryngitis, hoarseness of voice, chronic cough, sore throat and dental erosions. Furthermore, longstanding and untreated GERD leads to morbid complications such as esophageal ulcer, Barrett's esophagus, esophageal stricture and adenocarcinoma

Every year GERD affects approximately 4.5/1000 persons in the United Kingdom and 5.4/1000 persons in the United States.[2,3] In Western populations, the prevalence of GERD ranges from 10% to 20%. GERD symptoms occur at least once a month in 44%, once a week in 20% and daily in 7% of the adult US population.[4-6] However, studies describing the epidemiology of GERD in South-East Asia and for that matter in India are sparse; and traditionally GERD was thought to be uncommon in the developing countries, on the other hand, studies in the multiethnic population showed that people of Indian origin are at higher risk of GERD than ethnic Malay and Chinese.[7,8] And the studies done in India emphasize that the prevalence of GERD in India is likely to be between 8% and 20%, which is comparable with GERD prevalence rates published in western countries.[9] In addition, these studies highlight that the risk factors for GERD are related to diet and life-style preferences, which are both modifiable risk factors. Hence this study was conducted to evaluate the various symptoms and to analyze the lifestyle and dietary factors influencing it which can be modified. The study also evaluates the association of clinical, lifestyle and endoscopic characteristics with complications of GERD.

METHODS

It was a cross sectional observational study done between February 2016 to March 2017 at the Department of Medicine in a tertiary care hospital in south India. Total of 100 patients with upper gastrointestinal endoscopy proven Gastro-esophageal reflux disease of age more than 18 years were enrolled in the study. Patients with mass lesion in oesophagus or stomach, oesophageal varices, history of corrosive ingestion, pregnant women and terminally ill patients were excluded from the study.

Prior to the commencement of the study, ethical clearance was obtained from Institutional Human Ethical Committee. The selected patients were briefed about the nature of the study and written informed consent was obtained from them in regional language. Subsequently, patients were interviewed for demographic details, lifestyle information, and symptomatology data. The patients were divided into GERD with complications and GERD without complications. The demographic, lifestyle and symptoms of the two groups were compared.

Statistical analysis

Data was analyzed using SPSS version 20.0 statistical software. Categorical variables were expressed as percentages and the comparative analysis was done using chi-square test or Fischer exact test. Continuous variables were expressed as mean±standard deviation (SD) and the comparative analysis was done by independent sample 't' test. A probability value (p value) of less than or equal to 0.05 at 95% confidence interval was considered as statistically significant.

RESULTS

A total of 100 patients, diagnosed of Gastro-esophageal reflux disease (GERD) based on UGI scopy were enrolled in this study. Mean age of GERD patients was 56.09±15.93 years (Range: 20 - 82 years). Demographic parameters analyzed were age, sex and BMI of the patients. Lifestyle parameters assessed were smoking, alcohol, spicy food and fried food intake, intake of meat, tea / coffee, citrus fruits, aerated drinks, heavy meals, sleep disturbances and effect on daily work. Clinical symptoms evaluated were heartburn, regurgitation, retrosternal chest pain, dysphagia, odynophagia, positional variation of these symptoms. In addition, presence of *Helicobacter pylori*, GERD grades and its complications were also analyzed.

Table 1: Distribution of demographic parameters.

Sex	Distribution
Male	75
Female	25
Body mass index	
<25	70
>25	30
Number of co morbidities	
<3	48
>3	21
Absent	31

From the Table 1 it is seen that GERD is more prevalent in males than females with male to female ratio of 3:1. It is also seen that GERD is more frequent in BMI <25 and with greater number of co morbidities.

Table 2: Distribution of life style parameters.

Parameter	Present	Absent
Smoking	52	48
Alcohol	44	56
Non veg habit	75	25
Intake of spicy foods	59	41
Intake of fried foods	26	74
Intake of citrus fruits	13	87
Heavy meal intake	33	67
Sleep disturbance	32	68
Effect of work	9	9
Tea/coffee intake (>3 cups / day)	39	61
Aerated drinks intake (>5 drinks / week)	4	96

From the Table 2, it is seen that GERD is more prevalent in non-vegetarians than vegetarians. It is also seen that there was no strong association of smoking, alcohol, spicy foods, fried foods, citrus fruits, heavy meals, tea/coffee, aerated drinks, sleep disturbance or effect on work with GERD.

From the Table 3, it is seen that classical symptoms of GERD such as heartburn, regurgitation and retrosternal chest pain were not present in all the patients. It is also seen that dysphagia and odynophagia were less frequent in GERD.

Table 3: Distribution of clinical symptoms.

Clinical symptom	≤2/ Week	>2/ Week	Daily	Absent
Heart burns	11	41	22	26
Regurgitation	31	25	19	25
Retrosternal chest pain	32	9	25	34
Dysphagia	5	3	17	75
Odynophagia	1	3	14	82

Prevalence of GERD complications were 24% in present population. Most common complication was erosive esophagitis followed by Barrett's esophagus and esophageal stricture. Furthermore, we divided the total of 100 GERD patients into two groups: GERD with complications (24 patients) and GERD without complications (76 patients) and analyzed the documented variables between these two groups.

Table 4: Demographic variables between GERD with complication and without complications.

Demographic parameters	Independent 't' test		
	Complication Mean±SD	Without complication Mean±SD	P value
Age	67.00±11.78	52.64±15.68	0.000*
BMI	23.00±3.42	23.42±4.19	0.657
	Chi square test		
Sex	67% males	78% males	0.279
	33% females	22% females	

From the Table 4 it is seen that mean age of GERD with complications was 67±11.53 years (Range: 41 - 82 years) and mean age of GERD without complications was 52.64 ± 15.57 years (Range: 20 - 82 years). Age of the patient showed significant association with the presence of complications (p= 0.000). Higher the age of the patient, higher is the risk of complication. There was no significant difference in presence of complications with sex of the patient.

From the Table 5, it is seen that daily episodes of heartburn, regurgitation and retrosternal chest pain implies higher risk of complications (p=0018, 0.023, 0.016 respectively). It is also seen that, although dysphagia and odynophagia showed p value of < 0.05, they didn't exhibit strong association between these two groups due to lower likelihood ratio of 47.84 and 62.38 respectively.

Table 5: Clinical variables between GERD with complication and without complications.

Clinical parameters	Independent 't' test		
	GERD with complication Mean±SD	Without complication Mean±SD	P value
Number of co-morbidity	1.67±1.30	1.38±1.38	0.375
	Chi square test		
Heart burns	0% <2/wk	14 % <2/wk	0.018*
	17 % ≥2/wk	49 % ≥2/wk	
	83% daily	3% daily	
	0% absent	34% absent	
Regurgitation	0% <2/wk	41% <2/wk	0.023*
	25 % ≥2/wk	25% ≥ 2/wk	
	75% daily	1% daily	
	0% absent	33% absent	
Retrosternal chest pain	0% <2/wk	42 % <2/wk	0.016*
	17 % ≥2 /wk	7 % ≥ 2/wk	
	83% daily	6% daily	
	0% absent	45% absent	
Dysphagia	0% <2/wk	7 % <2/wk	0.025*
	13% ≥2/wk	0 % ≥2/wk	
	54% daily	4% daily	
	29% absent	89% absent	
Odynophagia	0% <2/wk	1 % <2/wk	0.035*
	13% ≥ 2/wk	0 % ≥ 2/wk	
	58% daily	0% daily	
	29% absent	99% absent	
Positional variation of symptoms	25% present	25% present	1.000
	75% absent	75% absent	

From the Table 6, it is seen that none of the lifestyle parameters had significant difference between two groups.

From the Table 7, it is seen that, presence of *Helicobacter pylori* in GERD patients signifies higher risk of complications (p=0.000).

DISCUSSION

In present study, authors found that out of 100 GERD patients, 75% were males and 25% were females with male to female ratio of 4:1. Present findings were in contrary to previous meta-analysis study by Kim YS et al, who inferred that GERD affects more frequently women than men.[10]

In this present study, we found that 70% of the patients had BMI <25 and 30% of the patients had BMI ≥25, contradicting the inference of previous study by Jacobson BC et al, who found that GERD symptoms exacerbation is more frequent in patients with BMI of ≥25.[11]

Table 6: Lifestyle parameters between GERD with complication and without complications.

Lifestyle parameters	Chi square test		
	GERD with complication	GERD without complication	P value
Smoking	50% present	53% present	0.822
	50% absent	47% absent	
Alcohol	37% present	46% present	0.462
	63% absent	54% absent	
Veg vs nonveg	37% Veg	21% veg	0.105
	63% Non veg	79% Non veg	
Spicy foods	50% present	62% present	0.304
	50% absent	38% absent	
Fried foods	29% present	25% present	0.685
	71% absent	75% absent	
Citrus fruits	4% present	16% present	0.140
	96% absent	84% absent	
Tea / coffee	38% frequent	39% frequent	0.978
	16% infrequent	18% infrequent	
	46% absent	43% absent	
Aerated drinks	0% frequent	5% frequent	0.305
	0% infrequent	4% infrequent	
	100% absent	91% absent	
Heavy meals	71% present	34% present	0.647
	29% absent	66% absent	
Sleep disturbance	71% present	33% present	0.733
	29% absent	67% absent	
Effect on work	4% present	11% present	0.343
	96% absent	89% absent	

Table 7: Analysis of reflux esophagitis grades and *H. pylori* between GERD with complications and without complications.

Parameters	Chi square test		
	GERD with complication	GERD without complication	P value
H. pylori	83% present	22% present	0.000*
	17% absent	78% absent	
Reflux esophagitis grades	0% A	75% A	0.000*
	8% B	16% B	
	46% C	8% C	
	46% D	1% D	

In addition, this study showed that out of 100 GERD patients, 69% had associated co-morbidities of which 48% had <3 co-morbidities and 21% had ≥3 co-morbidities. This finding supports the previous study by Moraes-Filho JPP et al, who postulated the strong association of co-morbidities with GERD and its worsening effect on GERD.[12]

Though heartburn, regurgitation and retrosternal chest pain are the classic presenting symptoms of GERD, in present study these symptoms were not seen in all the patients. Previous study by Kahrilas PJ et al, inferred that heart burn was present in nearly all GERD patients in their study and regurgitation was found in 80% of GERD patients, in contradiction to the results of our present study.[13] Furthermore, dysphagia and odynophagia have been described as third most common clinical symptom of GERD.[13] In contrary, in present study 75% of patients didn't have dysphagia and 82% of patients didn't have odynophagia. Amongst 100 GERD patients in our study, 75 patients didn't have positional variation of symptoms. In contrary to our study a recumbent (lying) posture after meals was observed as a precipitating factor by 42%of the cases as reported in one of the studies.[14]

In a previous study by Çela L et al, they inferred that the prevalence of GERD is significantly higher in smokers, alcoholics and individuals with increased frequency of consumption of meat, fried foods and spicy foods.[15] In accordance with these findings, present study showed more number of patients (75%) is non-vegetarians. Besides, we found the reverse trend in history of smoking, alcohol, intake of fried foods and spicy foods.

Literature search revealed the refluxogenic properties of the following products: citrus fruits and juices, tomatoes, coffee / tea, aerated drinks and chocolate.[16,17] Postulated mechanism by which these dietary products cause or aggravate GERD symptoms was by increased gastric juice secretion, delaying stomach evacuation and decreased LES pressure. However, current study did not show any significant association with these.

It was a common belief that eating habits such as heavy meals and eating directly before sleep might contribute to the occurrence of symptoms of GERD. Although previous studies by Iwakiri K et al, and Fujiwara et al, postulated the negative influence of these eating habits on the aggravation or occurrence of GERD symptoms. In our study we inferred that there was no significant contribution of heavy meal intake towards occurrence of GERD symptoms.[14,17]

A previous study by Gross M et al, postulated that GERD had substantial effect on work productivity in study of 249 German patients with GERD, although patients were on routine clinical care and proton pump inhibitors therapy.[18] In contrary to this finding we found that effect of work was not contributory to GERD.

In another study by Jung H et al, inferred that complex relationship between GERD and sleep exists and further they suggested modest bidirectional association of GERD and sleep disturbance.[19] In contrast to these findings, our study showed sleep disturbances were absent in 68% of the patients.

In this present study, authors found that *Helicobacter pylori* was present in 37% of the patients and was absent in 63% of the patients. Previous studies by many authors

proposed a strong argument regarding the protective role of *Helicobacter pylori* against GERD.[20,21] Prevalence of *Helicobacter pylori* was reported to be low about 5-10% in patients affected with GERD in comparison to the control groups by previous studies.[20,21] Present study findings were in contrast to these studies.

Los Angeles classification system published in 1999 was the widely accepted for categorizing reflux esophagitis on UGI scopy.[22] In this present study, 57% patients had Grade A reflux esophagitis, 14% patients had Grade B reflux esophagitis, 11% of the patients had Grade C reflux esophagitis and 12% patients had Grade D reflux esophagitis.

Complications of GERD include erosive esophagitis with ulcers, Barrett's esophagus and esophageal stricture. In previous study by Spechler SJ et al, showed that esophageal adenocarcinoma is the most common complication of GERD and warranted serial endoscopic screening for development of Barrett's esophagus.[23] In another study by Chait MM et al, postulated that 20% of the adults with GERD have serious complications.[24] Supporting this finding, our study showed that 24% of the patients had complications (12% esophageal ulcer, 6% Barrett's esophagus and 6% esophageal stricture).

Of the demographic parameters, age of the patient showed significant association with the presence of complications (p= 0.000). Higher the age of the patient, higher is the risk of complication. Reduced pain perception can increase the rate of GERD complications in the elderly, because acid injury can occur without the usual warning symptom of significant heartburn and acid reflux symptoms.[25] Another study by Thrift AP et al, inferred that risk of Barrett's Esophagus increased linearly with earlier age at onset of frequent GERD symptoms.[26] Age at symptom onset may help practitioners decide which patients with GERD symptoms to refer for endoscopic screening for Barrett's Esophagus.

Lifestyle factors can be associated with increased gastro esophageal reflux and more complications of GERD.[26] Tobacco smoking, caffeine, alcohol and fatty foods adversely affect GERD. Obesity, sedentary lifestyle and nocturnal gastro esophageal reflux are important mechanisms that are associated with more severe esophageal and extra esophageal complications of GERD in the elderly.[27,28] Obesity is a significant problem which increases acid reflux and thus increases GERD and its complications.[11] Nocturnal effects on GERD are reported by up to 78% of patients, with 75% of patients reporting that it negatively affects their ability to sleep.[28] Nocturnal gastro esophageal reflux and the recumbent, supine position remove the protective effect of gravity in GERD in the elderly patient.[29,30] Nocturnal GERD allows for more gastro esophageal reflux and further increases esophageal injury and GERD complications, especially in elderly patients who often spend more time in bed due to co morbid illness, such as dementia, Parkinson's disease, cerebrovascular disease, cardiovascular disease, pulmonary disease and diabetes mellitus. However, in the current study none of the lifestyle parameters showed any significant difference between GERD with complication and without complication.

In the present study we found that heart burn, regurgitation, retrosternal chest pain showed significant association between GERD with complications and without complications groups. It can be postulated that daily episodes of heart burn, regurgitation and retrosternal chest pain infers high risk of GERD complications.

In our study, we inferred that presence of *Helicobacter pylori* in GERD patients signifies higher risk of complications. *H. pylori* was present in 83% of patients in GERD with complications group and was absent in 78% of the patients in GERD without complications group. Among grades of reflux esophagitis, grades C and D were moderately higher in GERD with complications group. The worldwide variation in incidence of GERD may be inversely related to the prevalence of *H. pylori* infection.[27] Studies have found a negative association between the prevalence of *H. pylori* infection and GERD that is more marked with the more virulent CagA strains.[30]Additionally, they have shown a negative association of *H. pylori* status and the complications of GERD including Barrett's esophagus and esophageal adenocarcinoma.[30] A study by Labenz et al, revealed a possible protective effect of *H. pylori* infection in the subgroup analysis of patients with severe esophagitis.[31] In a study from China, a stepwise relationship was found between increasing grade of esophagitis and decreasing prevalence of *H. pylori*.[32] In a Swedish study, *H. pylori* was found to be associated with a significantly decreased risk of adenocarcinoma of the esophagus.[33] A subgroup analysis showed that the negative association was only apparent for the CagA positive strains of *H. pylori*. Another study shows that the persistent *H. pylori* infection in GERD has been reported to be a risk factor for a subtype of esophageal squamous cell carcinoma.[34]

Present study has few limitations as well. It was a single center experience. Terminally ill patients were not included in this study. Patients with esophageal mass were not included in this study, though adenocarcinoma of esophagus can occur secondary to GERD, but it has other multifactorial predispositions. Future studies with large scale, multicenter and case control design focused on this context are warranted.

CONCLUSION

Classical symptoms of GERD were not present in all the patients. Dysphagia and Odynophagia were less frequent presenting symptoms. GERD is more common in non-vegetarians than vegetarians. No strong association of smoking, alcohol, spicy foods, fried foods, citrus fruits,

heavy meals, tea/coffee, aerated drinks, sleep disturbance and effect on work was identified in GERD. Prevalence of GERD complications were 24% in studied population with order of erosive esophagitis >Barrett's esophagus and esophageal stricture. Higher age of the patient infers higher risk of complications. Daily episodes of heartburn, regurgitation and retrosternal chest pain implies higher risk of complications. Presence of *Helicobacter pylori* in GERD patients signifies higher risk of complications.

A prospective study on the clinical profile and outcome of meningoencephalitis in adults in a South Indian tertiary care centre

Velammal Petchiappan[1], Divya Pedireddy[2], Santni Manickam[3], Jayachandran Kuppusamy[4]

Abstract

Background Although there are numerous studies on meningitis and encephalitis separately, literature on meningoencephalitis is sparse. In this study we analysed the clinical profile of meningoencephalitis and its clinical outcome.

Methods Fifty adults diagnosed with meningoencephalitis from July 2014 to July 2015 in a tertiary care hospital in South India were studied prospectively and their clinical presentation, aetiology and outcome were analysed.

Results Among 50 patients, 33 (66%) were male; 39 (78%) were <50 years of age. Fever was the most common presenting symptom in 41 out of 50 patients (82%), followed by headache (74%) and altered sensorium (62%); only 18 patients (36%) had all three classical symptoms. Twenty-eight out of 50 patients (56%) did not have neck stiffness. A majority of patients had acute-to-subacute clinical presentation. *Mycobacterium tuberculosis* was identified in 58% (29 out of 50). Forty-seven patients (94%) recovered completely.

Conclusion Tuberculosis was the most common cause of meningoencephalitis in the studied population, often with subacute presentation, and outcome was good with early institution of antituberculous therapy.

Introduction

Meningitis is a clinical syndrome characterised by inflammation of the meninges surrounding the brain and the spinal cord. The classic triad of meningitis consists of fever, headache and neck stiffness.[1] Meningitis can be of infective or noninfective aetiology, occurring in any age group, with extremes of age being the most severely affected. The immune-compromised state also has high mortality and morbidity. The overall case fatality rate of bacterial meningitis in adult patients is around 30%.[2–4]

Although encephalitis by definition involves the brain parenchyma, it may also involve the meninges as well, which is termed as 'meningoencephalitis'. From an epidemiologic and pathophysiologic perspective, encephalitis is distinct from meningitis, though on clinical evaluation both can coexist. The clinical presentation is encephalopathy with diffuse or focal neurological symptoms, including behavioural and personality changes, decreased level of consciousness, neck pain/stiffness, photophobia, lethargy, generalised or focal seizures, acute confusion or amnesic states, and flaccid paralysis.[5]

Organisms responsible for bacterial meningitis are *Streptococcus pneumoniae*, *Neisseria meningitis*, Group B streptococci, *Listeria monocytogens* and *Haemophilus influenza* type b. Most patients recover completely if appropriate antibiotic therapy is instituted promptly. *Mycobacterium tuberculosis* is another major cause, especially in developing countries. Tuberculous meningitis is a critical disease in terms of fatal outcome and permanent sequelae, requiring rapid diagnosis and treatment.[6]

The term aseptic meningitis is used for all types of inflammation of the brain meninges not caused by pus-producing bacteria. It is usually a benign syndrome. Viral and aseptic meningitis are terms used interchangeably as, not only viruses are a major cause, other noninfective causes are equally attributable to the development of meningitis. Worldwide causes of viral meningitis include enterovirus, herpes, mumps, measles and HIV, with enterovirus being the most common cause of viral meningitis.

In the emergency setting differentiating bacterial meningitis from other causes, such as fungal, tuberculous, viral,

18–30	12	5	17
31–50	17	5	22
51–60	2	7	9
>60	2	0	2
Total	33	17	50

neoplastic, toxic or autoimmune causes, is extremely difficult. If a diagnosis of meningitis is made, it is prudent to start the patient on empirical antibiotics until the cultures and other results are awaited.[7] Whereas plenty of literature is available on meningitis, the clinico-aetiological profile and outcome in patients with meningoencephalitis remains not that well studied, except for in the paediatric population.[8] The present study was carried out to assess the causes, clinical profile and outcome in adults diagnosed with meningoencephalitis in a tertiary care hospital.

Methods

Patients

The study was based on prospective collection of data in adults aged 18 years and above who were diagnosed with meningoencephalitis of various aetiologies, confirmed with laboratory investigations and brain imaging. The study was conducted in a tertiary care centre, Coimbatore, South India, from July 2014 to July 2015.

Inclusion and exclusion criteria

Patients with community-acquired meningoencephalitis, those who underwent lumbar puncture for the diagnosis and those with both positive and negative cerebrospinal fluid cultures were included in the study. Patients with hospital-acquired meningitis, patients with myelitis, neurosurgical devices or a recent history of neurosurgery were excluded.

Assessments

Data were extracted using a proforma that included detailed history, clinical examination details and requisite investigations. History and clinical findings attributable to the meningitis and meningoencephalitis were collected in detail, which included fever, headache, vomiting, neck stiffness, seizures, altered sensorium, cerebrospinal fluid (CSF) rhinorrhoea and focal neurological deficits. In addition to basic investigations (which included complete blood count, blood sugar, renal and liver function tests, and chest X-ray), blood culture was also taken for all patients. All underwent lumbar puncture and CSF analysis was carried out that included sugar, protein, total count, differential count, Gram stain, bacterial culture, Ziehl Neelsen stain for acid-fast bacilli (AFB), India ink stain for *Cryptococcus,* cryptococcal antigen test and automated culture for AFB. Neuroimaging (CT or MRI brain) was carried out on all patients. CSF polymerase chain reaction (PCR) was carried out in selected patients. Herpes simplex virus (HSV) PCR was carried out in selected patients with suspected HSV encephalitis based on clinical, CSF and neuroimaging findings.

Acute pyogenic meningitis	8	16
Viral meningoencephalitis	8	16
Cryptococcal meningitis	2	4
Cerebral toxoplasmosis	2	4
Aspergillus meningitis	1	2
Total	50	100

Based on the duration of illness, patients were classified into acute (<1 week), subacute (1–4 weeks) and chronic (>4 weeks) and also grouped based on aetiology. To assess the clinical outcome of the patients the Barthel index was used.[9] Barthel index is an ordinal scale used to measure the performance in 10 activities of daily living with the score ranging between 0 and 20; functional evaluation was carried out at the end of the first month. A score of <12 is taken as a poor outcome and >12 as a good outcome; death is included in the poor outcome category. The results were analysed to assess the clinical presentation, aetiology and clinical outcome.

Ethical clearance

The study was approved by the Institutional Human Ethics Committee (Approval Number 14/193).

Results

The study included 50 consecutive patients with acute meningoencephalitis. Among 50 patients, 33 (66%) were male, 17 (34%) were female. The majority of them (78%) were <50 years of age (Table 1).

Clinical presentation

The common initial presenting symptoms were fever, headache and altered sensorium (Table 2). Among 50

Aetiology	Acute	Subacute	Chronic	Total
Tuberculous meningitis	4	21	4	29
Acute pyogenic meningitis	8	0	0	8
Viral meningoencephalitis	8	0	0	8

Total	23	23	4	50

Acute: clinical presentation <1 week; Subacute: clinical presentation between 1–4 weeks; Chronic: >4 weeks duration

Table 4 Mode of onset of symptoms in various aetiologies of meningoencephalitis

patients, 32 (64%) had both fever and headache; only 18 (36%) had all the three classical signs of meningitis – headache, fever and altered sensorium. Twenty-eight patients (56%) did not have neck stiffness, even though there was meningeal involvement as noted in neuroimaging. Six patients (12%) had seizures; five had generalised tonic–clonic seizures, while focal motor seizures was noted in one. Among those six patients, one had a parenchymal lesion in the MRI (granuloma), meningeal enhancement was noted in three and MRI was normal in two.

Altered sensorium was observed in 31 patients; of which 10 had significant deterioration in consciousness (Glasgow coma scale <10). Among those with poor Glasgow coma scale, one had pyogenic meningitis with extensive vasculitic infarcts in the bilateral cerebral hemisphere and brainstem; seven had abnormal findings in MRI like meningeal enhancement, granuloma or hydrocephalus; MRI was normal in the remaining two. All of these 10 patients with altered sensorium required ventilatory support in intensive care unit. See online for Supplementary Tables 1–4.

Aetiology and mode of onset

The aetiological profile of meningoencephalitis is listed in Table 3. The most common cause found in the present study was *M. tuberculosis*. Among eight patients with acute pyogenic meningitis, the microbiological diagnosis was confirmed in five; three had pneumococcal growth in CSF analysis, while blood culture was positive in two (*S. aureus*; pneumococci). The remaining three patients with acute pyogenic meningitis had sterile cultures due to prior antibiotic exposure. However, very high neutrophil count in the CSF suggested the diagnosis of acute pyogenic meningitis.

Acute and subacute clinical presentation was seen in 23 each while the remaining four presented with chronic symptoms. The mode of onset of symptoms in various aetiologies is listed in Table 4.

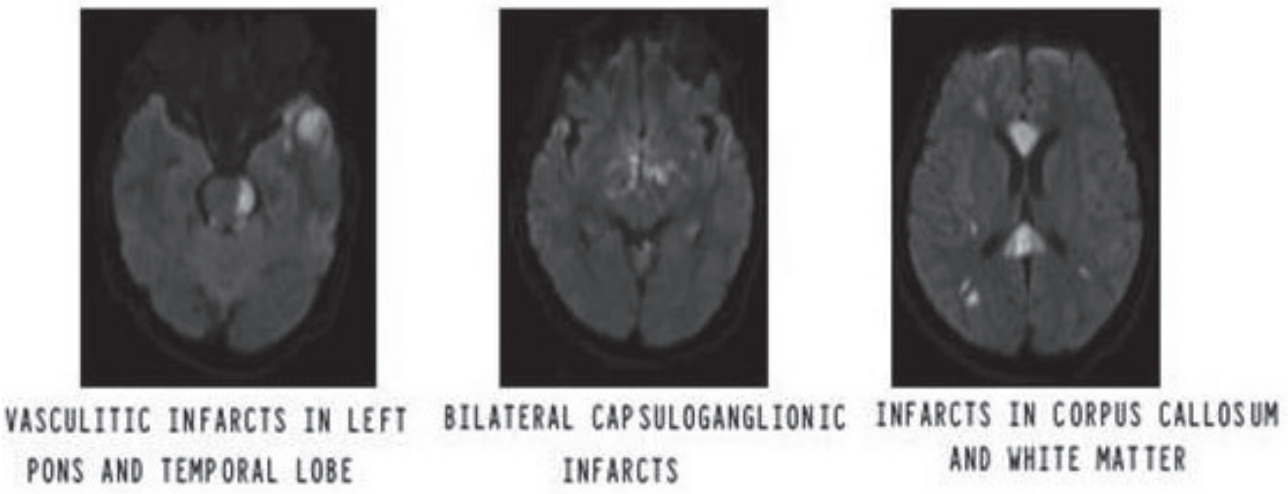
Outcome

Clinical outcome was assessed at the end of 1 month using the Barthel index. Among 50 patients, 47 (94%) recovered completely without any deficits; two had fulminant course and succumbed to the illness by the end of 1 month; one had Barthel index score of 0 (Table 5).

Discussion

The present study included 50 adult patients with meningoencephalitis, *M. tuberculosis* was the most common agent. Tuberculosis still poses a huge health threat in developing countries like India despite advances in the detection and management of the disease.

The common presenting symptoms were fever, headache and altered sensorium. This was similar to other studies with acute bacterial meningitis.[2,10,11] In the present study, nine did not have fever (five had tuberculous aetiology, two had cryptococcal meningitis, cerebral toxoplasmosis and *Aspergillus* meningitis in one each). All patients with acute pyogenic and viral meningoencephalitis presented with fever. Only 18 out of 50 patients (36%) had all the three symptoms – fever, headache and neck stiffness; a similar observation (41%) was noted in a prospective cohort study of community-acquired bacterial meningitis in adults in the Netherlands.[11] Neck stiffness was absent in 28 patients (56%), which indicates that absence of fever or neck stiffness does not exclude the possibility of infectious meningoencephalitis.



Diagnosis of pyogenic meningitis was made based on typical CSF findings (Supplementary Table 1) that showed high protein, low sugar and very high neutrophil count in the CSF (>1,000 cells/mm^3 in most of the patients). In five out of these eight patients with acute pyogenic meningitis, organisms could be isolated either in the blood or CSF. For the remaining three, the cultures were sterile possibly due to prior antibiotic exposure. In a retrospective study of 305 patients with acute bacterial meningitis, 53 (17.4%) had

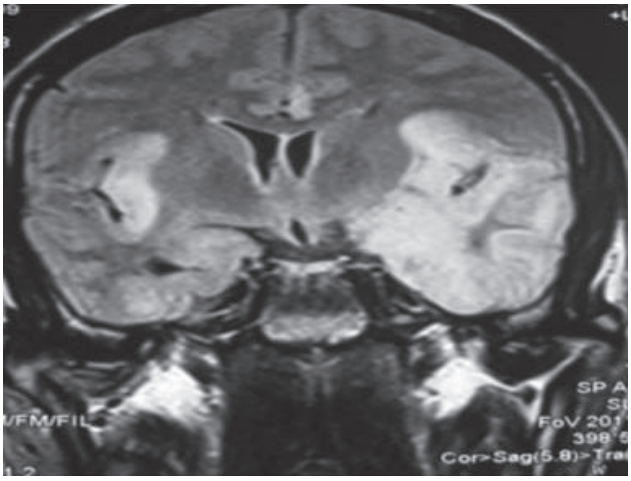
Outcome	TM	APM	VME	CM	CT	AM	Total
Good (n = 47)	29	6	8	1	2	1	47
Poor (n = 3)	0	2	0	1	0	0	3
Total	29	8	8	2	2	1	50

AM: *Aspergillus* meningitis; APM: acute pyogenic meningitis; CM: cryptococcal meningitis; CT: cerebral toxoplasmosis; TM: tuberculous meningitis; VME: viral meningoencephalitis

Table 5 Clinical outcome in various aetiologies of meningoencephalitis

Figure 1 Fulminant pneumococcal meningitis with extensive vasculitic infarcts in bilateral cerebral hemisphere and brainstem

received antibiotics before admission and among these, death occurred only in one. The death rate was high (12%) in the remaining 252 patients who had not received antibiotics before admission. This study indicates the importance of the early institution of antibiotic therapy.[12,13]



Surprisingly, four out of eight patients (50%) with acute pyogenic meningitis had a history of CSF rhinorrhoea before the onset of illness. Of these, three had a head injury in the past. MRI brain in one patient revealed a defect in the anterior cranial fossa that was the cause of CSF leak. One of them had recurrent episodes of pyogenic meningitis due to persistent CSF leak through the nose. After recovery from meningitis, he underwent a neurosurgical procedure for the correction of bony defects. This highlights the importance of elicitation of history for CSF rhinorrhoea in subjects with recurrent meningitis so that the underlying cause can be corrected. Six out of eight acute meningoencephalitis patients recovered completely without residual deficits; however, two had fulminant pneumococcal meningitis, of which one succumbed to the illness although treatment was initiated appropriately, the other survived with severe neurological disability, i.e. bilateral conjugate gaze paralysis of eyeballs and quadriparesis due to multiple infarcts (Figure 1). These outcomes highlight the fact that despite early diagnosis and appropriate treatment some patients with acute pyogenic meningitis may have a fulminant course with a severe neurological disability that can impair the quality of life.

Eight patients had acute viral meningoencephalitis, diagnosed based on CSF analysis and brain imaging features. A viral aetiology was considered when CSF had slightly elevated protein, low-to-normal blood sugar and moderately elevated lymphocyte count. Bacterial cultures, Gram stain, AFB stain and India ink stain were negative in these patients. Out of these eight patients, microbiological confirmation (positive HSV PCR in CSF) was possible in only two; both had temporal cortex hyperintense signals in MRI brain (Figure 2). All recovered completely with acyclovir and were asymptomatic during follow up. In many cases of presumed viral encephalitis (32–75%), the responsible organism could not be pin-pointed despite detailed diagnostic testing. In the California Encephalitis Project, 334 patients with encephalitis were studied from 1998 to 2000; aetiology could not be identified in 208 (62%), despite extensive testing and evaluation.[14]

Although commonly tuberculous and cryptococcal meningitis presents with subacute courses, four patients with tuberculous meningitis and one with cryptococcal meningitis presented with acute onset illness. Two patients presented with central nervous system toxoplasmosis and these patients were found to be HIV positive; they presented with hemiparesis; CSF serology for toxoplasma immunoglobulin G was positive; both the patients recovered well with treatment.

In the present study 15 had basal meningeal exudates on brain imaging. Hydrocephalus was present in five; of which two had significantly larger hydrocephalus, which progressively increased in size and both underwent ventriculoperitoneal shunt. In two large community-based series, hydrocephalus was seen in approximately 75% of

Figure 2 Herpes simplex encephalitis – T2-weighted MRI shows left temporal and right insular hyperintensity

patients, basilar meningeal enhancement in 38%, cerebral infarcts in 15–30% and tuberculomas in 5–10%.[15,16] With early appropriate antituberculous therapy and steroids, all patients with tuberculous meningitis in the present study recovered well without neurological deficits.

The present study had several limitations: PCR studies in all CSF culture-negative samples could not be performed and the study was conducted in a single centre with a limited number of patients. Further larger studies on meningoencephalitis would throw more light on the clinical profile and outcome.

In conclusion, the present study underscores the fact that the absence of fever or neck stiffness does not exclude the possibility of infectious meningoencephalitis. The focus in all cases should be on early diagnosis and appropriate treatment, though in some patients the outcome may not be uniformly good.

ABSTRACT

Background: Anaemia is almost universal in haemodialysis patients. Here, we evaluated the utility and clinical implications of the commonly employed tests in assessing iron status in haemodialysis patients.
Methods: In this prospective observational study, we enrolled 100 prevalent haemodialysis patients, and measured transferrin saturation (TSAT) and serum ferritin at enrolment. Patients were categorized to have normal, deficient, overload, or indeterminate status of iron based on KDOQI guidelines. To study anaemia trend, haemoglobin (Hb) level at time of enrolment, as well as levels 3-months before and 3-months after enrolment, were collected. Patient survival outcomes were also obtained till October 2016.
Results: Using serum ferritin and TSAT, iron status was determinable in 48% of the patients ie 20%-normal iron status, 25% - iron deficiency, 3% - iron overload. Fifty-two percent of the patients' iron status was indeterminate by current parameters. In spite of being on standard-of-care treatment in our centre, we observed that mean-Hb level of patients in the indeterminate group showed insignificant increases compared to normal- and deficient-groups. Mean delta-Hb levels over 6-months were 0.80±1.54 g/dl in the indeterminate group, compared to 1.87±1.95 g/dl in the deficient group (P=0.03). In our cohort, 57% had died and 5 lost follow-ups during the study (P=0.30 between groups).
Conclusions: Serum ferritin and TSAT accurately categorized the iron status of 48% haemodialysis patients in our study. Divergent serum ferritin and TSAT values, or an iron indeterminate state was prevalent in 52% of our urban dialysis cohort. The indeterminate group had inferior increases in Hb over time with current treatment, showing clinical relevance of this finding. Our data suggests the need for more sensitive indices to accurately assess iron status, and improve anaemia management.

Keywords: ESRD patients, Iron status, Serum ferritin, TSAT

INTRODUCTION

Anaemia is frequently found in chronic kidney disease (CKD) patients and is an almost universal finding in patients with end stage renal disease (ESRD).[1] Additionally, anaemia is associated with increased cardiovascular morbidity and mortality in this patient population.[2]

The pathophysiology of anaemia in CKD is multifactorial.[3] The proximate cause of the anaemia is relative deficiency of erythropoietin, a glycoprotein produced by renal tubular cells. Other factors which may cause or contribute to anaemia includes iron deficiency, vitamin B12 and/or folic acid deficiency, decreased erythrocyte survival, severe hyperparathyroidism, aluminium toxicity and hypothyroidism. The use of erythrocyte stimulating agents (ESA) such as recombinant human erythropoietin (EPO) began two decades ago and has revolutionized the treatment of anaemia in ESRD. This has decreased the need for blood transfusions and consequently the incidence of associated complications.[4]

Despite the widespread use of EPO, over 50% of the patients do not reach target haemoglobin levels.[1,5] Resistance to erythropoietin most commonly is due to iron deficiency but chronic inflammation, infection, and/or hyperparathyroidism also contribute.[6,7] Iron deficiency in ESRD is primarily due to impaired dietary intake and impaired gastrointestinal absorption but blood loss during haemodialysis and increased iron demands from ESA use also contribute.[8] Management of iron deficit is crucial in haemodialysis patients. Adequate treatment of iron deficiency is vital to attain target haemoglobin concentration and avoid excessively high EPO doses, which has been associated with increased risk of malignancy.[9] Furthermore, IV iron and blood transfusions both increase the risk of developing hospital acquired infections.[10,11] Therefore effective treatment of anaemia in haemodialysis patients requires continuous assessment of iron status.

Serum ferritin and transferrin saturation (TSAT) are the commonly used tests for the assessment of iron status in ESRD. However, measurement of these parameters in ESRD patients may be altered by inflammation, infection, or nutritional status.[12] Therefore, we conducted this study to evaluate the utility of the common tests, serum ferritin and TSAT, in assessing iron status in haemodialysis patients. In order to examine the clinical utility of iron status as defined by the current guidelines, we evaluated anaemia in this cohort, as well as patient outcomes.

METHODS

This study was conducted from August 2011 to March 2012 in a large tertiary care teaching hospital in South India. The study was conducted among the ESRD patients undergoing haemodialysis. All ESRD patients on haemodialysis for at least 3 months were enrolled in the study after the application of the exclusion criteria and after obtaining informed consent. The study was done after obtaining institutional ethical committee clearance. The exclusion criteria were: age less than 18 years old, evidence of acute or chronic infection, trauma within the previous 4 weeks, recent bleeding episodes, blood transfusion within the last one month, malignancy, post-transplant status, liver disease, haemoglobinopathies and other haematological diseases. The diagnostic biochemical tests used to assess the iron status were TSAT and serum ferritin.

Patients were categorized to have normal, deficient, overload, or indeterminate status of iron based on serum ferritin and TSAT values. Based on NKF-DOQI guidelines, iron deficiency is taken as ferritin level less than 200mg/dl and TSAT less than 20%, iron overload as ferritin level more than 500 mg/dl and TSAT more than 50%. The values in between the above ranges (ferritin between 200 and 500 mg/dl; TSAT between 20 and 50 %) are considered as normal iron status, whereas values not conforming to these categories are said to be indeterminate. The combined utility of the above tests in assessing iron status was determined by dividing the number of patients in whom iron status was detected (normal, deficient or overload) by total number of patients and expressed in percentage. The haemoglobin level of all the enrolled patients at time of enrolment was collected. To determine haemoglobin trend within each group, we collected haemoglobin levels 3-months before and 3-months after enrolment from chart review. Patient outcomes (death, alive and lost follow up) were obtained by chart review and telephone-follow up till October 2016.

Statistical analysis

The data were analysed using Statistical Package for Social Science (SPSS) Version 19.0, Graphpad Prism-6 and Microsoft Excel 2010. Non-parametric characteristics between any two groups were compared using Mann-Whitney test, and proportions using Chi-square test. For comparing more than two mean values we have used one-way analysis of variance. P value less than 0.05 was considered as statistically significant.

RESULTS

Demographics of study population

A total of 100 prevalent ESRD patients on haemodialysis were studied. The key demographics of the study cohort are summarized in Table 1. Patients ranged from 18 to 80 years. The mean age of the patients was 48.5 years. Among 100 patients, 63 were male and 37 were female.

Description by iron status

We classified these patients based on their iron status as per the NKF-KDOQI (see methods). Using serum ferritin and TSAT, iron status could be determined in 48% of the patients; 20% had normal iron status, 25% had iron deficiency, 3% had iron overload. The remaining 52% of the patient's iron status was indeterminate (Table 1 and 2). In univariate analysis, patients who were iron indeterminate were nearly indistinguishable from other groups by clinical and epidemiologic variables (as shown

in Table 1). However interestingly, iron indeterminate and overload groups had significantly greater dialysis vintage than the normal/iron-deficient groups.

Table 1: Baseline demographic characteristics.

	Total n=100	Diagnosed	n=48		Indeterminate n=52

TSAT: Transferrin saturation.

Outcomes by iron status

Anaemia outcomes: To examine the haemoglobin responses and anaemia, trends of patients according to iron status, we tabulated haemoglobin levels of patients in each group by iron status at enrolment at different time points before- and after- study enrolment (Figure 1 and Figure 2).

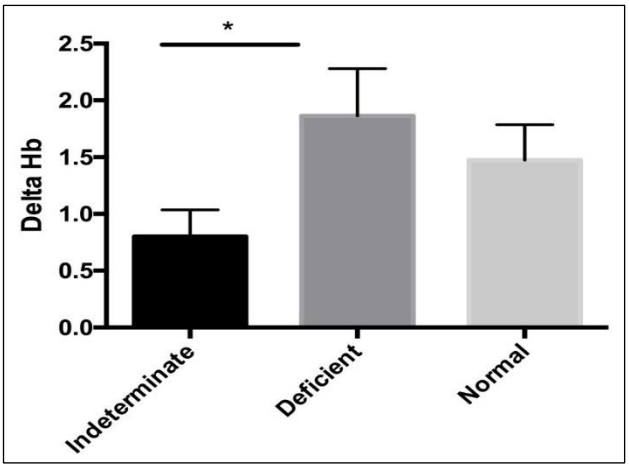

Figure 1: Compares Delta-haemoglobin in each study group, from 3-months before time of enrolment in study to 3-months after. [Columns represent means and error bars represent SEM. * = ANOVA (with post-test comparison) P< 0.05].

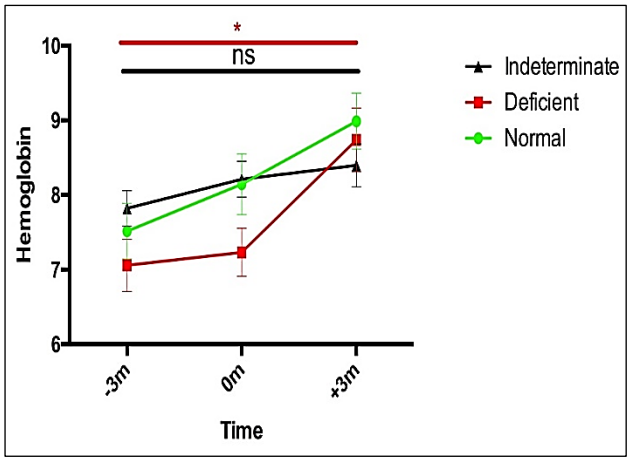

Figure 2: Trendlines of mean haemoglobin levels in each group by iron status. Indeterminate group had significantly inferior increases of haemoglobin over 6-months of follow-up. [Line represents mean, and error bars SD at each time point. * = Mann-whitney U P<0.05].

Table 3: Haemoglobin trend.

Groups	Total	Normal-1	Deficient-2	Overload-3	Indeterminate-4
	Mean (SD)	**Mean (SD)**	**Mean (SD)**	**Mean (SD)**	**Mean (SD)**
Haemoglobin 3months before (g/dL)	n=94 7.56(1.64)	n=19 7.51(1.61)	n=23 7.05 (1.67)	n=3 7.46 (1.15)	n=49 7.82 (1.66)
Haemoglobin 0 month (g/dL)	n=100 7.95(1.74)	n=20 8.14(1.76)	n=25 7.23 (1.60)	n=3 8.26 (2.39)	n=52 8.21 (1.71)
Haemoglobin 3 months after (g/dL)	n=90 8.64 (1.91)	n=19 8.98(1.63)	n=23 8.73 (2.00)	n=3 9.56 (3.13)	n=45 8.39 (1.92)

Table 3 summarizes haemoglobin levels and patients (n) in each group at each of the different time points studied. As the overload group consisted of 3 patients only, we excluded these from subsequent analysis. We interestingly observed that the mean haemoglobin level of patients in the Normal and Deficient groups showed significant increases over a 6-month time period, while those in the indeterminate group had insignificant increases in haemoglobin levels in this period (Figure 1). Mean delta haemoglobin levels over 6 months (3-months before enrolment to 3-months after enrolment) were 0.80±1.54 g/dl in the indeterminate group, compared to 1.87±1.95 g/dl in the deficient group (Mann Whitney P=0.03; Figure 2).

Patient outcomes

Overall during the follow up period, 29 patients continued on dialysis, 5 were at outside dialysis units, 8 patients received kidney transplants (4 of whom expired after transplantation). A total of 57 patients in our cohort had died during the follow up period (till October 2016). Five patients were lost to follow up in this time. There were no significant differences detectable in number of deaths between any of the groups by iron status in the duration of our follow-up, although all 3 patients in the overload group had expired (Table 1 and Figure 3).

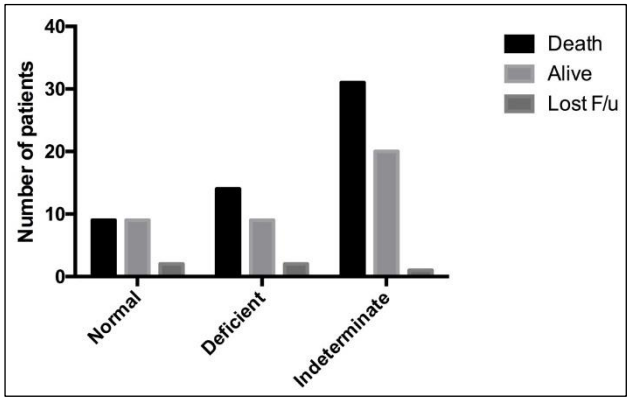

Figure 3: Patient outcomes in the study cohort till October 2016. No significant differences were observed in the proportion of patients that died in each group in this follow-up period (Chi square P=ns).

DISCUSSION

Anaemia contributes significantly to the morbidity and mortality in ESRD. ESA and iron supplementation are the most important factors in treatment of anaemia in ESRD patients.[13] Iron deficiency has been identified as a major factor for anaemia in CKD patients, with a 43-90% prevalence in different series.[6,14-16] Hence the periodical monitoring of iron status is crucial in ESRD.

There are two forms of iron deficiency, absolute iron deficiency and functional iron deficiency. Reduction of reticuloendothelial system iron in the bone marrow is referred to as absolute iron deficiency. Absolute iron deficiency may occur from impaired intestinal absorption, blood loss through the dialysis circuit, vascular access surgeries, repeated phlebotomies and increased iron utilization with erythropoietin therapy. In clinical practice, absolute iron deficiency is determined by serum ferritin less than 200ng/ml and TSAT less than 20%.[17] In the non-ESRD population, "functional" iron deficiency is ascribed when iron reserves in the bone marrow are adequate, but iron mobilization is impaired as in states of chronic inflammation.[18]

The current study assesses the utility of combining serum ferritin and TSAT to assess iron status among an Indian haemodialysis population. The evaluation of iron status is straightforward when both serum ferritin and TSAT are either high or low. But when these parameters are divergent, for instance, if the TSAT is low and serum ferritin is high, the accurate interpretation of iron status is difficult. This entity was common in our study where the iron status of only 48% of the patients were clearly determined (20% had normal iron status, 25% had iron deficiency and 3% had iron overload), and was indeterminate in the remaining 52% of patients. Interestingly in our study, the only epidemiologic factor associated significantly with indeterminate status was dialysis vintage. Why patients with indeterminate or overload status appeared to have longer durations of dialysis, is unclear but requires further exploration. Our data suggest that in a significant proportion of haemodialysis patients in a typical urban dialysis unit in India, the conventionally applied parameters were insufficient to accurately categorize iron status. Similar data has emerged from other groups.[19] Further, our data crucially demonstrates that patients with indeterminate status by conventional assessment have significantly inferior increases in haemoglobin levels with current therapy, suggesting the need for development of more specific diagnostic strategies to ascertain iron status in this group, to accurately manage iron status and anaemia.

Most studies have revealed that serum ferritin is very well related with iron stores in the bone marrow is the best surrogate of iron status in healthy individuals.[20-22] However, ferritin is an acute phase reactant increasing in states of chronic inflammation (such as dialysis), malignancy, or systemic disease, and ferritin levels alone may not reflect iron stores available for haematopoiesis. Thirty-six patients had low ferritin (<200) in our study. Only 25 of them had iron deficiency (combined with low-TSAT), whereas ~31% of them were in indeterminate group. Further, 29 patients had high serum ferritin. Only 3 of these had iron overload (combining TSAT), while 4/29 had low TSAT (<20%). Hence, decision to treat these patients with iron supplements based on these parameters would likely be imprecise. Similarly, a transferrin saturation of less than 20% in patients on haemodialysis is considered to be suggestive of iron deficiency whereas other studies have suggested that a transferrin saturation < 20% versus >20% alone may be inaccurate for assessing iron deficiency.[23-28] While most patients with TSAT less than 20% are iron deficient, few patients don't respond to an increase in iron supplements with either increase in haematocrit or maintenance of haematocrit with a decreased ESA requirement. On the other hand, numerous patients with a TSAT greater than 20% have functional iron deficiency respond to increased iron doses with elevations in the haematocrit, or maintenance of their haematocrit at decreased erythropoietin doses.[25-28] In our study, 43 patients had low TSAT (<20%); only 25 of them had iron deficiency (combined with ferritin). We found that 57 patients had TSAT values more than 20%, out of which 11 had low ferritin (<200). TSAT values in these 11 patients may be falsely high because of low total iron binding capacity (TIBC) during inflammation and infection.

The difficulties in the interpretation of iron status using TSAT and serum ferritin in ESRD patients and the consequent hematologic implications we show, warrant the application of other erythrocyte and reticulocyte based indices, such as the percentage of hypochromic red blood cells (Hypo) and the reticulocyte haemoglobin content (CHr). CHr requires a special analyser and is recommended as an alternative iron status indicator as well as an initial measure of the response to iron treatment in haemodialysis population.[29-31] Fishbane et al evaluated the reticulocyte haemoglobin content among 32 haemodialysis population and showed it to have a sensitivity of 100% and specificity of 80%.[29] Mittman et al evaluated reticulocyte haemoglobin content among 364 haemodialysis population receiving EPO and proved it to be an indicator of functional deficiency of iron.[30] Based on these and other data, NKF DOQI recommends a target of CHr greater than 29pg/cell.[32-35] The Hypo is an indicator of the percentage of red blood cells that contain low haemoglobin. Thus, it indicates only the functional iron availability and does not reflect storage iron. A Hypo level of greater than 10% indicates definitive functional iron deficiency. European Best Practice Guidelines stated that Hypo >10% is the most accurate marker for ID.[36] However, there are other studies which suggested lower threshold values for Hypo.[32,37-40] Both these tests are not widely available in India.

Here, we report that the combination of serum ferritin and TSAT accurately categorized the iron status in only 48%

of ESRD patients in our study. When serum ferritin and TSAT values diverged, they become unreliable for accurate interpretation of iron status, signaling an iron indeterminate state that was prevalent in 52% of our urban dialysis cohort. As we show here, this group of iron-indeterminate patients has inferior increases in haemoglobin over time, showing clinical relevance of this finding. Our data suggests that more sensitive indices such as Hypo and/or CHr may need to be employed (along with conventional tests) to accurately assess iron status, and improve management tools. This could lead to more accurate dosing of iron and ESAs, decrease overtreatment of anaemia, and possibly translate to cost savings from medication usage. Future studies on iron markers including both traditional and newer indices are required to improve iron management in ESRD population, especially in Indian population, where iron deficiency is common and similar studies are lacking.

Association of N-terminal-Pro-B-type Natriuretic Peptide with Localization of Thrombus and Clinical Outcome in Acute Pulmonary Embolism

Santni Manickam[1], Yoganathan Chidambaram[2], Jayachandran Kuppusamy[3], Clement Jenil Dhas[4], Sujith Kumar[5]

ABSTRACT

Introduction: Pulmonary Embolism is a major health problem which is associated with significant mortality and morbidity. It is a common and lethal condition. This study was undertaken to find the association between NT-Pro-BNP levels and the localisation of thrombus in acute Pulmonary Embolism and to prognosticate the patients.

Material and methods: Prospective study conducted at a tertiary care hospital.Thirty patients with Pulmonary Embolism of various etiologies, confirmed with clinical features, laboratory investigations and imaging and fulfilling the inclusion and exclusion criteria were included. After getting informed consent, Blood samples for assessment of NT-Pro-BNP levels were collected within 24 hours of admission.

Results: In 19 patients, the thrombus was located centrally (in main pulmonary artery) whereas in 11 patients, the thrombus was located in the peripherally (in segmental and subsegmental pulmonary arteries). 22 participants of the study had normal clinical outcome. 5 patients were morbid (oxygen dependant/ heart failure) whereas 3 patients died. Patients with central pulmonary embolus had higher NT-Pro-BNP levels whereas patients with pulmonary embolus in the segmental or subsegmental pulmonary arteries had relatively less NTPro-BNP levels. Patients with high NT-Pro-BNP levels had complicated in-hospital course/ mortality whereas, patients with relatively lower NT-Pro-BNP had uncomplicated in-hospital course.

Conclusion: This study shows that higher NT-Pro-BNP levels indicate higher probability of a more central location of thrombus in pulmonary embolism and also right ventricular overload. Also patients with higher NT-Pro-BNP levels had a complicated in hospital course.

Key words: Pulmonary Embolism, Pulmonary Arteries, Right Heart Failure, NT Pro-BNP

INTRODUCTION

Pulmonary Embolism (PE) is a major health problem which is associated with significant mortality and morbidity. It is a common and lethal condition. Pulmonary Thrombo Embolism (PTE) and deep vein thrombosis (DVT) collectively known as venous thromboembolism (VTE) encompass one disease entity. Among cardiovascular diseases, VTE along with stroke and myocardial infarction rank as three big cardiovascular killers. PTE implies partial or complete occlusion of pulmonary arterial circulation by the clot formed elsewhere usually in deep veins of the leg. Less than 5% of venous thrombosis occurs in other sites. The incidence of PE in non-hospitalised patients is 3.5 per 10,000 person years while the incidence rate in hospitalised in-patients can be above 500 per 10,000 person years.[1] In India, VTE is a common cause of mortality and morbidity in patients hospitalized for medical or surgical illnesses. It is often misdiagnosed and not intervened in time. Though the exact magnitude of problem is not known in India, the clinical relevance and incidence is not expected to be different from Western countries. Acute PE has high early mortality rates. Despite the advances in diagnosis and treatment, the early mortality rates have not changed significantly. Due to the embolus obstructing the pulmonary bed, PE can result in a life threatening condition, acute right ventricular (RV) failure.[2] Early diagnosis is of paramount importance since most patients die within the first hours of presentation. Timely management is usually highly effective in reversing RV failure. The diagnosis of acute PE is based on the assessment of clinical likelihood, ECG, CXR, echocardiography, laboratory investigations, mainly D-dimer and cardiac biomarkers and imaging techniques (CT pulmonary angiogram). Several cardiac biomarkers have emerged as indicator of right ventricular dysfunction and clinical outcome predictor in patients with acute PE. Brain type natiuretic peptide (BNP) is a marker of ventricular dysfunction. Following cardiac myocyte stretch, this compound is released into the circulation. It is synthesized as an inactive pro hormone (Pro-BNP) which is split into active hormone BNP and an inactive N-terminal fragment (NT-Pro-BNP).[3] This study was undertaken to find the association between NT-Pro-BNP levels and the localisation

BY-NC-ND

of thrombus in acute PE, to monitor and prognosticate the patients closely.

Primary objectives of the study were to study the association of N-terminal-Pro-B-Type Natriuretic Peptide with localisation of thrombus in Acute Pulmonary Embolism and to study the association between NT-Pro-BNP levels and clinical outcome in patients with Acute Pulmonary Embolism and secondary objectives were to study on the various risk factors in patients diagnosed with acute pulmonary thrombo embolism and to follow up the patients at the end of 1 month to know the clinical outcome.

MATERIAL AND METHODS

Prospective study was conducted at a tertiary care hospital, PSG Hospitals, Coimbatore. Thirty consecutive patients diagnosed to have pulmonary embolism were included in this study with the following criteria.

Inclusion criteria

All patients of age more than 18 years with clinical and radiological evidence of acute PE will be included in the study.

1) Clinical evidence

Patients presenting with dyspnoea, hemoptysis and chest pain with no acute ischemic changes in ECG and with normal Ejection fraction. ECG in acute pulmonary embolism will shows S1Q3T3 pattern.

2) Radiological evidence

CT pulmonary angiogram showing filling defects within the pulmonary vasculature.

Exclusion criteria

Patients with COPD, known case of Congestive cardiac failure and chronic kidney disease are excluded from this study.

After getting informed consent, Blood samples for assessment of NT-Pro-BNP levels were collected within 24 hours of admission. Risk factors for pulmonary thrombo embolism were noted such as prolonged bed rest, hypertension, malignancy etc. Thrombi located in main/ right/left pulmonary artery were classified as central while the others at segmental/sub-segmental levels were classified as peripheral. Echocardiographic findings such as ejection fraction, functions of right and left ventricle, pulmonary artery pressure were noted. Clinical course of the patient and clinical outcome were also noted. Clinical outcome of the patient at the end of one month was recorded by following up. Then descriptive and statistical analysis of location of thrombus and clinical outcome in relation with NT-Pro-BNP levels was done.

Risk factors	Frequency (n)	Percent (%)
Prolonged immobilization	13	43.3
Carcinoma	4	13.3
Unprovoked	13	43.3
Total	30	100.0

Table-1: Risk factors of the study participants

Clinical Outcome	Frequency (n)	Percent (%)
Normal	22	73.3
Morbid	5	16.7
Death	3	10.0
Total	30	100.0

Table-2: Clinical Outcome after 30 Days

STATISTICAL ANALYSIS

The data collected from the patients was tabulated using Microsoft excel. The data are reported as mean +/- SD depending on their distribution. Risk factors will be described in numbers and percentage. Any association will be analysed using chi-square test. Correlation will be analysed by Pearsman correlation. A p value of <0.05 using two tailed test was taken as being significant for all statistical tests. All data were analysed with statistical software package (SPSS version 24.0)

RESULTS

In our study, we included 30 patients diagnosed with acute pulmonary thromboembolism. The mean age of study population is 57.6 years. 11 patients belonged to the group of 51 to 60 years. Only 2 patients were younger adults and 2 patients were old adults. Among the study group 17 patients were male (56.7%) and 13 patients were female (43.3%).In our study population following were the risk factors noted. Thirteen patients had prolonged immobilisation following road traffic accident or following major orthopaedic surgeries. 4 patients had underlying malignancy such as Ca lung or Ca breast. 13 patients had unprovoked PTE.(Table 1) The thrombus was located unilaterally in 19 patients whereas 11 patients have bilateral thrombus. In 19 patients, the thrombus was located centrally (that is, in main pulmonary artery) whereas in 11 patients, the thrombus is located in the peripherally (segmental and sub segmental pulmonary arteries).22 participants of the study had normal clinical outcome. 5 patients were morbid (oxygen dependant/ heart failure) whereas 3 patients died.(Table 2)

Patients with central pulmonary embolus have higher NT-Pro-BNP levels whereas patients with pulmonary embolus in the segmental or subsegmental pulmonary arteries have relatively less NT-Pro-BNP levels. And the difference between the two was statistically significant. (P= 0.02)(Table 3)

Patients with high NT-Pro-BNP levels had complicated in-hospital course/mortality whereas, patients with relatively

	Localisation	N	Mean	Std. Deviation	P value
PROBNP	Central	19	6196.27	4377.75	.02*
	Peripheral	11	1529.10	2636.40	

Table-3: Association of PROBNP with localization

	Clinical Outcome	N	Mean	Std. Deviation	P value
PROBNP	Normal	22	3814.15	3860.52	.005*
	Morbid	5	3009.16	4033.77	
	Death	3	11864.00	1417.83	

Table-4: Association of PROBNP with Clinical Outcome

lower NT-Pro-BNP had uncomplicated in-hospital course. (P = 0.005)(Table 4)

DISCUSSION

Acute PE shows wide variations in clinical presentation from asymptomatic course to a massive pulmonary embolism that may be fatal. When planning treatment for this condition, risk stratification is important. In this study 30 patients diagnosed with pulmonary embolism were included. The mean age of study population is 57.6 years.17 patients were male(56.7%) and 13 patients were female (43.3%). The thrombus was located unilaterally in 19 patients whereas 11 patients had bilateral thrombus. In 19 patients, the thrombus was located centrally (main pulmonary artery) whereas in 11 patients the thrombus was located in the peripheral pulmonary artery (segmental and subsegmental pulmonary arteries). 22 participants of the study had normal clinical outcome. 5 patients were morbid (oxygen dependant/ heart failure) whereas 3 patients died. Patients with central pulmonary embolus have higher NT-Pro-BNP levels whereas patients with pulmonary embolus in the segmental or subsegmental pulmonary arteries have relatively less NTPro-BNP levels. And the difference between the two is statistically significant. (P= 0.02).

Patients with high NT-Pro-BNP levels had complicated in-hospital course/ mortality whereas, patients with relatively lower NT-Pro-BNP had uncomplicated in hospital course. (P = 0.005).From this study, it is evident that patients with higher NT-Pro-BNP levels have more central thrombus, have complicated in-hospital course and also cause morbidity and mortality. Whereas patients with comparatively lower NT-Pro-BNP levels have thrombus in segmental or subsegmental pulmonary arteries and they have an uncomplicated course.

The findings of our study were consistent with many other similar studies.

In a prospective study conducted by Akpinar et.al in turkey in Forty-nine patients concluded that higher pro bnp levels indicate higher probability of a more central location of thrombus in pulmonary embolism, resulting a more adverse clinical course and also leading to right ventricular overload..

In a prospective study done by Pruszcyk et.al in Poland in 79 patients found NT-Pro-BNP to be a prognostic marker in acute pulmonary embolism.[5]

An Egyptian prospective study by A.Selem et al conducted in 64 patients concluded elevated NT pro-BNP in PE was associated with worse short term prognosis in terms of higher morbidity and mortality.[6] Another study, Heleder Dores et al a retrospective study also had similar results as that of our study which concluded that elevated NT pro-BNP in PE identified worse short term prognosis and also had excellent power to predict 30 day all cause mortality.[7]

In a meta analysis conducted by Frederikus et.al, in the Netherlands, they found that higher concentrations of NT-Pro-BNP distinguish patients with pulmonary embolism at higher risk of complicated in-hospital course and death from those with low NT-Pro-BNP levels.[8] In another meta analysis conducted by Cavallazzi et.al in USA, they found that NT-Pro-BNP levels are significant predictors of all cause in hospital or short term mortality.[9] A meta analysis by Guillaume Coutance et al concluded while elevated BNP levels can help to identify high risk of death and adverse outcome, the high negative predictive value of normal BNP levels is certainly more useful.[10]

From our study it is evident that NT-Pro-BNP levels are significant predictor of all cause in- hospital mortality in patients with acute PE. The potential outcome of our study is that patients with normal levels of NT-Pro-BNP have a high negative predictive value for unfavourable outcome. Patients with normal NT-Pro-BNP levels have low risk of death as well as for hemodynamic collapse.This was consistant with a study conducted by Nils Kucher in 73 patients which predicted that lower the pro-BNP levels, lower would be the hospital stay.[11]

Our study have a few limitations. First, the sample size is limited. Further studies including larger number of patients are necessary to clarify this point. Secondly, NT-pro-BNP is a precursor of BNP. The conversion of BNP to NT-Pro-BNP may take several minutes after myocardial stretch which may lead to false negative results in patients who present early. Serial monitoring of NT-Pro-BNP (eg. At admission and 6 hours later) may overcome this limitation.

CONCLUSION

This study shows that higher NT-Pro-BNP levels indicate higher probability of a more central location of thrombus in pulmonary embolism and also leading to right ventricular overload.Also patients with higher NT-Pro-BNP levels had a complicated in-hospital course.Further studies with large number of patients were undertaken to determine the exact cut off levels of NT-Pro-BNP to help in treatment decisions.

Ethical approval

The study was approved by the Institutional Ethics Committee

ABSTRACT

Background: Anaemia is almost universal in haemodialysis patients. Here, we evaluated the utility and clinical implications of the commonly employed tests in assessing iron status in haemodialysis patients.
Methods: In this prospective observational study, we enrolled 100 prevalent haemodialysis patients, and measured transferrin saturation (TSAT) and serum ferritin at enrolment. Patients were categorized to have normal, deficient, overload, or indeterminate status of iron based on KDOQI guidelines. To study anaemia trend, haemoglobin (Hb) level at time of enrolment, as well as levels 3-months before and 3-months after enrolment, were collected. Patient survival outcomes were also obtained till October 2016.
Results: Using serum ferritin and TSAT, iron status was determinable in 48% of the patients ie 20%-normal iron status, 25% - iron deficiency, 3% - iron overload. Fifty-two percent of the patients' iron status was indeterminate by current parameters. In spite of being on standard-of-care treatment in our centre, we observed that mean-Hb level of patients in the indeterminate group showed insignificant increases compared to normal- and deficient-groups. Mean delta-Hb levels over 6-months were 0.80±1.54 g/dl in the indeterminate group, compared to 1.87±1.95 g/dl in the deficient group (P=0.03). In our cohort, 57% had died and 5 lost follow-ups during the study (P=0.30 between groups).
Conclusions: Serum ferritin and TSAT accurately categorized the iron status of 48% haemodialysis patients in our study. Divergent serum ferritin and TSAT values, or an iron indeterminate state was prevalent in 52% of our urban dialysis cohort. The indeterminate group had inferior increases in Hb over time with current treatment, showing clinical relevance of this finding. Our data suggests the need for more sensitive indices to accurately assess iron status, and improve anaemia management.

Keywords: ESRD patients, Iron status, Serum ferritin, TSAT

INTRODUCTION

Anaemia is frequently found in chronic kidney disease (CKD) patients and is an almost universal finding in patients with end stage renal disease (ESRD).[1] Additionally, anaemia is associated with increased cardiovascular morbidity and mortality in this patient population.[2]

The pathophysiology of anaemia in CKD is multifactorial.[3] The proximate cause of the anaemia is relative deficiency of erythropoietin, a glycoprotein produced by renal tubular cells. Other factors which may cause or contribute to anaemia includes iron deficiency, vitamin B12 and/or folic acid deficiency, decreased erythrocyte survival, severe hyperparathyroidism, aluminium toxicity and hypothyroidism. The use of erythrocyte stimulating agents (ESA) such as recombinant human erythropoietin (EPO) began two decades ago and has revolutionized the treatment of anaemia in ESRD. This has decreased the need for blood transfusions and consequently the incidence of associated complications.[4]

Despite the widespread use of EPO, over 50% of the patients do not reach target haemoglobin levels.[1,5] Resistance to erythropoietin most commonly is due to iron deficiency but chronic inflammation, infection, and/or hyperparathyroidism also contribute.[6,7] Iron deficiency in ESRD is primarily due to impaired dietary intake and impaired gastrointestinal absorption but blood loss during haemodialysis and increased iron demands from ESA use also contribute.[8] Management of iron deficit is crucial in haemodialysis patients. Adequate treatment of iron deficiency is vital to attain target haemoglobin concentration and avoid excessively high EPO doses, which has been associated with increased risk of malignancy.[9] Furthermore, IV iron and blood transfusions both increase the risk of developing hospital acquired infections.[10,11] Therefore effective treatment of anaemia in haemodialysis patients requires continuous assessment of iron status.

Serum ferritin and transferrin saturation (TSAT) are the commonly used tests for the assessment of iron status in ESRD. However, measurement of these parameters in ESRD patients may be altered by inflammation, infection, or nutritional status.[12] Therefore, we conducted this study to evaluate the utility of the common tests, serum ferritin and TSAT, in assessing iron status in haemodialysis patients. In order to examine the clinical utility of iron status as defined by the current guidelines, we evaluated anaemia in this cohort, as well as patient outcomes.

METHODS

This study was conducted from August 2011 to March 2012 in a large tertiary care teaching hospital in South India. The study was conducted among the ESRD patients undergoing haemodialysis. All ESRD patients on haemodialysis for at least 3 months were enrolled in the study after the application of the exclusion criteria and after obtaining informed consent. The study was done after obtaining institutional ethical committee clearance. The exclusion criteria were: age less than 18 years old, evidence of acute or chronic infection, trauma within the previous 4 weeks, recent bleeding episodes, blood transfusion within the last one month, malignancy, post-transplant status, liver disease, haemoglobinopathies and other haematological diseases. The diagnostic biochemical tests used to assess the iron status were TSAT and serum ferritin.

Patients were categorized to have normal, deficient, overload, or indeterminate status of iron based on serum ferritin and TSAT values. Based on NKF-DOQI guidelines, iron deficiency is taken as ferritin level less than 200mg/dl and TSAT less than 20%, iron overload as ferritin level more than 500 mg/dl and TSAT more than 50%. The values in between the above ranges (ferritin between 200 and 500 mg/dl; TSAT between 20 and 50 %) are considered as normal iron status, whereas values not conforming to these categories are said to be indeterminate. The combined utility of the above tests in assessing iron status was determined by dividing the number of patients in whom iron status was detected (normal, deficient or overload) by total number of patients and expressed in percentage. The haemoglobin level of all the enrolled patients at time of enrolment was collected. To determine haemoglobin trend within each group, we collected haemoglobin levels 3-months before and 3-months after enrolment from chart review. Patient outcomes (death, alive and lost follow up) were obtained by chart review and telephone-follow up till October 2016.

Statistical analysis

The data were analysed using Statistical Package for Social Science (SPSS) Version 19.0, Graphpad Prism-6 and Microsoft Excel 2010. Non-parametric characteristics between any two groups were compared using Mann-Whitney test, and proportions using Chi-square test. For comparing more than two mean values we have used one-way analysis of variance. P value less than 0.05 was considered as statistically significant.

RESULTS

Demographics of study population

A total of 100 prevalent ESRD patients on haemodialysis were studied. The key demographics of the study cohort are summarized in Table 1. Patients ranged from 18 to 80 years. The mean age of the patients was 48.5 years. Among 100 patients, 63 were male and 37 were female.

Description by iron status

We classified these patients based on their iron status as per the NKF-KDOQI (see methods). Using serum ferritin and TSAT, iron status could be determined in 48% of the patients; 20% had normal iron status, 25% had iron deficiency, 3% had iron overload. The remaining 52% of the patient's iron status was indeterminate (Table 1 and 2). In univariate analysis, patients who were iron indeterminate were nearly indistinguishable from other groups by clinical and epidemiologic variables (as shown

in Table 1). However interestingly, iron indeterminate and overload groups had significantly greater dialysis vintage than the normal/iron-deficient groups.

Table 1: Baseline demographic characteristics.

TSAT: Transferrin saturation.

Outcomes by iron status

Anaemia outcomes: To examine the haemoglobin responses and anaemia, trends of patients according to iron status, we tabulated haemoglobin levels of patients in each group by iron status at enrolment at different time points before- and after- study enrolment (Figure 1 and Figure 2).

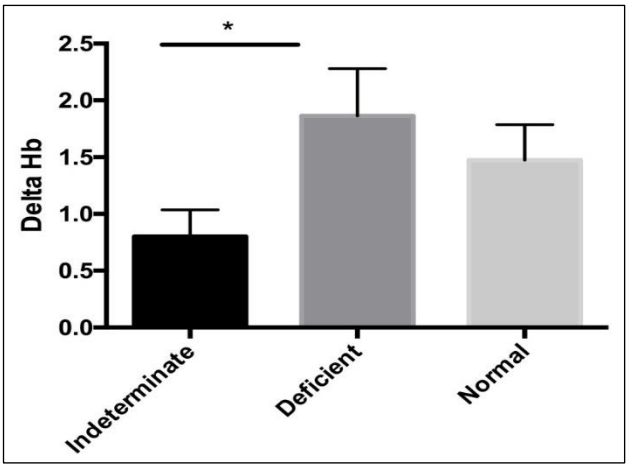

Figure 1: Compares Delta-haemoglobin in each study group, from 3-months before time of enrolment in study to 3-months after. [Columns represent means and error bars represent SEM. * = ANOVA (with post-test comparison) P< 0.05].

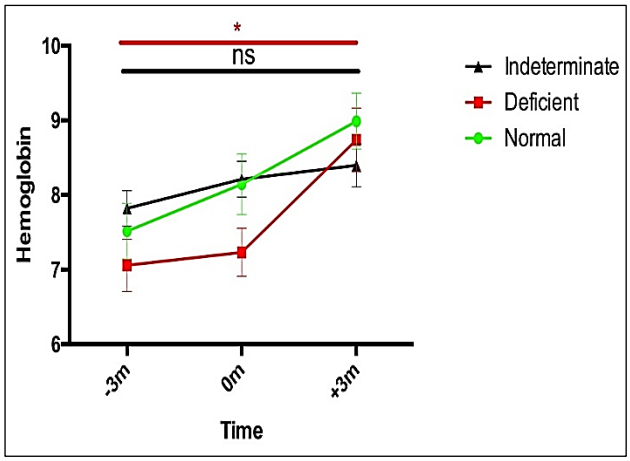

Figure 2: Trendlines of mean haemoglobin levels in each group by iron status. Indeterminate group had significantly inferior increases of haemoglobin over 6-months of follow-up. [Line represents mean, and error bars SD at each time point. * = Mann-whitney U P<0.05].

Table 3: Haemoglobin trend.

Groups	Total	Normal-1	Deficient-2	Overload-3	Indeterminate-4
	Mean (SD)	**Mean (SD)**	**Mean (SD)**	**Mean (SD)**	**Mean (SD)**
Haemoglobin 3months before (g/dL)	n=94 7.56(1.64)	n=19 7.51(1.61)	n=23 7.05 (1.67)	n=3 7.46 (1.15)	n=49 7.82 (1.66)
Haemoglobin 0 month (g/dL)	n=100 7.95(1.74)	n=20 8.14(1.76)	n=25 7.23 (1.60)	n=3 8.26 (2.39)	n=52 8.21 (1.71)
Haemoglobin 3 months after (g/dL)	n=90 8.64 (1.91)	n=19 8.98(1.63)	n=23 8.73 (2.00)	n=3 9.56 (3.13)	n=45 8.39 (1.92)

Table 3 summarizes haemoglobin levels and patients (n) in each group at each of the different time points studied. As the overload group consisted of 3 patients only, we excluded these from subsequent analysis. We interestingly observed that the mean haemoglobin level of patients in the Normal and Deficient groups showed significant increases over a 6-month time period, while those in the indeterminate group had insignificant increases in haemoglobin levels in this period (Figure 1). Mean delta haemoglobin levels over 6 months (3-months before enrolment to 3-months after enrolment) were 0.80±1.54 g/dl in the indeterminate group, compared to 1.87±1.95 g/dl in the deficient group (Mann Whitney P=0.03; Figure 2).

Patient outcomes

Overall during the follow up period, 29 patients continued on dialysis, 5 were at outside dialysis units, 8 patients received kidney transplants (4 of whom expired after transplantation). A total of 57 patients in our cohort had died during the follow up period (till October 2016). Five patients were lost to follow up in this time. There were no significant differences detectable in number of deaths between any of the groups by iron status in the duration of our follow-up, although all 3 patients in the overload group had expired (Table 1 and Figure 3).

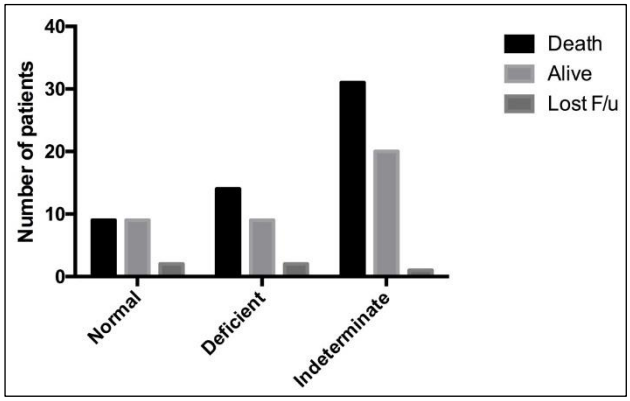

Figure 3: Patient outcomes in the study cohort till October 2016. No significant differences were observed in the proportion of patients that died in each group in this follow-up period (Chi square P=ns).

DISCUSSION

Anaemia contributes significantly to the morbidity and mortality in ESRD. ESA and iron supplementation are the most important factors in treatment of anaemia in ESRD patients.[13] Iron deficiency has been identified as a major factor for anaemia in CKD patients, with a 43-90% prevalence in different series.[6,14-16] Hence the periodical monitoring of iron status is crucial in ESRD.

There are two forms of iron deficiency, absolute iron deficiency and functional iron deficiency. Reduction of reticuloendothelial system iron in the bone marrow is referred to as absolute iron deficiency. Absolute iron deficiency may occur from impaired intestinal absorption, blood loss through the dialysis circuit, vascular access surgeries, repeated phlebotomies and increased iron utilization with erythropoietin therapy. In clinical practice, absolute iron deficiency is determined by serum ferritin less than 200ng/ml and TSAT less than 20%.[17] In the non-ESRD population, "functional" iron deficiency is ascribed when iron reserves in the bone marrow are adequate, but iron mobilization is impaired as in states of chronic inflammation.[18]

The current study assesses the utility of combining serum ferritin and TSAT to assess iron status among an Indian haemodialysis population. The evaluation of iron status is straightforward when both serum ferritin and TSAT are either high or low. But when these parameters are divergent, for instance, if the TSAT is low and serum ferritin is high, the accurate interpretation of iron status is difficult. This entity was common in our study where the iron status of only 48% of the patients were clearly determined (20% had normal iron status, 25% had iron deficiency and 3% had iron overload), and was indeterminate in the remaining 52% of patients. Interestingly in our study, the only epidemiologic factor associated significantly with indeterminate status was dialysis vintage. Why patients with indeterminate or overload status appeared to have longer durations of dialysis, is unclear but requires further exploration. Our data suggest that in a significant proportion of haemodialysis patients in a typical urban dialysis unit in India, the conventionally applied parameters were insufficient to accurately categorize iron status. Similar data has emerged from other groups.[19] Further, our data crucially demonstrates that patients with indeterminate status by conventional assessment have significantly inferior increases in haemoglobin levels with current therapy, suggesting the need for development of more specific diagnostic strategies to ascertain iron status in this group, to accurately manage iron status and anaemia.

Most studies have revealed that serum ferritin is very well related with iron stores in the bone marrow is the best surrogate of iron status in healthy individuals.[20-22] However, ferritin is an acute phase reactant increasing in states of chronic inflammation (such as dialysis), malignancy, or systemic disease, and ferritin levels alone may not reflect iron stores available for haematopoiesis. Thirty-six patients had low ferritin (<200) in our study. Only 25 of them had iron deficiency (combined with low-TSAT), whereas ~31% of them were in indeterminate group. Further, 29 patients had high serum ferritin. Only 3 of these had iron overload (combining TSAT), while 4/29 had low TSAT (<20%). Hence, decision to treat these patients with iron supplements based on these parameters would likely be imprecise. Similarly, a transferrin saturation of less than 20% in patients on haemodialysis is considered to be suggestive of iron deficiency whereas other studies have suggested that a transferrin saturation < 20% versus >20% alone may be inaccurate for assessing iron deficiency.[23-28] While most patients with TSAT less than 20% are iron deficient, few patients don't respond to an increase in iron supplements with either increase in haematocrit or maintenance of haematocrit with a decreased ESA requirement. On the other hand, numerous patients with a TSAT greater than 20% have functional iron deficiency respond to increased iron doses with elevations in the haematocrit, or maintenance of their haematocrit at decreased erythropoietin doses.[25-28] In our study, 43 patients had low TSAT (<20%); only 25 of them had iron deficiency (combined with ferritin). We found that 57 patients had TSAT values more than 20%, out of which 11 had low ferritin (<200). TSAT values in these 11 patients may be falsely high because of low total iron binding capacity (TIBC) during inflammation and infection.

The difficulties in the interpretation of iron status using TSAT and serum ferritin in ESRD patients and the consequent hematologic implications we show, warrant the application of other erythrocyte and reticulocyte based indices, such as the percentage of hypochromic red blood cells (Hypo) and the reticulocyte haemoglobin content (CHr). CHr requires a special analyser and is recommended as an alternative iron status indicator as well as an initial measure of the response to iron treatment in haemodialysis population.[29-31] Fishbane et al evaluated the reticulocyte haemoglobin content among 32 haemodialysis population and showed it to have a sensitivity of 100% and specificity of 80%.[29] Mittman et al evaluated reticulocyte haemoglobin content among 364 haemodialysis population receiving EPO and proved it to be an indicator of functional deficiency of iron.[30] Based on these and other data, NKF DOQI recommends a target of CHr greater than 29pg/cell.[32-35] The Hypo is an indicator of the percentage of red blood cells that contain low haemoglobin. Thus, it indicates only the functional iron availability and does not reflect storage iron. A Hypo level of greater than 10% indicates definitive functional iron deficiency. European Best Practice Guidelines stated that Hypo >10% is the most accurate marker for ID.[36] However, there are other studies which suggested lower threshold values for Hypo.[32,37-40] Both these tests are not widely available in India.

Here, we report that the combination of serum ferritin and TSAT accurately categorized the iron status in only 48%

of ESRD patients in our study. When serum ferritin and TSAT values diverged, they become unreliable for accurate interpretation of iron status, signaling an iron indeterminate state that was prevalent in 52% of our urban dialysis cohort. As we show here, this group of iron-indeterminate patients has inferior increases in haemoglobin over time, showing clinical relevance of this finding. Our data suggests that more sensitive indices such as Hypo and/or CHr may need to be employed (along with conventional tests) to accurately assess iron status, and improve management tools. This could lead to more accurate dosing of iron and ESAs, decrease overtreatment of anaemia, and possibly translate to cost savings from medication usage. Future studies on iron markers including both traditional and newer indices are required to improve iron management in ESRD population, especially in Indian population, where iron deficiency is common and similar studies are lacking.

ABSTRACT

Introduction: Electrocardiogram (ECG) is the simplest tool for diagnosing ST Elevation Myocardial Infarction (STEMI). We can use a12 lead ECG for prognostication purposes also.

Aim: The aim of the study was to find out the role of ECG as a prognostic marker in terms of clinical outcome and wall motion abnormality.

Materials and Methods: It was a prospective study done in PSG Institute of Medical Sciences and Research, Coimbatore, Tamil Nadu, India, from January 2014 to September 2014. Patients aged above 18 years admitted with first episode of ST EMI as per the inclusion and exclusion criteria were recruited for the study. Presence of reciprocal changes and QRS amplitude was measured from ECG. Presence of Left Ventricular Dysfunction (LVD) and wall motion score were calculated from ECG along with clinical outcome during first follow up visit. Statistical analysis was done using SPSS software. Probability was calculated using chi-square test, independent t-test and ANOVA analysis.

Results: A total of 120 patients were recruited for the study of which six were excluded based on the exclusion criteria. Among 114 patients analysed, 55 had reciprocal changes; 38 of them developed LVD which was statistically significant (p=0.002). Of the 78 patients with Anterior Wall Myocardial Infarction (AWMI), 35 had reciprocal changes; 15 (42.9%) of them had NYHA Class 1 symptoms, 14 (40%) had Class II and 4 (11%) had class III symptoms at follow up. The association was statistically significant (p=0.001). Similar statistically significant association was found in patients with Inferior Wall Myocardial Infarction (IWMI) who had reciprocal changes and NYHA symptoms at follow up (p=0.004). The mean wall motion score in patients with AWMI and reciprocal changes was 24.83 ± 4.1; whereas, without reciprocal changes was 23.98 ± 3.6; the association was not statistically significant. The mean QRS amplitude of all patients with LVD was 33.25 ±16.34. The association between QRS amplitude and LVD was not statistically significant. The overall mean wall motion score was 24.86 ± 3.91. The association between QRS amplitude and wall motion score was statistically significant (r value = 0.210). The association between QRS amplitude and wall motion score was statistically significant when we analysed AWMI (r= -0.147, p=0.199) and IWMI (r= -0.359, p=0.031) separately.

Conclusion: ECG can be used as a tool for prognostication in acute STEMI. The presence of reciprocal changes in the ECG can signify poorer outcome on follow up. Lower QRS amplitude can be used as a predictor of larger infarct.

Keywords: Coronary artery disease, Heart failure, Prognostic marker

INTRODUCTION

Myocardial infarction is one of the most important causes for hospitalization and is commonly seen in all populations worldwide [1]. The clinical approach to a patient suspected to have an acute coronary syndrome consists of detailed history taking, ECG changes, cardiac biochemistry evidence and imaging. The reliability of each of these modalities as a diagnostic tool is dependent on multiple factors, the most significant being the window period between the time of infarction and the time the patient seeks medical attention [2]. The current approach to patients presenting with typical or atypical features of myocardial ischemia or infarction starts with making the provisional diagnosis of acute coronary syndrome [3,4]. Depending on the changes seen on the 12 lead ECG, acute coronary syndrome is classified into STEMI, Non ST Elevation Myocardial Infarction (NSTEMI) or unstable angina [5].

Inspite of major leaps in the diagnostic tools and treatment of myocardial infarction, STEMI persists as one of the leading cause for mortality and morbidity in both the developed and developing world [6]. The prevalence of coronary disease and myocardial infarction is also on rise in the developing countries, with further worsening of adverse cardiovascular events due to disadvantages like inadequate primary prevention policies and limited availability of medical help [7].

There has been extensive research done in the field of cardiovascular medicine focused on ST elevation myocardial infarction and the dynamics of complications surrounding it. One particular area of interest in recent studies appears to be the study of extent of infarct over imaging modalities and its correlation with various events in the course of infarction [8,9]. Other parameters gaining importance are non traditional ECG changes like reciprocal changes, ST depression, QRS morphology, q waves etc., [10-17].

The simplest and oldest diagnostic tool for myocardial infarction is the 12 lead ECG. In daily practice, even though the ECG remains an important test in diagnosis and detection of progression of disease, there still remains ample potential for its role as a prognostic marker [18,19]. The fundamental advantage that stands to be gained by

realizing this potential is the time it saves for immediate intervention. In addition, it can serve as an instant and cost effective method for risk assessment instead of waiting for biochemical and angiography results. The purpose of this study was to observe the association between ECG changes (reciprocal changes and QRS amplitude) with left ventricular function, wall motion score and clinical outcome in patients with first episode of STEMI.

MATERIALS AND METHODS

It was a prospective study done in PSG Institute of Medical Sciences and Research, Coimbatore, Tamil Nadu, India, from January 2014 to September 2014. The study population comprised of patients hospitalized after being diagnosed with STEMI based on ST elevation seen on ECG done at admission. All those patients aged above 18 years admitted with first episode of STEMI, who underwent uncomplicated thrombolysis, were included in the study. Those patients with bundle branch blocks, pre-existing cardiac illness, re-infarction, with clinical findings of severe LVD at presentation and who underwent angioplasty were excluded from the study. Informed consent was obtained from the patients.

The patient's age, gender, risk factors for myocardial infarction were documented at admission. The first ECG taken was studied for presence or absence of reciprocal changes. The total of R wave amplitude in mm and S wave amplitude in all the leads of the ECG was taken and the sum was noted as the QRS amplitude. Left ventricular function was assessed by 2-D echocardiogram based on ejection fraction using eyeballing method. Patients were graded as having mild LVD if the ejection fraction was 45%-50%, moderate LVD if ejection fraction was 35%-45% and severe LVD if ejection fraction was less than 35% [20].

Regional wall motion abnormality was assessed using American Society of Echocardiography (ASE) method by grading wall motion of all 17 left ventricular segments. This was represented as wall motion score. For each of the individual 17 segments, score of 1 was taken as normal regional wall motion; score of 2 was given for hypokinesia, score of 3 for akinesia, score of 4 as dyskinesia and 5 for anuerysm. So, if a patient's echo showed normal left ventricular function, the total wall motion score was 17 for all segments together [21]. Clinical outcome of the patient was assessed in terms of New York Heart Association (NYHA) classification based on symptoms at first follow up after discharge from the hospital (which was commonly three to four weeks after infarction) [22].

STATISTICAL ANALYSIS

The data collected from the patients was tabulated using Microsoft excel. Statistical analysis was done using SPSS software. Probability was calculated using chi-square test, independent t-test and ANOVA analysis. The p-value was considered significant if it was found to be less than 0.05.

RESULTS

A total of 120 patients were included in the study. Six patients were excluded because the area of STEMI was inferior wall and posterior wall. So, a total of 114 patients presenting with STEMI were included.

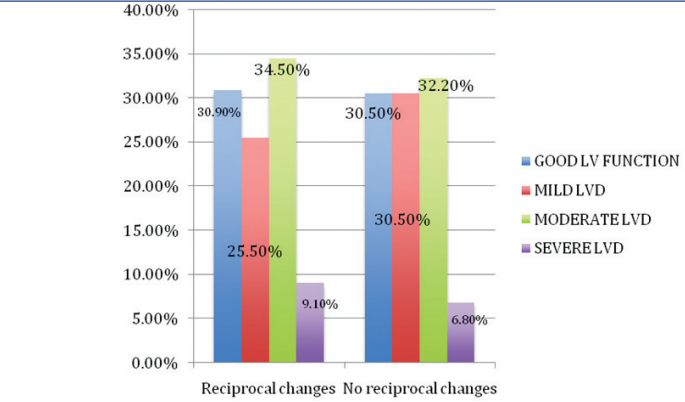
Out of the total 114 patients studied, 78 (68.4%) had AWMI and 36 (31.6%) had IWMI. Among the total study population, 55 (48.2%) patients had reciprocal changes in ECG. Of the 78 patients with AWMI, 35 (63.6%) had reciprocal changes in ECG. Of the 36 patients with IWMI, 20 (36.4%) had reciprocal changes.

Association between Reciprocal Changes and LVD

Out of 55 patients with reciprocal changes, 38 patients (69.1%) developed LVD [Table/ Fig-1]. The association between the two variables was found significant (chi-square test value = 0.002).

Of the 55 patients who had reciprocal changes in their ECGs, 17 (30.9%) had adequate left ventricular function, 14 (25.5%) patients had mild LVD, 19 (34.5%) had moderate LVD and the remaining 5 (9.1%) patients had severe LVD [Table/ Fig-2].

In the 78 patients with AWMI, 35 patients had reciprocal changes. The association between presence of reciprocal changes and LVD was found using Chi-square test and was insignificant (p-value = 0.843). Out of the 35 patients with reciprocal changes, 6 (40%) patients had adequate left ventricular function and out of the 43 patients without reciprocal changes, 9 (60%) patients had adequate left ventricular function [Table/ Fig-3].



In the 36 patients with IWMI, 20 patients had reciprocal changes. The association between presence of reciprocal changes and LVD was found using chi-square test and was insignificant (p-value = 0.856). Out of these 20 patients with reciprocal changes, 11 (55%) patients had adequate left ventricular function and out of the 16 patients without reciprocal changes, 9 (56.3%) patients had adequate left ventricular function [Table/ Fig-4].

Association between Reciprocal Changes and Wall Motion Score

In the 78 patients with AWMI, the association between reciprocal changes and wall motion score was analysed. The mean wall motion score in patients with and without reciprocal changes were 24.83 ± 4.1 and 23.98 ± 3.6 respectively [Table/ Fig-5]. The difference between the two groups was not significant (p-value = 0.342).

Reciprocal Changes	Left Ventricular Dysfunction		Pearson Chi-square p-value
	Yes	No	
Yes	38(69.1%)	17 (30.9%)	0.002
No	41(69.5%)	18(30.5%)	

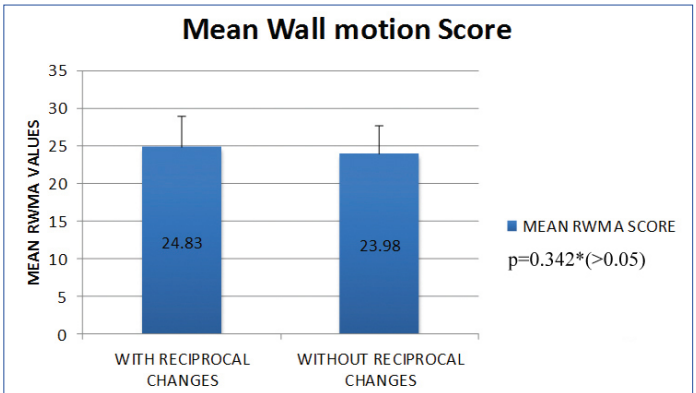
[Table/Fig-1]: Correlation between reciprocal changes and LV dysfunction.

[Table/Fig-2]: Reciprocal changes and LV dysfunction.

LVD	Reciprocal changes		Total
	No	Yes	
No LVD	9(60%)	6(40 %)	15(100%)
Mild LVD	13(59.1%)	9(40.9%)	22(100%)
Moderate LVD	19(52.8%)	17(47.2%)	36(100%)
Severe LVD	2(40%)	3(60%)	5(100%)
Total	43(53.1%)	35(44.9%)	78(100%)

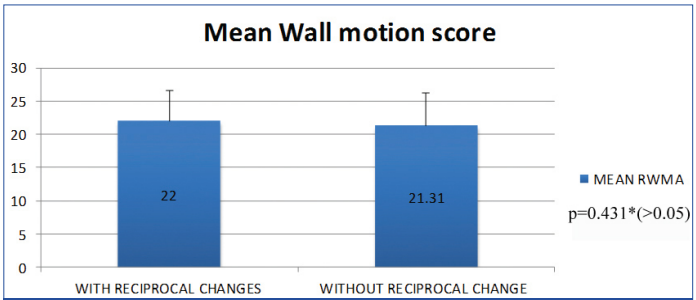
[Table/Fig-3]: AWMI - reciprocal changes vs. LV dysfunction.

Reciprocal Changes	No LVD	Mild LVD	Moderate LVD	Severe LVD	Total
No	9 (56.3%)	5 (31.3%)	0 (0%)	2 (12.5%)	16 (100%)
Yes	11(55%)	5 (25%)	2 (10%)	2 (10%)	20 (100%)
Total	20 (55.6%)	10 (27.8%)	2 (5.6%)	4 (11.1%)	36 (100%)



[Table/Fig-4]: IWMI - Reciprocal changes v/s LV dysfunction.

In the 36 patients with IWMI, the association between reciprocal changes and Wall motion score was analysed. The mean Wall motion score in patients with and without reciprocal changes were 22 ± 4.623 and 21.31 ± 4.99 respectively [Table/ Fig-6].The difference between the two groups was not significant (p-value = 0.431).



Association between Reciprocal Changes and Symptoms at Follow up

A total of 35 out of 78 patients with anterior wall infarction had reciprocal changes in their ECGs. Among these 35 patients, 15 (42.9%) had NYHA Class I symptoms, 14 (40%) patients had NYHA Class II symptoms, 4 (11.4%) patients had NYHA Class III symptoms and 2(5.7%) were lost to follow up [Table/ Fig-7]. The p-value calculated using Pearson chi-square test and was found to be statistically significant (p = 0.001). This indicates those patients who had reciprocal changes are at high risk to develop cardiac failure symptoms at follow up.

Out of the 36 patients with IWMI, 20 patients had reciprocal changes in their ECGs. Among those 20 patients, 9 (45%) had no symptoms NYHA Class I, 10 (50%) patients had NYHA Class II symptoms and 1 (5%) patient had NYHA Class III symptoms [Table/ Fig-8). The p-value calculated using Pearson Chi square test was statistically significant (p = 0.004). This also indicates those patients who had reciprocal changes are at high risk to develop cardiac failure symptoms at follow up.

YES	9(45%)	10(50%)	1(5%)	0(0%)
NO	15(93.8%)	0(0%)	0(0%)	1(6.3%)

[Table/Fig-8]: Correlation of reciprocal changes and clinical outcome in IWMI.

Association between QRS amplitude and LV Dysfunction

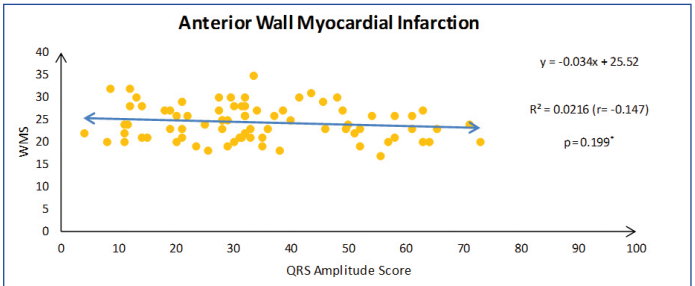
The mean QRS amplitude of all patients with LVD was 33.25 ±16.34.The mean QRS amplitude in patients with AWMI was 34.17 ± 16.93 and with IWMI was 35.03 ± 14.42. The association between QRS amplitude and LVD was analyzed [Table /Fig-9a] in patients with AWMI using ANOVA test and was found to be statistically insignificant (p-value = 0.307). The association between QRS amplitude and LVD was analyzed in patients with IWMI using ANOVA test and was found to be statistically insignificant (p-value 0.156) [Table /Fig-9b].

Association between QRS Amplitude and Wall Motion Score

The mean QRS amplitude in all the 114 patients was 34.17 ± 16.929. The mean wall motion score in all 114 patients was 24.36 ± 3.915. Using Pearson chi-square test, the correlation was statistically significant (r-value = - 0.210). The mean QRS amplitude in AWMI patients was 34.17 ± 16.9 [Table /Fig-10]. The mean wall motion score in AWMI patients was 24.36 ± 3.9. Using the Pearson chi-square test, the correlation was found to be statistically significant (r-value = -0.147, p= 0.199).

The mean QRS amplitude in IWMI patients was 35.03 ± 14.4. The mean wall motion score in IWMI patients was 21.69 ± 4.7 [Table /Fig-11]. Using the Pearson chi-square test, the correlation was found to be statistically significant (r-value = - 0.359, p= 0.031)

Association between QRS Amplitude and Symptoms at Follow up



Among the 78 patients with anterior wall STEMI, 48 patients had no symptoms at first follow up (NYHA Class I), 23 patients were symptomatic (NYHA Class II and above) and seven patients lost to follow up. In these 48 patients under NYHA Class I, the mean QRS amplitude was 33.95 ± 18.17. In these 23 patients under NYHA Class II and above, the mean QRS amplitude was 35.30 ± 15.12. The difference between the two groups was statistically insignificant (p = 0.759). Among the 36 patients with IWMI, 24 patients had no symptoms at first follow up (NYHA Class I), 11 patients were symptomatic (NYHA II and above) and one patient lost to follow up. In these 24 patients under NYHA Class I, the mean QRS amplitude was 34.70 ± 13.47. In these 11 patients under NYHA Class II and above, the mean QRS amplitude was 36.72 ± 17.17. The difference between the two groups was statistically insignificant (p = 0.706).

LVD	QRS Amplitude Score				p-value (ANOVA)
	n	Mean	Std. Deviation	Std. Error of Mean	
No	15	34.03	18.564	4.793	0.307
Mild	22	39.36	19.638	4.187	
Moderate	36	32.14	14.54432	2.424	
Severe	5	26.4	13.198	5.902

DISCUSSION

In our study, reciprocal changes in the ECG were seen in about half of the patients (48.2%), of which around two thirds had AWMI and the remaining had IWMI. Majority of the patients studied (69.3%) had LVD following STEMI. The presence of reciprocal changes in ECG showed significant association with development of LVD when analyzed in all the patients in total. When the subset of patients with reciprocal changes in AWMI and IWMI were considered separately, the association with LVD was statistically insignificant. This was in-contrast to the study by Peterson ED et al., which showed ST depression in precardial leads in IWMI had poor prognosis [11].

A similar result was found in a study done by Atroush HE et al., ejection fraction was not statistically different in patients with acute IWMI with and without precordial ST segment depression [23]. This was in contrast to the study by Parale GP et al., where they found that patients with AWMI and IWMI with reciprocal changes had significant LVD compared to those without [24]. Zoghi M et al., also found that patients of AWMI with reciprocal ST depression and without had significant difference with regard to ejection fraction [25]. Atroush HE et al., in their study, found that patients with AWMI infarction with precordial ST segment depression had significant complications during hospital course than patients without reciprocal changes [23]. Salcedo JR et al., also found that complications during hospital stay were more in patients of AWMI with precardial ST segment depression [26].

In AWMI patients, the presence of reciprocal changes did not reflect in an increase in the wall motion score. When a similar association was analyzed in IWMI patients, it was also found to be insignificant. The association between reciprocal changes and clinical outcome in terms of NYHA class of symptoms on first follow up was found to be significant. This may imply that the presence of reciprocal changes can spell worse outcome following STEMI when compared to those without reciprocal changes in their ECG.

On analyzing the association between QRS amplitude and wall motion score revealed that a decrease in QRS amplitude was associated with an increase in wall motion score in both AWMI and IWMI patients. When the association between QRS amplitude and degree of LVD was found, it was statistically insignificant. This meant that low QRS amplitude did not reflect the degree of LVD.

This is the first study of this kind correlating reciprocal changes and QRS amplitude with LVD and clinical outcome in STEMI.

LIMITATION

The limitation of the study is the small sample size; we need a larger study with higher sample size to extrapolate the findings. We also agree the assessment of outcome at follow up has confounding factors like compliance with medication, diet and lifestyle modification measures.

CONCLUSION

In STEMI, the patients who had reciprocal changes in their ECG were more prone to develop LVD, but this significance was lost when individual areas of infarction were considered. The presence of reciprocal changes in the ECG can signify poorer outcome on follow up at three to four weeks after infarction. In patients with lower QRS amplitudes, higher wall motion scores were observed, indicating that low voltage of QRS complexes in the ECG can be predictive of larger extent of the infarct. Even though we are in the era of primary PTCA and early re-vascularisation therapy for STEMI, ECG is a very useful tool to prognosticate where early revascularization option is not available.

Effects of Sleep Deprivation on the Cognitive Performance of Nurses Working in Shift

DEEPALAKSHMI KALIYAPERUMAL[1], YAAL ELANGO[2], MURALI ALAGESAN[3], ISWARYA SANTHANAKRISHANAN[4]

ABSTRACT

Introduction: Sleep deprivation and altered circadian rhythm affects the cognitive performance of an individual. Quality of sleep is compromised in those who are frequently involved in extended working hours and shift work which is found to be more common among nurses. Cognitive impairment leads to fatigability, decline in attention and efficiency in their workplace which puts their health and patients' health at risk.

Aim: To find out the prevalence of sleep deprivation and its impact on cognition among shift working nurses.

Materials and Methods: Sleep deprivation among 97 female and three male healthy nurses of age 20–50 years was assessed by Epworth Sleepiness Scale (ESS). Cognition was assessed by Montreal Cognitive Assessment (MoCA) questionnaire. Mobile applications were used to test their vigilance, reaction time, photographic memory and numerical cognition. The above said parameters were assessed during end of day shift and 3-4 days after start of night shift.

Results: Poor sleep quality was observed among 69% of shift working nurses according to ESS scores. The cognitive performance was analysed using Wilcoxon signed rank test. The MoCA score was found to be lesser among 66% of nurses during night (25.72) than day (26.81). During the night, 32% made more mathematical errors. It was also found that, 71%, 83% and 68% of the nurses scored lesser during night in the Stroop's colour test, vigilance test and memory tests respectively. Thus, impairment in cognitive performance was statistically significant ($p<0.001$) among shift working nurses.

Conclusion: Cognitive performance was found to be impaired among shift working nurses, due to poor sleep quality and decreased alertness during wake state. Thus, shift work poses significant cognitive risks in work performance of nurses.

Keywords: Circadian rhythm, Night shift, Sleep quality

INTRODUCTION

Sleep plays an integral part in the health and well-being of the individual. Sleep is controlled by the Supra Chiasmatic Nucleus (SCN) of the hypothalamus, endogenous clock which regulates the production of melatonin, a hormone that induces sleep [1]. Physiological systems that follow circadian rhythm like sleep-wake cycle, hormone secretions, core body temperature are influenced by signals from the environment especially light [2]. Altered circadian rhythm results in physiological and psychological variations [3].

The recommended sleep duration for a healthy adult is seven to nine hours per day [4]. Shift work results in a conflict between a days oriented circadian physiology and requirement for work and sleep at the wrong biological time of day. Internally driven circadian biological clocks regulate the periods of sleepiness and wakefulness. Disruption of circadian rhythm and inadequate sleep are associated with derangement of physiological functions and leads to obesity, cardiovascular disease, and cognitive impairment. Thus, shift work, night work, and longer, irregular working hours are associated with reduced sleep duration and poor quality of sleep [5,6].

Sleep Deprivation (SD) is defined as, "obtaining inadequate sleep to support adequate daytime alertness" [7]. Long-term SD has a detrimental effect on cognitive function, attention, learning, and working memory and is associated with exaggerated neural reactivity [8]. Moreover, it is also associated with mal adaptations of physiological and behavioral functions. Sleep deprivation affects the ability of health workers who are involved in multitude of life saving tasks which need more attention and concentration. Extended work shifts of twelve hours or longer is common with nurses, whose insufficient sleep puts patients' health and their health at risk [9]. SD among nurses is the major cause for making an error in patient care and significant decrease in vigilance of the job [10]. The aim of this study was to assess the prevalence of SD among nurses working in shift and its impact on their cognitive performance.

MATERIALS AND METHODS

This cross-sectional study was conducted among staff nurses of Peelamedu Samanaidu Govindasamy Hospitals, Coimbatore, Tamil Nadu, India, who were on a rotating work schedule i.e., staff posted to day shift for one month and the same staff posted to night shift for the next one month during August 2016 to September 2016 after obtaining the ethical clearance from the Institution Ethical Committee.

Sample Size

Hundred staff nurses were chosen whose age ranged from 20 years to 50 years. Sample size (96), was calculated considering prevalence of sleep deprivation among staff nurses as 51% with 20 % precision [11].

Inclusion Criteria

Staff nurses of all departments like Medicine, Surgery, OBG, Paediatrics, etc., who were working eight hours shift a day for six days a week, not suffering from any known medical or mental illness and had a previous work experience of at least one year in rotating shift work, were included.

Exclusion Criteria

Staff nurses with a history of medical illness especially neurological diseases, sleep disorders (insomnia, somnolence, etc.,) and smoking, alcohol, any other drug consumption or any medications (within the last 14 days), those who do overtime and other jobs during off duty were excluded from the study.

The participants were informed about the test procedure and a written consent was obtained from them. The staff nurses were assessed for sleep deprivation using the Epworth Sleepiness Scale (ESS) [12]. The ESS was used to measure day time sleepiness and

hence to diagnose sleep deprivation. The probability of falling asleep of the subject was rated from 0 to 3 during eight different situations in their day to day activities, not necessarily every day. The total score was calculated by adding the scores for the eight questions.

The study participants were assessed for any alterations in their cognitive performance as a result of sleep deprivation by using a series of tests. These tests were conducted twice, at the end of their eight hour duration day shift work and end of eight hour duration night shift work after 3-4 days of the commencement night shift. This ensured enough time for the circadian rhythm to reset according to the changed working hours [13]. The tests assessed general intellectual function, numerical cognition, execution, vigilance and memory.

General Intellect

The Montreal Cognitive Assessment (MoCA) Version 7.3 was used to assess various cognitive domains concerned with visuospatial skill, naming, memory recall, attention, language, abstraction, delayed recall and orientation [14]. This test can be easily completed within 10 minutes. The total possible score is 30 points. The scores obtained during the day shift and night shift hours were compared.

Executive Function (Response Inhibition and Working Memory)

Executive function includes control and coordination of cognitive skills like analytical thinking, working memory, planning, cognitive flexibility, analysing the problem and as well as control over attention and inhibition. In this study, response inhibition and visual working memory was assessed. Mobile applications (Confusing colours (stroop test), Memoryze) were used for this purpose [15,16]. Response inhibition was found using an application that worked on the principle of Stroop effect [15].

Attention (Vigilance)

Attention deficit is more commonly reported in sleep deprivation. Failure of vigilant attention affects the individual's ability to respond to stimuli on time. A mobile application (Vigilance test) which works like the Mackworth clock test was used to assess sustained attention. The application only picked up accuracy in terms of number of targets detected and false alarms [17].

Simple Reaction Time

Simple reaction time is the test to assess the processing speed and motor control of the individual by providing a known stimulus to elicit the response. The participant was asked to press a button as soon as a colour change occurs. This was done using a mobile application (reaction time test) [18].

Numerical Cognition (Mental Speed)

The mental speed was assessed by asking the participants to solve a worksheet having 25 maths problems. This worksheet had problems of addition, subtraction, multiplication and division of 2-digit numbers. The time taken for solving the worksheet at different shift hours was noted and compared [19].

STATISTICAL METHODS

Data was analyzed using SPSS Version 19.0. Prevalence of sleep deprivation was expressed in percentage. A Wilcoxon Signed-Ranks test was used to compare non-parametrical values. The p value < 0.001 was considered statistically significant.

RESULTS

Of the 100 participants, 97 of them were females and the rest were male staff nurses. The mean age of the participants was 25.06 years.

The sleep deprivation was assessed at the end night shift work on day 3 or 4 of the night shift. From the scores obtained from ESS, it was found that 69% had disturbed sleep patterns due to shift work. The average ESS score obtained was 9.37 (± 4.225). Majority of the nurses (42%) had mild SD (ESS scores of 8 to 11 [Table/Fig-1].

The maximum score that was obtained in MoCA during night shift and day shift hours was 29 and 30 respectively. The minimum score was found to be 21 during night and 23 during day. The mean score for general intellect and attention was decreased during night, while the mean scores for mental speed and reaction time were increased during the night hours [Table/Fig-2].

Sleep deprivation	Epsworth Sleepiness Score	Prevalence (%)
Normal sleep	Less than 8	31
Mild	8-11	42
Moderate	12-15	17
Severe	16-24	10

[Table/Fig 1]: Prevalence of sleep deprivation (n=100).

A Wilcoxon Signed-Ranks test was used to compare these non-parametrical values. This test indicated that MoCA test score obtained during the day shift hours was statistically significantly higher than the scores of night shift hours (Z=-5.872, p<0.001). Also, the scores obtained for execution (Z=-5.056, p<0.001) and memory tests (Z=-5.241, p<0.001) during the day shift hours were significantly higher than those obtained at night. The time taken to complete the math worksheet was significantly lower during the day than at night (Z=-5.762, p<0.001). The response time for the vigilance test was statistically significantly quicker during the day than at night (Z=-7.241, p<0.001). The number of targets detected was significantly higher during the day shift hours (Z=7.163, p<0.001) and the number of false alarms was significantly higher during the night hours (Z=-7.373, p<0.001) [Table/Fig-2].

Domain		Day Shift		Night Shift		Wilcoxon Signed-Ranks Test	
		Mean	SD	Mean	SD	Z*	p
General intellect (MoCA)		26.81	1.368	25.72	1.590	-5.872	<0.001
Mental speed (Maths)		2.14	0.689	2.34	0.740	-5.672	<0.001
Response Inhibition		8.48	4.602	4.91	3.210	-5.056	<0.001
Simple Reaction time		0.33	0.142	0.54	0.148	-7.241	<0.001
Working Memory		12.66	4.848	8.85	4.398	-5.241	<0.001
Attention (Vigilance)	Targets detected	5.03	1.794	2.53	1.666	7.163	<0.001
	False alarms	1.37	1.195	3.07	0.832	-7.373	<0.001

[Table/Fig 2]: Cognitive performance.
*Based on positive ranks (night shift – day shift) p (2 – tail) < 0.001 is statistically significant.

DISCUSSION

Our present study reported 69% of shift working nurses were affected with sleep deprivation. Thus, the poor quality and inadequate quantity of sleep among the participants in the present study could be due to extended shift work (more than 13 to 14 hours for each shift, including transportation time), irregular sleep wake cycle due to their disrupted circadian rhythms. This is in line with the results observed among physicians having the similar work schedules [20].

There has been increased interest in the effects of sleep deprivation among health care personnel's as it relates to patient care. Moreover, working at night and working excessive hours restrict sleep duration, as a result of fatigue concentration decreases and there will be increase in cognitive defects and also leads to compromised health and safety at work [21,22]. Research conducted among night shift residents' and nurses' reported that poor concentration hinders their efficiency, decision making capacity and also causes increased error rates [23].

Our present study aimed to compare cognitive functions of the shift working nurses at the end of the day shift and night shift hours. Better cognitive ability was be reported among those who have never exposed to shift work compared to those who have exposed

to sleep deprivation, altered circadian rhythm and extended shift work duration [10]. Lower level of scores was observed in general intellectual ability, maths, response inhibition, attention, simple reaction time and working memory. This decline may be due to an increase in prevalence of sleep deprivation among shift working nurses, as sleep deprivation affects the frontal and prefrontal cortex [24].

Partial sleep deprivation had brought about a decline in response inhibition during night shift in the present study indicates the greater vulnerability of frontal lobe to sleep deprivation. This is in line with results of the study conducted among BPO workers in India [25].

Working memory and episodic memory was found to be associated with temporal lobe function. As the shift work is known to produce deleterious effects on mental health, which is responsible for the impairment of memory, concentration and thinking ability. We found that visual working memory was better during the day shift than at night. Thus, memory also becomes enslaved to sleep deprivation [26,27]. Moreover, we observed that the maths problems were solved at a slower pace during the night shift hours. Our findings were consistent with the results of a study conducted among a group of interns in the medical field in US [28].

Furthermore, simple reaction time was found to be delayed during the night hours as a result of SD. Vigilance test showed that there were lesser target detections and more false alarms during the night hours. There are studies which prove that tests of vigilant attention during periods of SD are sensitive to both circadian and homeostatic drives and that SD causes an overall slowing of reaction times, results in increased errors of omission and commission, and enhances the time-on-task effect [29-31].

Overall irregularities in circadian rhythm and natural sleep wake cycle resulted in the impairment of cognitive function during the night shift, than at day. Some studies state that, though day and night shift work are of the same duration, those who work night shift are more liable to have sleep deprivation and hence more vulnerable to its various deteriorating effects [32-34].

LIMITATION

ESS is quite reliable and stable measure of sleep quality, it is not as accurate as an actigraph or actimetry sensor in detection of SD. All domains of cognition were also not tested in this study. Moreover, mobile application software utilized to test cognition were subjected to internal face validation due to resource constraints. Further studies on a larger population are needed with the aid of actigraphy to assess the prevalence of SD and its impact on all the cognitive domains.

CONCLUSION

This study shows that SD is prevalent among staff nurses working in shift. The various cognitive domains like general intellect, reaction time, attention, vigilance and memory are impaired as a result of SD, which increases the chances of error at work place. Hence, it is necessary to incorporate measures like rest breaks, napping, exercise, and bright light at work place.

ABSTRACT

Background: Microalbuminuria is considered as an early marker and strongly associated with risk of cardiovascular complications in diabetic patients. Autonomic imbalance due to micro vascular damage to parasympathetic and sympathetic fibers results in reduced heart rate variability; also predicts increased risk for cardiovascular events in diabetics. Hence it is necessary to identify an early and effective predictor of diabetic micro vascular complications. Objective of the study was to compare heart rate variability of controls with type 2 diabetes with and without microalbuminuria.
Methods: This comparative study was conducted among individuals without diabetes, hypertension and dyslipidemia (controls) and Type II diabetics with and without microalbuminuria (cases). Cases and controls were subjected to general clinical examination; microalbuminuria and HbA1C were noted. heart rate variability was assessed using digital physiograph. Frequency (HF, LF, LF/HF ratio) domain readings were noted.
Results: Mann Whitney U test was employed to analyze nonparametric data. Diabetics with microalbuminuria when compared with controls showed statistically significant (p-value=0.015) reduction in vagal activity. When compared with diabetics without microalbuminuria (180.4±151.7) they showed reduction in HF with no statistical significance. When diabetic group without microalbuminuria (0.56±0.31) was compared with controls they showed alternation in LF/HF ratio which has no statistical significance. Diabetics with microalbuminuria when compared with controls showed a statistically significant (p-value=0.009) alternation in LF /HF ratio implying an autonomic imbalance.
Conclusions: This study shows there is significant vagal inhibition and autonomic imbalance in diabetic patients with microalbuminuria compared to controls. To ascertain the role of HRV as an early predictor of cardiovascular complications we propose to conduct study with a larger sample size in future.

Keywords: Autonomic imbalance, Diabetes mellitus, Heart rate variability, Microalbuminuria

INTRODUCTION

The magnitude of non-communicable diseases (cardiovascular diseases, diabetes, malignancies and chronic respiratory diseases) has brought about a negative socioeconomic impact and sufferings to the mankind.[1] 36 million deaths have been reported every year due to diabetes and its complications. Moreover, 9 million people succumb to death prematurely.[2] Improved and effective medications have increased the lifespan of diabetic population. Hence there is a need to identify and intervene at the earliest in order to prevent complications and provide them a better quality of living. Microalbuminuria is considered as an early marker. It

causes endothelial dysfunction and predisposes atherosclerotic coronary artery disease, stroke, peripheral vascular disease, and cardiovascular mortality among diabetic population.[3,4] It was stated in heart outcomes prevention evaluation study, that diabetic patients with microalbuminuria are more prone for cardiovascular complications thus periodic screening for microalbuminuria could allow early identification of vascular disease.[5] Moreover, microvascular damage to parasympathetic and sympathetic fibers cause autonomic imbalance also predicts increased risks for cardiovascular arrhythmias, sudden death, and myocardial infarction in adults with diabetes.[6] HRV rate variability is a non-invasive indicator of cardiac autonomic function that predicts mortality and morbidity.[7]

However, the studies available till date give no conclusive answer to the concurrent association between lower cardio vascular autonomic function and microalbuminuria. Our objective was to compare heart rate variability of normal individuals with type 2 diabetics with and without microalbuminuria.

METHODS

This comparative study was conducted after obtaining clearance from institutional human ethics committee and informed consent from study participants. Individuals without diabetes, hypertension and dyslipidemia were recruited as controls (n=14). Type II diabetics with and without microalbuminuria of both sexes with age ranging from 45-65 years were included as cases (n=14). Patients with hypertension, coronary artery disease, cerebrovascular accident, family history of young MI, hyper or hypothyroidism, and beta blocker treatment were excluded. Cases and controls were subjected to general clinical examination. Presence of microalbuminuria and HbA1C values were noted from their clinical records.

Heart rate variability

Cases and controls were instructed to refrain from smoking, caffeine intake for 2 hours and alcohol intake for 36 hours. It was ensured they had adequate rest, got at least 8 hours of uninterrupted sleep on the night before the assessment of HRV and had normal breakfast on the day of assessment. They were made to lie quietly in a couch in supine position for five minutes to alleviate the anxiety in a sound attenuated room with dim lighting and the temperature ranging from 20 to 25°Celsius.

After explaining the procedure to the subject, heart rate variability, a quantitative marker of the autonomic activity was assessed using an ambulatory ECG system (INCO digital NIVIQURE, Bangalore, India) in lead II for 5 minutes. It is a multi-channel digital data acquisition system which enables to acquire, analyze and store ECG data. ECG data was obtained at a sampling rate of 1024 Hz in standard lead II configuration. The interface RS232C-compatible module was used to transfer data from the recording unit to the computer. The transferred data was analyzed using inbuilt software system. The series of RR intervals obtained was subjected to frequency domain analysis.

Frequency domain variables low frequency (LF) and high frequency (HF) power of HRV spectrum in normalized units and LF/HF ratio were measured. Descriptive statistics and Mann Whitney U test was employed to analyze nonparametric data.

RESULTS

42 individuals participated in the study, out of which 14 were non-diabetics, who acted as controls and the remaining 28 diabetics acted as cases. Out of 28 diabetics, 14 were presented without microalbuminuria and 14 with microalbuminuria. Results were expressed in mean±standard deviation. The mean age of the control group was found to be 45.78±6.8 and that of cases without microalbuminuria was 53.07±10.9 and with microalbuminuria was found to be 53±10.8.

When the diabetic group was compared with the non-diabetics HF showed statistically significant reduction (p=0.041) and the LF/HF ratio showed a significant alteration (p=0.015) (Table 1).

Table 1: Comparison between diabetics and non-diabetics.

Variables	Mean±standard deviation		P-value
	Non - diabetics N=14	Diabetics N=28	
HBA1C	5.71±0 .23	8.55±2.57	0.000*
HF	281±262	136.7±123.5	0.041*
LF	82.8±64.8	74.8±43.5	0.883
LF/HF	0.47±0.3	0.73±0.35	0.053

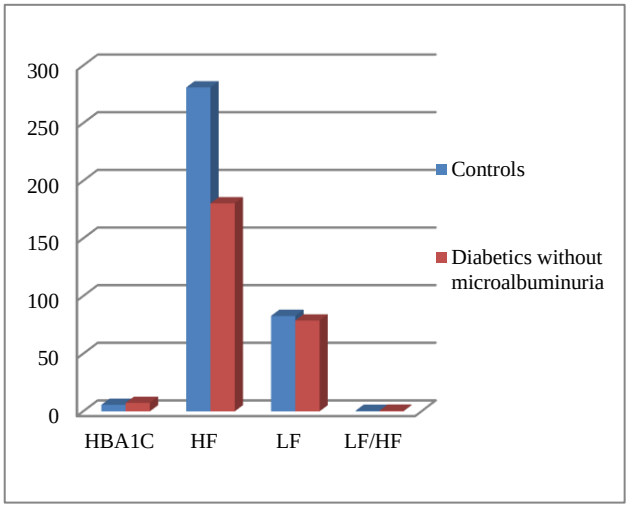

Figure 1: Comparison between the controls and diabetics without microalbuminuria.

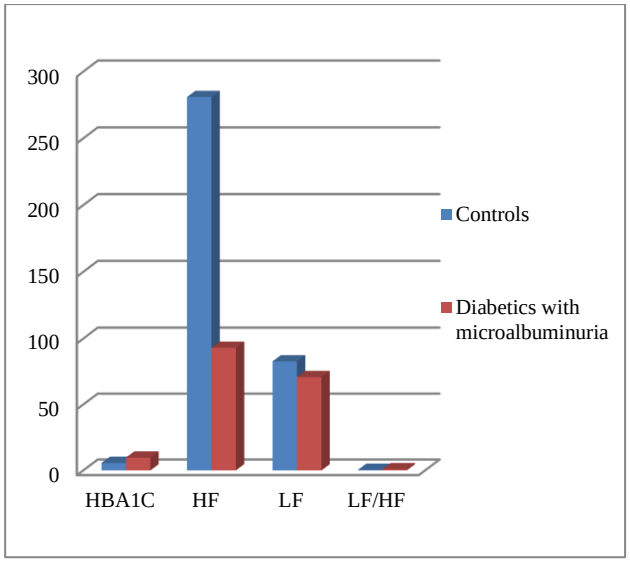

Figure 2: Comparison between the controls and diabetics with microalbuminuria.

On analysis of short term HRV, the mean HF was found to be 281±262 in controls. When the diabetic group without microalbuminuria (180.4±151.7) was compared with the controls reduction in HF was observed with no statistical significance (Figure 1). However, the diabetic group with microalbuminuria (93.05±67.6) when compared with controls showed statistically significant (p=0.015) reduction in HF (Figure 2).

LF/HF ratio was found to be 0.47±0.3 in controls. When diabetic group without microalbuminuria (0.56±0.31) was compared with controls they showed an alteration which has no statistical significance. However when the diabetic group with microalbuminuria was compared with controls they showed a statistically significant (p=0.009) alteration in LF/HF ratio (Table 2).

DISCUSSION

Microalbuminuria and heart rate variability are considered as the early predictors and prognostic markers of impending microvascular complications in diabetic population.[8,9] Increased prevalence of microalbuminuria (10 to 40%) was found to be reported in diabetic population when compared normal healthy individuals (5 to 7%).[10] This finding substantiates the presence of microalbuminuria as an early marker for diabetic complications.

Table 2: Comparison between diabetics with and without microalbuminuria.

Variables	Mean±standard deviation		p-value
	Diabetics without microalbuminuria n=14	Diabetics with microalbuminuria n=14	
HBA1C	7.37±1.25	9.72±3.02	0.021*
HF	180.42±151.71	93.05±67.6	0.08
LF	78.79±35.83	70.86±51.06	0.38
LF/HF	0.56±0.31	0.89±0.32	0.004*

HRV analysis is a noninvasive method to assess cardiac autonomic function. It is quantified in time and frequency domains. Time domain is based on statistical operation on R-R intervals and frequency domain is based on spectral analysis of an array of R-R intervals. Frequency domain measures are considered to be more sensitive according to the suggestion of Task force of the European society of Cardiology.[11] This suggestion led to the usage of frequency domain measures in our study.

The frequency domain measures such as LF indicates sympathetic activity, HF assesses cardiovagal activity and the LF/HF reflects the sympathovagal balance. In present study we observed that the frequency domain parameters (HF, LF and HF/LF) which assess the autonomic balance showed an alteration suggesting autonomic dysfunction in diabetic patients with and without microalbuminuria.

Many researchers have reported that there is 2 to 4 times increased risk for cardiac dysautonomia in a diabetic population when compared to controls.[12] In accordance with this study, our findings report a significant reduction in HF (136.7±123.5) and an alteration in LF/HF (0.73±0.35) which suggests a significant cardiovagal inhibition and sympathovagal imbalance in the diabetic group when compared with the nondiabetic population. In a comparative study conducted among diabetics and controls, Mirza M observed both sympathetic and parasympathetic dysfunction with parasympathetic dominance in diabetic group[13,14]

Furthermore, present study also revealed a nonsignificant decrease in HF among the diabetics without microalbuminuria whereas a statistically significant decrease among the diabetics with microalbuminuria. This finding proved that there exists a significant cardiovagal inhibition in the diabetics with microalbuminuria. This observation is in line with the

other studies which report a decrease in time and frequency domain parameters of HRV before the clinical evidence of autonomic neuropathy in diabetic patients.[15] Carnethon et al, in their study found out that reduced HRV leads to complications and found to be independent prognostic marker in patients with type 2 diabetes.[16]

In our study LF/HF ratio was found to be altered in diabetics without microalbuminuria with no statistical significance. However, the diabetic group with microalbuminuria showed a statistically significant alternation implying an autonomic imbalance. In another study conducted by Colhoun et al among type 1 diabetic patients power spectral analysis of HRV was found to be reduced and was associated with cardiovascular risk factors such as increased HbA1c, dyslipidemia, higher BMI hypertension and albuminuria.[17]

It was observed in previous studies that there was a higher incidence of myocardial Ischemia in Type 1 diabetes patients with microalbuminuria.[18] However, several studies confirmed the association of microalbuminuria and alteration in vascular tone are the results of endothelial dysfunction which predicts cardiovascular events in diabetic population.[19] The results of a study which employed heart rate reserve and rating of perceived exertion in prescribing intensity of exercise also strongly support the proposed role of reduced heart rate variability along with microalbuminuria as a sensitive marker in predicting cardiovascular complications.[20]

Prevention plays a key role in quality health care delivery so it is necessary to identify early, noninvasive, feasible and effective tool to predict cardiovascular complications in diabetic population. Our pilot study is in favor of the positive role of short term HRV as a tool which fulfils all the aforementioned criteria in predicting cardiovascular complications

CONCLUSION

This study shows there is significant vagal inhibition and autonomic imbalance in diabetic patients with microalbuminuria when compared to controls. To ascertain the role of HRV as an early predictor of cardiovascular complications we propose to conduct the study with a larger sample size in future.

Case Report

Eosinophilic gastroenteritis in an immunosuppressed patient: a case report

ABSTRACT

Eosinophilic gastroenteritis is a rare disease that is characterized by Eosinophil infiltration in one or multiple segments of the gastrointestinal tract. The etiology of this condition remains unknown. Eosinophilic gastroenteritis has heterogeneous clinical manifestations that depend upon the location and depth of infiltration in the gastrointestinal tract, and eosinophilia may or may not be present. This article reports a case of Eosinophilic Gastroenteritis in a 57 years old retroviral male patient, who presented with chronic diarrhea, bilateral pedal edema and eosinophilia. Ultimately, the diagnosis of eosinophilic gastroenteritis was clinched. The rare character of eosinophilic gastroenteritis and its varied clinical presentations often lead to delayed diagnosis and complications. Case reports may help to disseminate knowledge about the disease, thereby increasing the likelihood of early diagnosis and intervention to prevent complications.

Keywords: Chronic diarrhea, Eosinophilic gastroenteritis

INTRODUCTION

Eosinophilic gastroenteritis (EG) is classified in a group of diseases known as eosinophilic gastrointestinal disorders (EGIDs). The primary EGIDs are defined as diseases that selectively affect the gastrointestinal tract with the presence of inflammatory infiltrate that is rich in eosinophils in the absence of other causes of eosinophilia, such as drug reactions, parasitic infections, or malignancies. This group of diseases, the incidence of which has increased over the last few decades, includes eosinophilic esophagitis, eosinophilic gastritis, eosinophilic enteritis, eosinophilic colitis, and EG.[1] All of these conditions exhibit significant infiltration of eosinophils in the gastrointestinal tract and a very strong association with allergies.[2] In 1970, Klein classified the disease according to the predominance of eosinophilic infiltration in different layers of the intestinal wall, namely, the mucosal, muscle, and sub serosal layers.[3]

The involvement of different layers usually gives rise to different clinical manifestations. Mucosal disease generally presents with bleeding, protein-losing enteropathy, or malabsorption. Involvement of the muscle layer may cause bowel wall thickening and subsequent intestinal obstruction. The sub serosal form usually presents with eosinophilic ascites. The diagnosis for EGIDs is established after ruling out other causes of an eosinophilic disease, particularly atopy, parasitic infestations, vasculitis, and hyper eosinophilic syndrome (HES). Authors report a typical case of widespread EG with associated involvement of colonic mucosa in which symptoms dramatically responded to a course of steroids, as evidenced by careful follow up.

CASE REPORT

57 years old male, diagnosed with HIV 1 infection 2 months back, started on anti-retroviral drugs (Tenofovir,

Lamivudine, Efavirenz) presented with complaints of loose stools (3-4 episodes/day) for 2 months and B/L swelling of legs for 4 days. He also had history of loss of weight and appetite. He had no history of atopy/ food or drug allergies. He was treated with nitazoxanide but without any improvement. His CD_4 count was 751 cells and HIV viral load was 880IU/L. HBsAg, anti HCV and TPHA were negative.

On examination he was thin built and had pitting pedal edema. Systemic examination revealed no abnormalities. Investigations showed anaemia (Hb-9.8 g%) and eosinophilia (67.1%) (Absolute eosinophil count 8,700 cells/cu.mm). Liver function test showed hypoproteinemia, elevated alkaline phosphatase and GGT levels. serum LDH, uric acid were within normal limits. Since he was an immunosuppressed host, opportunistic infections were first considered. Stool examination with modified ZN stain for microsporidium, isospora and cryptosporidium were negative.

Stool examination for other ova and parasites were also negative. Radio allegro sorbent test (RAST) for a battery of allergens including common foods were negative. As he had granulomatous hepatitis picture, CECT abdomen was done to look for intraabdominal lymphadenopathy which showed transmural thickening in caecum, ascending colon and proximal transverse colon, with few enlarged mesenteric lymph nodes. Upper GIscopy and deep duodenal biopsies were normal. Colonoscopy showed ileal nodularity, biopsies were taken from multiple sites of colon.

As a part of workup for granulomatous hepatitis, liver biopsy was done. Histopathological examination of liver biopsy showed lobular inflammation with many eosinophils, heavy inflammatory infiltrate including many eosinophils. Ileal biopsy also demonstrated tissue eosinophilia. He was started on T. prednisolone 60 mg (1mg/kg/day). Complete remission of the diarrhea occurred in about one week. One month later, the patient's bowel habits were normal, and he had gained 4 kg.

DISCUSSION

Eosinophilic gastroenteritis can involve any part of gastrointestinal tract from the esophagus down to the rectum. The stomach and duodenum are the most common sites of involvement.[4-7] Four criteria are required for the diagnosis of EG: the presence of gastrointestinal symptoms, eosinophilic infiltration of the gastrointestinal tract, exclusion of parasitic disease or other identifiable cause of eosinophilia and the absence of other systemic involvement.[8-10]

Eosinophils are normal constituents of the mucosa of the gastrointestinal tract; however, the number of eosinophils that can be defined as normal in a biopsy specimen has not been clearly defined.[10] Peripheral eosinophilia is not necessary to make a diagnosis, but it is present in approximately two-thirds of patients and is more prevalent in the serosal than in the mucosal and muscular disease forms.[11,12] The presence of peripheral eosinophilia, abundant eosinophils in the gastrointestinal tract, and a dramatic response to corticosteroid provide some support that the disease is mediated by a hypersensitivity-type reaction. Moreover, a study at Mayo Clinic showed that 50% of patients with EG give a history of allergy such as asthma, allergic rhinitis, urticaria, drug allergy, and eczema.[13]

It must be emphasized that in the mucosal form of the disease, multiple biopsies must be taken during endoscopy, because mucosal involvement is often patchy in nature. Treatment with a steroid is the mainstay in the management of EG. Dramatic clinical improvement is seen after treatment with a low dose of steroid. The duration of treatment is controversial, however. This patient was started with prednisolone 60 mg daily, then tapered over (a period of 6 weeks) and responded favourably.

Due to the positive retroviral status in present patient, authors at first, ruled out opportunistic infections. Not many cases of EG in immunosuppressed patients are reported in literature. Bacterial infections (*Helicobacter pylori*, etc) and parasitic infestations (Ascaridosis, Anisakiasis, Enterobiasis, Anchylostomiasis, Trichina, Teniasis, etc) are a well-known cause of EG, but in present patient neither bacteria in gastric biopsies or stool culture nor ova and parasites were found in the stools.[14-16]

Hypereosinophilic syndrome (HES) may be associated with gastroenteritis but was ruled out because it is an idiopathic condition characterized by marked peripheral eosinophilia exceeding 1500 cells/ml for six consecutive months and its major targets are the heart, lung, brain and kidneys, with>55% of patients presenting with a complication in≥ 1 of these sites.[17] Celiac disease was excluded since deep duodenal biopsy showed normal histologic pattern. In present case, no positive food allergen could be demonstrated, and the colonic involvement makes it similar to the pure form of EG, in which a positive RAST test is rarely found.[3]

CONCLUSION

Eosinophilic gastroenteritis is an uncommon disease with signs and symptoms similar to many other diseases. It is quite rare in immunosuppressed patients, which is why it is often not considered in the differential diagnosis. Histology is essential for the diagnosis of EG and should be considered. Making the correct diagnosis early may result in effective treatment, thereby achieving quicker remission.

Effect of Age and Hypertension on Cognition: A Cross-sectional Study

DEEPALAKSHMI KALIYAPERUMAL[1], VIJAYABAS KARAN SHANMUGA VARADHARAJAN[2], VARSHA VISWANATHAN[3], MURALI ALAGESAN[4]

ABSTRACT

Introduction: Cognitive impairment has evolved as major health and social issue. As age advances cognitive tasks involving processing speed, working memory and executive function get affected. Cognitive impairment is also influenced by modifiable risk factors such as hypertension, diabetes mellitus and hypercholesterolemia.

Aim: To find out the effect of age and hypertension on cognition.

Materials and Methods: The total study participants were divided into three groups based on their age as group I (18-29) group II (30-59) and group III (above 60) with 20 participants (n= 20) in each group. Their cognition was assessed using Mini Mental State Examination, Picture word Learning test, Stroop colour word test, Letter digit coding test, Verbal fluency and Logic memory tests. Disease history and known co morbidities (hypertension) were noted. Post-hoc test (Bonferroni) was employed to assess age-wise comparison of cognition and Pearson's chi-square test was used to compare cognition between hypertensive and normotensives.

Results: Group II had impaired cognition when compared with group I (p-value- 0.000). Group III had impaired cognition when compared with group I (p-value- 0.000) and group II (p-value 0.001). The hypertensives in group II and III had statistically significant impairment in cognition when compared with normotensives (p-value -0.001) in the same group.

Conclusion: Cognitive functions are impaired as a result of increase in age. Furthermore, there is also a significant decrease in cognitive functions amongst those suffering from hypertension. Hence, we conclude there is decrease in cognitive function as age advances and the co-existence of hypertension hastens this decline.

Keywords: Cognitive impairment, Mini mental state examination, Old age

INTRODUCTION

The word cognition comes from the Latin verb *cognosco* meaning 'I know, perceive' or 'to recognise or conceptualise. Cognitive functions are those which include cerebral activities that lead to knowledge and encompass reasoning, memory, attention and language. Ageing can also have diverse effects on cognitive function. The spectrum of cognitive decline ranges from normal cognitive ageing (healthy" or "successful" Ageing), mild Cognitive impairment (does not prevent them from performing daily activities) and severe cognitive deficits (impede the ability to live independently [1]. Cognitive impairment has evolved as major health and social issue as the life span of both men and women has increased dramatically. Cognitive impairment accounts for about 40% of hospital admissions among the older individuals [2]. As age advances cognitive tasks involving rapid processing and transformation of information, which includes processing speed, working memory and executive function gets affected [3].

These age-related cognitive declining results from structural and functional changes that affect neuronal structure like loss of synapses and dysfunction of neuronal networks [4]. Cognitive impairment is also influenced by modifiable risk factors such as hypertension, diabetes mellitus and hypercholesterolemia [5]. Among these factors hypertension, which causes vascular changes resulting in cerebral infarction and diffuse ischaemic changes contribute to cognitive impairment [6].

Age related cognitive decline is already stated by several studies [7,8] earlier; but none of them used six tests which examine the different domains of cognition and there are only a few studies [9,10] that have included co-morbid condition such as hypertension to study the decline in cognition as age advances.

Hence, we aimed to conduct a study to find out the effect of age on cognition with the help of series of cognitive assessment tests. In this study we also analysed the effect of more common and prevalent (33.8% in urban parts of India) [11] co-morbid condition, hypertension on cognition especially amongst the vulnerable elderly group of individuals.

MATERIALS AND METHODS

This cross-sectional study was conducted during the month of January 2014 for the period of two months among students, staff and patients of PSG Institute of Medical Sciences and Research, Coimbatore after obtaining the ethical clearance from institutional ethical committee (Ethics registration file No 13/328). A total of 60 participants after getting their written informed consent were included in the study. Participants were grouped based on their age Group-I (18-29), Group II (30-59), Group III (above 60). Participants younger than 18 years of age and those suffering from co-morbidities apart from hypertension such as diabetes mellitus; chronic respiratory diseases, chronic liver diseases, thyroid diseases, renal and neurological disorders were excluded from the study. Hypertensive participants (Systolic BP of more than 140mm Hg, Diastolic BP of more than 90 mm Hg) for more than two years duration and on anti hypertensive treatment were included the study.

Study participants were assessed for their cognitive performance by using a series of tests. An initial interview of subjects was conducted where they were asked about their education, occupation and age at retirement for group III. Disease history and known co-morbidities (hypertension) were noted.

Mini Mental State Examination [12]

It is an 11 question measure that tests five areas of cognitive function: orientation, registration, attention and calculation, recall and language. The maximum score is 30, a score of 23 or lower is indicative of cognitive impairment.

Picture Word Learning Test [13] Verbal Learning Test of Long-Term Memory

Fifteen pictures were successively presented at a rate of 1 per 2 seconds and the subjects were asked to recall as many pictures as possible. This was carried out three times. After 20 minutes delayed recall was performed. The main outcome variables are the accumulated number of recalled pictures over the three learning trials and the number of pictures recalled at delayed recall.

Stroop Colour Word Test [13]

This test involves reading colour names printed in incongruously coloured ink for example "green" printed in blue letters where the subject is to say "blue". The main outcome variable is the time needed for the test.

Letter Digit Coding Test [14]

This test is used as a measure of the speed of processing the general information. The subject is asked to fill in digits near letters, according to a key presented on the top of the test sheet (with 9 consonants in random order), and to work as fast as possible. The outcome variable in the total number of correct variable is 60 seconds.

Verbal Fluency [15]

The participant has to say as many words as possible from a category in a given time (usually 60 seconds). This category can be phonemic for example words starting with the letter "p". The outcome measure is the total number of words in 60 seconds.

Logic Memory I [16]

A story was read out to the participants and they were asked a few questions based on it. The outcome measure was the number of correct answers to the questions.

The test results were scored as good, moderate and severe and decline in cognition was noted. Data acquisition was done in an excel sheet and the scores were analysed among different age groups to study the effect of age and hypertension on cognitive function.

STATISTICAL ANALYSIS

Data was entered, analysed using SPSS software version 19. Descriptive statistics was employed for analysis. Data was expressed in percentages for categorical variables. Post-hoc Test – Bonferroni and Pearson's chi-square test was used to analyse categorical variables.

RESULTS

Study participants were divided into three groups based on their age as group I (18-29), group II (30-59) and group III (above 60) with 20 participants in each group and their mean age in each group was found to be 19.3,40.75,67.75 years, respectively. In group I there were 12 males and 8 females, group II comprised of 11 males and 9 females and group consisted of 15 males and 5 females. Group I had nil hypertensives whereas group II and group III had three and six hypertensives respectively.

On analysing the scores of the cognitive tests in the age group I (18-29), 15% of the individuals had cognitive impairment based on Picture Word Learning test, 5% based on Letter Digit Coding, 65% based on verbal fluency and 20% based on logic memory. In group II (30-59), we observed cognitive impairment in all the individuals based on verbal fluency, 70-75% based on picture word learning test and logic memory. Less (10-40%) individuals were found to have cognitive impairment based on Mini mental state examination, stroop colour word test and logic memory. In group III (above 60 years) cognitive impairment was found to be 100% based on verbal fluency, logic memory and picture word learning test, 45% impairment based on Mini mental state examination, stroop colour word test and 65% based on letter digit coding [Table/Fig-1]. Significantly low scores of cognition were observed in group II and group III when compared between the three groups [Table/Fig-2].

When the hypertensives and normotensives were compared, group II hypertensives showed a statistically significant impaired cognition based on stroop colour word, verbal fluency and logic memory test whereas group III did not show statistically significant difference in their cognition level [Table/Fig-3].

DISCUSSION

In the present study it was observed that certain cognitive domains are subjected to the decline as age advances. This may be due to physiological process such as inflammation, neurobiological changes, diet and life style [17]. In our study, we found that there is increase in cognitive impairment among older individuals when compared to middle-aged and younger individuals as there occurs changes in sensory perception inhibitory ability, processing speed, memory and reasoning which lead to cognitive decline.

Results from this study revealed ability of processing speed starts to decline from the third decade of life and the impact of the loss of speed processing affects other cognitive domains such as memory, spatial ability, reasoning, working memory, executive functions, orientation, recall ability, registration and calculation. Salthouse TA had also suggested that processing speed affects cognitive function [7].

Tests	Group I		Group II		Group III	
	Good cognition	Impaired cognition	Good cognition	Impaired cognition	Good cognition	Impaired cognition
Picture word learning test	85% (17)	15% (3)	30% (6)	70% (14)	10% (2)	100% (18)
Stroop colour word	100% (20)	-	70%(14)	30% (6)	55% (11)	45% (9)
Letter digit coding	95% (19)	5% (1)	60% (12)	40% (8)	35% (7)	65% (13)
Mini mental state examination	100% (20)	-	90% (18)	10%(2)	55% (11)	45% (9)
Verbal fluency	35% (7)	65% (13)	-	100% (20)	25% (5)	100% (15)
Logic memory	16% (16)	20% (4)	25% (5)	75% (15)	-	100% (20)

* Significant (p-value <.05)

Slowing of speed processing plays an integral role in age-related memory changes as well. In our study memory is found to be affected more in older and middle-aged individuals. Burke DM et al., had suggested that as age advances the word-finding difficulties may occur due to weaker memory system which is unable to link one unit to another [18]. Naveh-Benjamin M et al., had also proposed that associative memory deficit in older adults' is due to loss of episodic memory [19].

In our present study, changes were observed among group II and III in mini mental state examination, verbal fluency and stroop colour word tests which gives information on selective and divided attention of the individuals. Hasher L et al., had proposed that older adults' are unable to concentrate on irrelevant information while they are focusing attention on relevant information [20]. Attention impairment was found to be associated with increased incidence of automobile accidents among older individuals [21].

Genetic, medical, psychological, social and lifestyle factors which determines cognitive ageing that impaires people's independence and quality of life [22]. In our study there exists a significant increase in the cognitive impairment among hypertensives belonging to group II and III. It was well-supported by many longitudinal studies that elevated blood pressure is associated with cognitive decline [23].

In our study hypertensives belonging to the age group II showed a statistically significant impaired cognition based on stroop colour word test, verbal fluency and logic memory. Long standing hypertension in some patients may cause not only stroke but also chronic end organ damage of the brain in the form of demyelination of the white matter, with cognitive decline [24]. In the Framingham study, Elias MF et al., had opined that untreated BP level is inversely proportional to cognitive function [25]. Launer LJ et al., had reported in his study that midlife systolic blood pressure is a significant predictor of reduced cognitive function in later life. He also suggested that early control of systolic blood pressure levels may reduce the risk of cognitive impairment in old age [26].

Several follow-up studies conducted among hypertensives showed inverse relationship of systolic as well as diastolic blood pressure with their cognitive performance [25,27]. In a study conducted among hypertensives of various stages, Andre-Petersson L et al., observed stage 3 Hypertension was associated with lower performance on psychomotor, speed and visuo-spatial memory tests; stage 1 hypertension is associated with higher performance on tests measuring verbal and constructional ability [28].

LIMITATION

The small sample size is a limitation of this study. The factors like ethnicity, hyperinsulinaemia, homocystinaemia, duration of hypertension, level of blood pressure control and choice of antihypertensive treatment affect cognition. There are studies that have mentioned the protective effect of antihypertensive drugs over cognitive decline on hypertensive patients as age advances. In this study these factors were not taken into account and add to the limitations.

CONCLUSION

Cognitive domains such as general intellect, reaction time, memory, vigilance and attention are impaired as a result of increase in age. Furthermore, there is also a significant decrease in cognitive functions amongst those suffering from hypertension. Hence, we conclude there is decrease in cognitive function as age advances and the co existence of hypertension hastens this decline.

ABSTRACT

Clinical human brucellosis is quite rare in India, that too in an non susceptible host. This report describes a case of clinical human brucellosis in India. This case involved a 36 years old male, a professor in an Engineering college. He presented with complaints of fever for 4 months with myalgia, generalized tiredness, loss of weight and loss of appetite. On evaluation, total counts and ESR was elevated and all other investigations were normal. Based on history, common causes like occult tuberculosis or autoimmune diseases were considered. But, blood cultures grew *Brucella melitensis* in all 2 samples and a diagnosis of brucellosis was made. He was treated with Rifampicin and Doxycycline. Suspicion of brucellosis in this patient is low because the patient has no history of contact with animals, consumption of unpasteurized milk or occupational exposure. So, the health care practitioners should be aware of this possibility of this zoonotic infection as a differential diagnosis in patients with nonspecific symptoms and unexplained prolonged fever.

Keywords: Brucellosis, Non-susceptible host, Prolonged fever

INTRODUCTION

Burcellosis is a multisystem disease with a broad spectrum of nonspecific symptoms that usually occurs within 2 weeks but up to 3 months after inoculation. It is usually due to consumption of unpasteurized contaminated goat's milk or soft cheese that had been infected with *Brucella melitensis*.[1] They are small non-motile, nonsporing, non-capsulated gram-negative coccobacilli that usually infects goats and sheep.[2] The principal organizsm causing worldwide brucellosis is *Brucella melitensis*. It is the most pathogenic and invasive one, followed by *Brucella suis*, *Brucella abortus*, *Brucella canis*, *Brucella pinnipediae* and *Brucella cetaceae*.[3]

Human brucellosis is commonly found in countries with rural communities that live with close association with animals and its prevalence in a region depends on factors such as methods of processing milk and milk products, food habits, social economic status, hygiene and climate.[4] Both human and animal brucellosis are still endemic in some parts of the world such as Pakistan, China and Srilanka.[5-7]

The clinical features of brucellosis are nonspecific and depends upon the stage of the disease and the organs and systems involved. The most commonly reported symptoms are undulating fever, fatigue, malaise, chills, sweats which may be characterized by a peculiar odour at night, insomnia, headache, myalgia, arthralgia, anorexia, weight loss, hepatomegaly and splenomegaly. Brucellosis can also manifest as a localized disease affecting the central and peripheral nervous system, gastrointestinal tract, genitourinary tract and heart.[8]

Without the critical epidemiological clue to exposure to animals or consumption of unpasteurized dairy products,

this disease can pose a great diagnostic challenge to the clinician. Authors report a case of human brucellosis in a non- susceptible host.

CASE REPORT

36 years old male presented with complaints of fever for 4 months, which was associated with myalgia, generalized tiredness, loss of weight and loss of appetite. There was no history of contact with animals, consumption of unpasteurized milk or occupational exposure. General examination was unremarkable. Abdominal palpation revealed hepatosplenomegaly. His hemoglobin and platelet levels were within normal limits, while total counts showed leucopenia with monocytosis. Erythrocyte sedimentation rate was also elevated. Other basic biochemical tests were within normal limits, except for mild transaminitis.

At this moment, either occult tuberculosis or autoimmune diseases were suspected based on the history, clinical and laboratory findings. However, blood cultures were taken, and broad-spectrum antibiotics were started. CECT chest and CECT abdomen were not suggestive of occult TB infection. Autoimmune workup was negative. As a part of workup for fever of longer duration, Brucella agglutination test and scrub IgM serology were sent. Brucella agglutination test turned out to be positive. Simultaneously, blood culture grew *Brucella melitensis* in all 2 samples.

Based on his serological test and blood cultures, a diagnosis of brucellosis was made. He was eventually prescribed Rifampicin once daily and Doxycycline BD for 6 consecutive weeks.

DISCUSSION

In this case, the patient did not have any history of living in close association with animals or consumption of unpasteurized milk. He also did not have any occupational risk of exposure to brucella. Nevertheless, human brucellosis is quite rare in South India, making the suspicion level among clinicians to be quiet low.

There was a long interval between onset of symptoms and diagnosis in our patient. A lot of health care practitioners do not consider the possibility of brucellosis, especially in patients with prolonged fever. Delay or misdiagnosis can lead to treatment failure, relapses, focal complications and high case fatality rate.[9]

This patient showed many of the symptoms of brucellosis which included undulating fever, myalgia and other clinical features such as hepatomegaly and splenomegaly.[10]

Infective endocarditis is a rare devastating complication from systemic brucellosis and could require surgical intervention. Splenic, hepatic or pulmonary abscess can also develop. Other rare complications include deep vein thrombosis, arthritis, spondylitis, meningitis and nephritis. Ocular manifestations include optic neuritis and uveitis.[11] Common hematological manifestations include leucopenia, anemia and thrombocytopenia.[12]

The standard treatment for human brucellosis is doxycycline, 100mg BD and rifampicin 600-900mg once a day for 6 consecutive weeks. A combination of doxycycline and gentamycin is also preferred. However, the standard treatment varies depending on the patients' age, pregnancy status, CNS involvement and cardiovascular involvement.[13] For children less than 8 years of age, a combination of TMP-SMX and aminoglycoside or a combination of rifampicin and TMP-SMX for 45 days is needed.[14,15]

CONCLUSION

Diagnosis of brucellosis is generally not considered in a non-endemic country. Health care practitioners should be aware of this possibility of this zoonotic infection as a differential diagnosis in patients with nonspecific symptoms and unexplained prolonged fever.

Abstract

Human immunodeficiency virus causes chronic infection of the immune system leading to reduction of CD4 helper cells, making the patient prone for many opportunistic infections. The incidence of opportunistic infections is increased in the presence of low CD4 count. Here, we present a case of HIV infection presenting with mediastinal lymphadenopathy, treated as disseminated tuberculosis which then developed pancytopenia with hyperbilirubinemia. He was finally diagnosed to have non Hodgkin's lymphoma of B cell type with hemophagocytic syndrome at postmortem. We emphasize that when a HIV patient has a relatively higher CD4 count non infectious causes should be kept in mind while empirically treating for opportunistic infections.

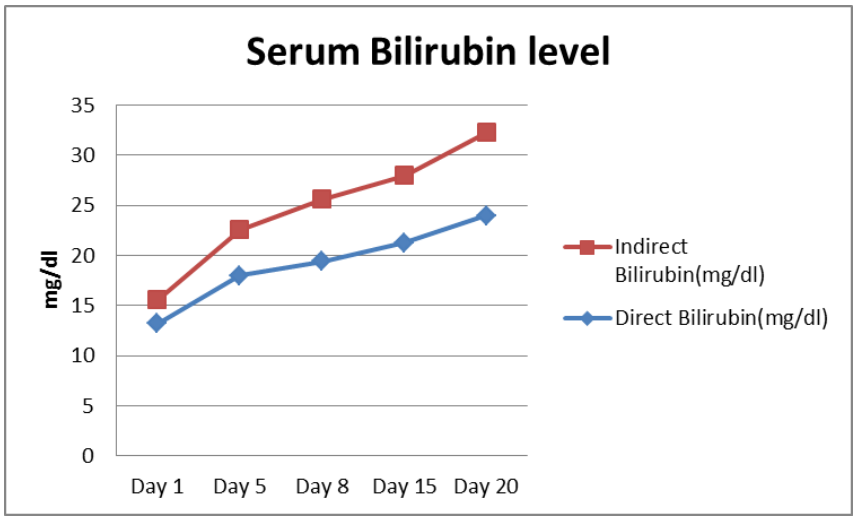
Keywords

AIDS/HIV; chronic infection; mmune system

Introduction

Acquired immuno deficiency syndrome (AIDS) is the end stage of the spectrum of disease caused by human immuno deficiency virus (HIV). Decline in the immunity is a direct result of CD4 cell destruction by the virus, leading to increase in occurrence of neoplasms and opportunistic infections. Lower CD4 counts can be correlated with higher incidence of opportunistic infections. We present a 45 year old male with HIV infection, on empirical anti-tuberculosis therapy (based on pulmonary imaging) who developed pancytopenia with indirect hyperbilirubinemia. Analysis of this case allows a focused approach to arriving at differentials in patients presenting as such. This case also stresses the importance of considering non infectious causes during evaluation of opportunistic infections in AIDS and also the consequences of delay in diagnosis, a compromise usually made in resource limited settings.

Case Report



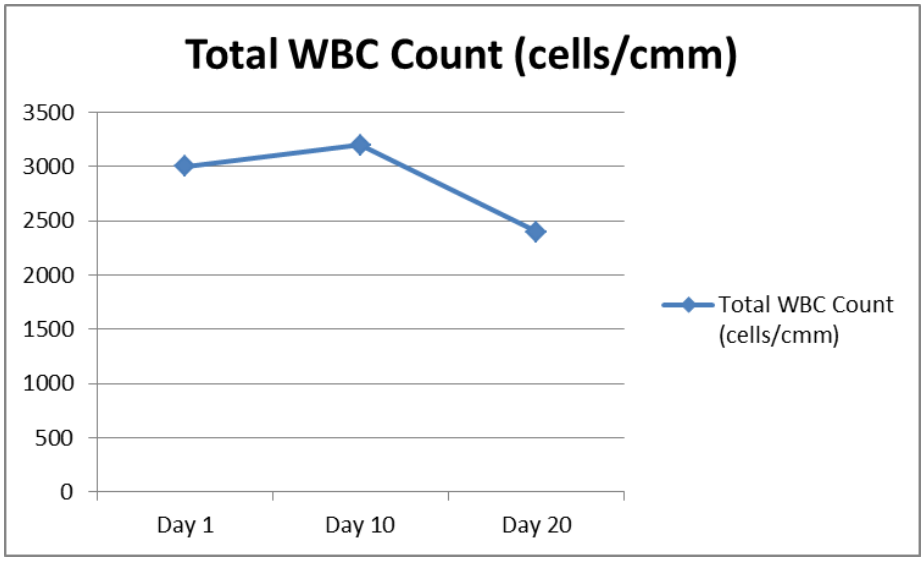
A 45 year old male with retroviral infection for six months presented with yellowish discoloration of sclera, abdominal pain for two days associated with loss of weight and appetite, pale colored stools and pruritus.

Two months prior to current admission, he presented to another center with fever of one month

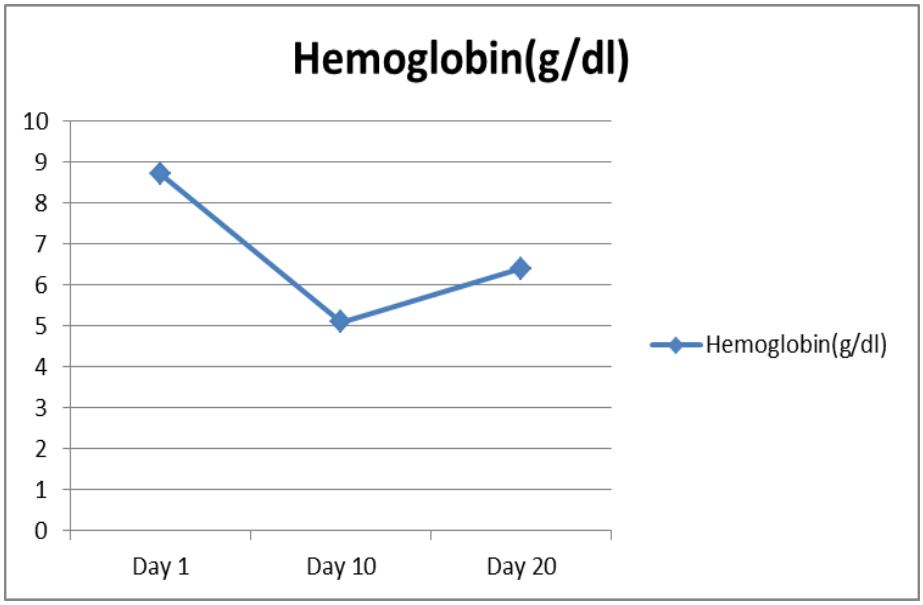
duration lacking localizing symptoms. Computed Tomography study of the chest and abdomen revealed the presence of multiple retroperitoneal lymph nodes and bronchiectasis, for which antituberculous therapy was initiated. (Isoniazid + Rifampicin + Pyrazinamide + Ethambutol). Investigations done two months prior to current admission as per the records were: Hemoglobin (Hb) – 12.3 g%, Total WBC count – 6300 cells/cmm, Platelets – 1,40,000 cells/cmm, Erythrocyte Sedimentation Rate (ESR) – 88mm in 1 hour, Creatinine – 0.8mg/dl, Bilirubin – 0.6 mg%, Alanine Transaminase (ALT) – 34IU/L, Aspartate Transaminase (AST) – 24IU/L, Alkaline Phosphatase (ALP)- 258 IU/L, Gamma-Glutamyl Transpeptidase (GGTP)- 312 IU/L. His Prothrombin Time (PT) was 12 seconds and International Normalised ratio (INR) was 1.0. He had tested Human Immunodeficiency Virus (HIV) positive then with a CD4 count at that time of 326 and HIV viral load was 120000 copies. He was initiated on Anti- Retroviral Therapy (ART) with Tenofovir, Emtricitabane and Efavirenz.

He was conscious and oriented on presentation. He was found to exhibit pallor, jaundice and per abdominal examination revealed splenomegaly. He did not have asterixis and there were no focal neurological deficits.

His investigations during the current admission were: Complete haemogram (CBC) revealed pancytopenia (Hb – 8.7g/dl; Total WBC count -3000 cells/cmm; Platelets- 68,000/cmm, ESR -86mm in 1 hour). Renal function tests were normal. His liver function test (LFT) showed hyperbilirubinemia with normal ALT and AST with increase in ALP (324 IU/L) and GGTP (314IU/L). INR was 1.1. In view of hyperbilirubinemia with normal ALT, Rifampicin was stopped and other medications were continued. Despite these efforts, there was a progressive worsening of his LFT (Graph 1), hence ATT and ART drugs were withheld. Ultrasound of abdomen showed normal liver echo texture, no intra hepatic biliary radicle dilatation or common bile duct dilatation and splenomegaly. Serology for Hepatitis A, B, and C, E viruses, Cytomegalovirus (CMV) and Epstein Barr virus (EBV) were negative. Hepatitis B and Hepatitis C viruses were not detectable. Autoimmune workup (Anti-nuclear antibody (ANA), Anti Liver Kidney Microsomal (LKM) antibody) was also negative. Serum procalcitonin was carried out to rule out bacterial sepsis as a cause for cholestasis, but was found to be within normal limits. Repeated blood, urine cultures for bacteria and fungi (using Sabouraud dextrose agar incubated at 22 and 30 degree Celsius) were sterile. Finally, Magnetic resonance cholangio pancreatogram (MRCP) was done to rule out any obstructive pathology and was normal.

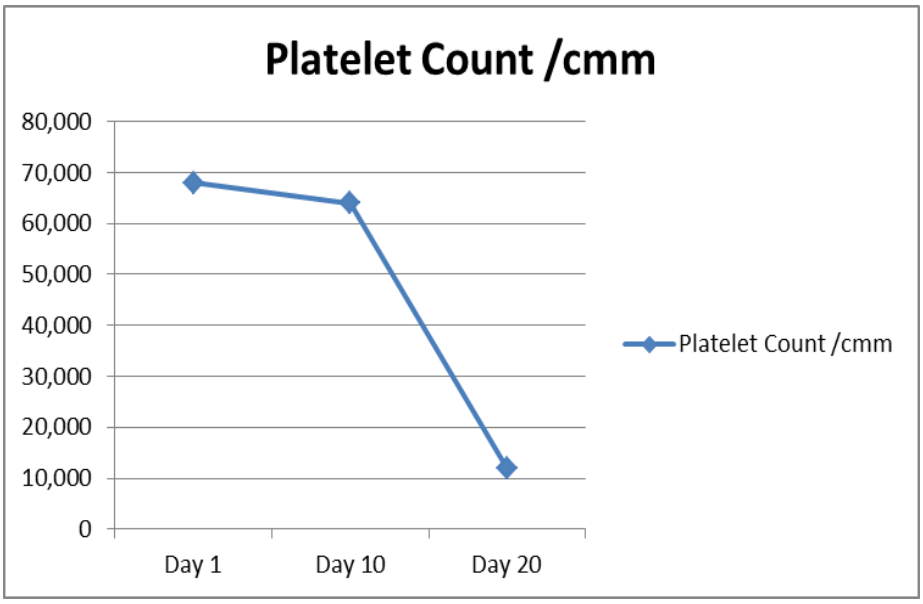


Graph 1: Serum Bilirubin level during the hospital stay.



On the tenth day of admission at our centre, a complete blood count was done, showing pancytopenia (Total WBC count – 3200 cells/cmm, Hb – 5.1g/dl, Platelet count – 64,000 cells/cmm) and reticulocyte count was 14%. Serum vitamin B12 and Folic acid were within normal limits. Anaemia profile was suggestive of anaemia of chronic disease. Subsequently, bone marrow aspiration and biopsy showed a hypercellular marrow without any granuloma, fibrosis, atypical cells, hemophagocytic macrophages or infiltrative lesions.

During the course of his hospital stay, it was seen that his blood counts displayed a decreasing trend.



The changing trend in Total WBC counts, Hb and Platelet count during the course of hospital stay was as follows:

Graph 2: Total WBC count during hospital stay

Graph 3: Hemoglobin changes during hospital stay

Graph 4: Platelet count during hospitalization

He was treated with supportive medications including blood and blood product transfusions. Lymph node/liver biopsy was planned, but decision to carry out the procedure was deferred in view of thrombocytopenia. In spite of these efforts, the patient developed complications of intracranial cranial hemorrhage and expired. After obtaining the required permissions from his near relations, postmortem liver and spleen biopsy were done.

The sections taken from the biopsied spleen and liver showed fragments of splenic tissue and liver tissue with congestion and one fragment showed infiltration by a population of pleomorphic cells. Morphologically, the cells were round with abundant cytoplasm and irregular vesicular nuclei. Occasional giant cells were seen (Figure 1A&1B). Portal tracts were not visualised in the sections studied. In addition to these findings, the liver tissue showed intracellular cholestasis, evidence of hemophagocytosis in liver cells and sinusoidal dilation (Figure 1C&1D). The atypical cells were showing positivity for CD 45 (leukocyte common antigen) and CD 20 (Figure 2A &2B) cellular markers. These findings were consistent with non-Hodgkin's lymphoma of B-cell type with associated hemophagocytosis of liver.

Discussion

The hallmark of infection by the human immunodeficiency virus is the depletion of CD-4 T helper cells and defective macrophage and monocyte functioning. A direct consequence of this is the greater tendency of past tuberculosis reactivation with hastening of its clinical manifestations. Thus, its presentation is more sub-acute than chronic in these patients [1].

Two months prior to admission, our patient was started on ART for retroviral disease and ATT for suspected pulmonary and extra pulmonary tuberculosis. He developed cholestatic jaundice and pancytopenia and deteriorated despite discontinuing possible causative medications. In the setting of HIV infection, possible differential diagnoses for cholestatic jaundice would be medications, opportunistic infections, neoplasms, AIDS cholangiopathy and sclerosing cholangiopathy [2].

In this particular case the cause for cholestasis remained elusive despite extensive investigations.

There was no evidence of any intra-hepatic biliary radicle dilatation on ultrasonography of the abdomen, confirmed by MRCP. Hence intra-hepatic cholestasis was unlikely [3]. Then, cultures of the blood and urine including fungal cultures were done to rule out infections. Procalcitonin was also normal. These findings point towards a non-infectious cause. As certain pharmacological therapies can cause cholestatic jaundice, a detailed drug history was also elicited and none of the drugs he was taking have been implicated as causing cholestasis and pancytopenia. The possibility of HIV cholangiopathy was considered but was thought to be unlikely in view of the progressive cholestasis, no evidence of intrahepatic biliary radicle dilatation in imaging (USG or MRCP) and negative stool for Cryptosporidium parvum [4]. In fact, the presence of jaundice itself is an unusual feature of AIDS cholangiopathy [5] .

On evaluation of progressive pancytopenia, the cause was ultimately not discernible. In view of this bone marrow biopsy was done which showed the presence hypercellular marrow. The common causes for pancytopenia in HIV infection without fever diagnosed using bone marrow biopsy are [6]:

1. Infection

    Parvovirus infection

    Histoplasma capsulatum

    Mycobacterium tuberculosis

    Mycobacterium avium complex

    HIV

    Salmonella typhi

2. Miscellaneous

    Hodgkin's disease

    Hypersplenism

    Hemophagocytic syndrome

The presence of hypercellular marrow, reticulocytosis and splenomegaly was suggestive of either immune pancytopenia [7,8] or hypersplenism. Autoimmune workup (ANA, Coombs test) was negative. The possibility of haemophagocytic lymphohistiocytosis was considered in view of pancytopenia, liver involvement and increased ferritin. However this diagnosis was thought to be unlikely due to the observation that triglycerides were under normal limits, patient was afebrile and bone marrow and peripheral smear analysis did not reveal any correlative evidence. The cause for pancytopenia in this case could be explained by hypersplenism rather than the infiltrative disorder per se due to the combination of elevated reticulocyte count and splenomegaly. An additional explanation for pancytopenia is a paraneoplastic manifestation of lymphoma. However, the negative Coombs test disaffirms this as a cause for this presentation.

Hence the working diagnosis was vanishing bile duct syndrome with hypersplenism leading to pancytopenia (or a coexisting autoimmune pancytopenia). The other likelihood was lymphoma with hemophagocytosis which was ruled out in view of inconclusive bone marrow findings (no atypical cells and no evidence of hemophagocytosis). A liver biopsy was planned but was deferred in view of the

coagulopathy and thrombocytopenia. Our patient's condition continued to decline during the hospital stay and died due to intracranial bleed. Postmortem liver and spleen biopsy revealed non Hodgkin's lymphoma of B cell type with hemophagocytosis. Conclusively, this underscores the importance of arriving at a histopathological diagnosis before initiating ATT.

The final diagnosis was determined to be haemophagocytosis. Its presentation in this patient was nothing short of unusual. This patient was afebrile (although fever occurs in 70% to 100% of haemophagocytic syndromes), had hypertriglyceridemia and bone marrow aspiration and biopsy did not reveal any siginficant evidence to support the diagnosis. A study done by McCall et al has shown that few patients with HLH did not show marrow evidence of haemophagocytosis in the first biopsy but showed it only on later biopsies [9].

Diagnosis of hemophagocytic lymphohistiocytosis (HLH) syndrome relies on clinical, laboratory, and histopathological findings. Diagnostic guidelines were proposed by the Histiocytic Society in 1991 and updated in 2004 is as follows [10]:

The diagnosis of HLH can be established if one of either 1 or 2 of the criteria below is fulfilled.

1. A molecular diagnosis consistent with HLH

2. Diagnostic criteria for HLH are fulfilled (5 of the 8 criteria below):*

Fever

Splenomegaly

Cytopenias (affecting 2-3 lineages in the peripheral blood)

Hypertriglyceridemia and/or hypofibrinogenemia

Hemophagocytosis in BM, spleen, or lymph nodes

Low or absent NK-cell activity (according to local laboratory reference)

Ferritin - 500 g/L

Soluble CD25 (sIL2r) - 2400 U/ml.

Our patient fulfilled only three of the total eight criteria during the diagnostic workup but was established to have haemophagocytosis in liver biopsy at postmortem. This underscores the fact that the diagnostic criterion is primarily implied for conduct of clinical trials and it does not include all the clinical and laboratory features [11,12]. As a result of the complex diagnostic criteria and rarity of the condition the diagnosis is often delayed. Hence a high degree of clinical suspicion is very important in early diagnosis and preventing the high mortality associated with the disease [13]. There have been various causes that have been implicated in the etiology of HLH. The association of lymphoma as an etiology is well known but B cell lymphoma presenting with HLH is quite rare. The cause for pancytopenia was hemophagocytosis with or without paraneoplastic manifestation of Lymphoma [14].

The incidence of Lymphomas is much higher in HIV patients than in the general population [15]. The mode of transmission is not associated with any increase in risk of lymphomas in contrast to Kaposi sarcoma which is much more common in men who have sex with men. Most of the opportunistic

infections occur in low CD4 counts which also holds true for EBV associated Non Hodgkin's Lymphoma but HIV associated Hodgkin's lymphoma occurs in most patients with relatively intact CD4 count [16]. The initial presentation of AIDS related Lymphomas can be very subtle while in others it may be very obvious. Symptoms include but are not limited to low grade fever, unexplained fever, night sweats, adenopathy or organomegaly. The challenge lies in the exploration of various differentials that come up as a result of the incidence of these symptoms, in people diagnosed with AIDS. A high level of lactate dehydrogenase (LDH) is found in aggressive lymphomas and has prognostic implications. Excision biopsies are preferred over needle procedures as they preserve the architecture and immunophenotyping done whenever needed. Neuroimaging should be done at diagnosis as more than 17% of peripheral lymphomas in AIDS patients involve CNS. Treatment of Lymphomas is similar for AIDS and non-AIDS patients. Though with the introduction of HAART the prognosis of lymphomas has improved, the prognosis of lymphomas is worse in AIDS patients than for the same lymphomas in non AIDS patients [17,18,19].

Conclusion

We hereby have described an unusual presentation of lymphoma in a retroviral positive patient. Hemophagocytic syndrome is known to occur with lymphomas but its association is more common with T cell lymphoma than B cell lymphoma, as was concluded in this case. The diagnostic criteria for Hemophagocytic syndrome is meant for conduct of clinical trials. It should be noted, however, that these diagnostic criteria do not reflect all of the typical clinical or laboratory features of patients with HLH, many of which are helpful in making the diagnosis. Hence treatment should not be delayed in fulfilling the criteria. A high degree of clinical suspicion is essential in early diagnosis of hemophagocytic syndrome. The microbiological diagnosis is very important when we evaluate a HIV infected patient for opportunistic infections. It is imperative that non infectious etiologies are considered during evaluation, especially when the CD4 count is not low. There is no role for empirical anti-tuberculous therapy even in resource limited settings.

Abstract

Cryptococcus neoformans is a fungus which causes opportunistic infection in patients with Human Immunodeficiency Virus/ Acquired Immunodeficiency Syndrome (HIV/AIDS) with meningitis being the commonest presentation in HIV affected individuals. A CD4 T cell count <200 has been shown to be the strongest risk factor for meningitis, and the mean CD4 count in HIV-related cryptococcal disease is <100 with a range of 75 to 125. Affected individuals are put on secondary fluconazole prophylaxis, in the absence of which 50 to 60% develop relapse. As virtually all patients receive anti-retroviral therapy (ART), relapse and immune reconstitution inflammatory syndrome (IRIS) following ART are well described in the initial months after starting ART. We report a case of late onset IRIS in an immune reconstituted patient with a high CD4 count and suppressed viral load.

Keywords

cryptococcal meningitis relapse, CD4 counts, cryptococcus in HIV

Case Presentation

A 44 year old male was diagnosed with HIV/AIDS (CDC C, WHO 4) in 2004 after presenting with cryptococcal meningitis. His baseline CD 4 count was 16 cells/cmm and HIV viral load was 47,259 copies / ml. His serum and cerebrospinal fluid (CSF) cryptococcal antigen (CRAG) were positive and CSF India ink preparation was positive for cryptococcus. He also had hepatitis B co-infection with a hepatitis B viral load of 750000. He was treated with intravenous amphotericin B deoxycholate and high dose fluconazole. He was then started on ART (zidovudine, lamivudine and efavirenz), improved clinically and was maintained on chronic suppressive therapy with fluconazole till 2006. His serial CD4 counts and HIV viral loads are given in Table 1.

His ART was switched to Tenofovir, Emtricitabine, Efavirenz (TDF/FTC/EFV) in 2009 to treat concomitant hepatitis B. He was admitted in March 2014 with difficulty in walking, increased forgetfulness and severe headache. On examination he had mild neck stiffness. Investigations showed normal haemogram, renal and Liver Function Tests. At this time, CD4 count was 485 cells/cmm and HIV viral load was undetectable [<Less than Detectable Limit (LDL)] (Table 1). MRI brain showed leptomeningeal contrast enhancement suggestive of meningitis with non uniform hydrocephalus with

multiple segmentation (Figure 1, 2).

CSF analysis showed a WBC count of 280 (Neutrophils 1%, Lymphocytes 98%), protein level was 580mg/dl and glucose was 29mg/dl. Serum and CSF cryptococcal antigen (CRAG) were positive. CSF India ink preparation for cryptococci was negative. Gene Xpert for MTB done on CSF was negative. CSF culture for bacteria, fungi and mycobacteria were negative. CSF HIV viral load was 126 copies / ml. He was treated with intravenous amphotericin B and flucytosine, and then switched to fluconazole prophylaxis. He improved clinically and was doing well at 6 month follow up.

Discussion

AIDS related cryptococcal meningitis has been of utmost concern as it is associated with high mortality if not treated with appropriately. Though Cryptococcus affects skin and lungs, meningitis is very common in the HIV affected individuals. It chiefly chooses to affect the severely immune compromised especially in those whose CD4 count is less 100 [1]. It is the second leading cause of morbidity and mortality in AIDS patients [2,3]. Those who are already known cases of HIV, developing cryptococcal meningitis if not under treatment are associated with higher mortality. The other problem encountered in HIV is immune reconstitution inflammatory syndrome which occurs in those who are initiated on ART [4]. "Immune reconstitution inflammatory syndrome" (IRIS) is condition where paradoxical worsening of preexisting infectious processes or unmasking of hidden infections occurs after the initiation of highly active antiretroviral therapy (HAART) in HIV-infected individuals [5]. As the immune function improves after the initiation of HAART, systemic or local inflammatory reactions may occur at the site or sites of the preexisting infection. IRIS is usually a self-limiting condition; but can be life threatening if central nervous system is involved.

Two important complications of cryptococcal meningitis are relapse and IRIS. Relapse has been defined as the reappearance of clinical symptoms (symptomatic relapse) and the recovery of viable cryptococci in previously sterile CSF (microbiological relapse) [6,7] . Our patient did not fit criteria for microbiologic relapse. Reasons for relapse include absence of secondary prophylaxis after an episode of meningitis [8], poor compliance with fluconazole therapy [9] and fluconazole resistance [10,11].

An important cause of symptomatic meningitis is IRIS following immune reconstitution with ART. Fungal cultures are typically negative, and the diagnosis is made by cryptococcal antigen testing and the temporal occurrence after ART [4,7]. Typical risk factors include low CD4 count (usually <50) or early initiation of ART. As we could not see or grow cryptococci from CSF, our patient appeared to have IRIS rather than relapse.

Our patient was unusual in that he became symptomatic 10 years after initiation of ART and 8 years after secondary prophylaxis with fluconazole was discontinued and had a CD4 count of 485 when IRIS occurred. This is distinctly different from the literature which describes IRIS in the first few months after ART inititiation and at low CD4 counts, typically <100 [4,7].

Table

Table 1: CD4 count and HIV viral load over 10 year period

Year	2004	2005	2006	2007	2008	2009	2010	2011	2012	2013
Cd4 (cells/cmm)	16	85	125	215	175	183	277	300	254	485
HIV Viral load (copies/ml)	47259	<LDL	<LDL	<LDL	<LDL	<LDL	<LDL	<LDL	<LDL	<LDL

Figures

Figure 1: MRI brain showed leptomeningeal contrast enhancement suggestive of meningitis with non uniform hydrocephalus with multiple segmentation

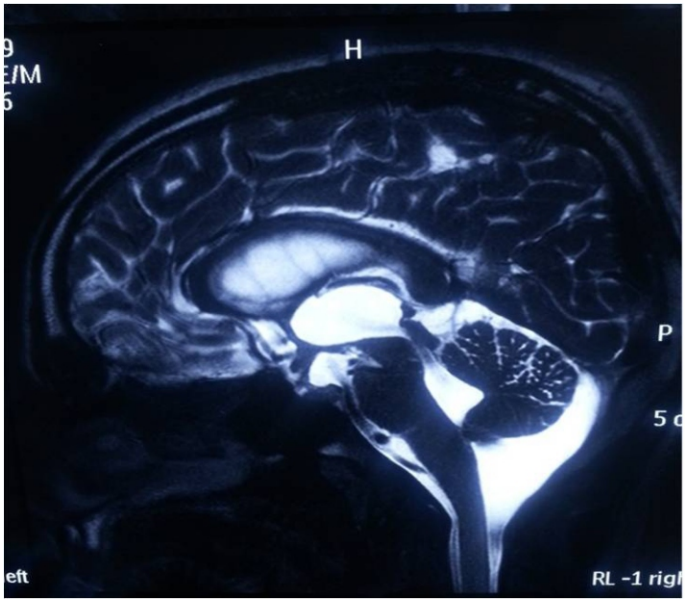

Figure 2: MRI brain showing non uniform hydrocephalus with multiple segmentation

Conclusion

Our case illustrates the importance of remaining vigilant for IRIS in patients with a history of cryptococcal meningitis, even in patients with high CD4 counts and suppressed viral loads many years after the initial episode of meningitis.

Basidiobolomycosis - Miss Me; It Hurts You

Murali Alagesan[1], Joel Franklin[2], J Jayalakshmi[3], TM Subba Rao[4], V Chaithra[5]

Abstract

Basidiobolomycosis is a subcutaneous infection of the limbs and trunk caused by *Basidiobolus ranarum*. It is one of the under diagnosed infection which usually occurs in tropical areas. High index of clinical suspicion is needed to diagnose this condition. We hereby report a case of basidiobolomycosis in a 25 year old male who presented to us with a non healing ulcer in left thigh. Biopsy showed granulomatous inflammation with fungal infection suggestive of phycomycosis. Fungal culture grew *Basidiobolus ranarum*. Patient was treated with oral itraconazole. The ulcer resolved completely after 3 months of treatment.

Introduction

Zygomycosis is an infection caused by fungal agents belonging to the phylum Zygomycota. These are saprophytic fungi and are found ubiquitously in the environment. The class Zygomycetes includes two fungal orders: Mucorales and Entomophthorales. They have different pathogenic potentials; the order Mucorales primarily affects the immunocompromised patients causing invasive diseases like rhino cerebral or pulmonary mucormycosis with high mortality, where as the order entomophthorales, which include *Basidiobolus* and *Conidiobolus* genera, cause chronic infection in the subcutaneous tissue in the immune competent individual.[1] Basidiobolomycosis is caused by the fungus *Basidiobolus ranarum*. Here we present a case of subcutaneous basidiobolomycosis which was misdiagnosed as mucormycosis by histopathological examination.

Case Details

A 25 year old male software engineer from Coimbatore was referred to us for intravenous amphotericin B, for the treatment of his non healing ulcer over the anterior aspect of left thigh as biopsy of the lesion was reported as mucormycosis. He had this lesion for the past 3 months which started as a painless nodular swelling (Figure 1A). He had consulted many clinicians earlier and was on multiple antibiotics, but his skin lesion progressively increased in size. He had no co-morbid illness and was apparently normal 3 month back. Ultra sonogram of the thigh was suggestive of abscess in subcutaneous plane. He underwent incision and drainage (I and D) of the abscess which resulted in a deep cavitatory lesion. Culture from the material during I and D was sterile. As the lesion was worsening (Figure 1B) he underwent another debridement. Gram's stain, AFB stain of the tissue didn't reveal any organisms and bacterial culture of the pus was sterile. Biopsy of the ulcer was performed and sent for histopathological examination (HPE). The HPE was reported as extensive ulceration and dense inflammation of dermis and subcutaneous area with fat necrosis and abscess formation composed of neutrophils and eosinophils along with thin walled broad aseptate fungal hyphae branching at right angles and surrounded by fibrosis and dense inflammation with giant cells. PAS stain was positive. Final report was foreign body granuloma with many fungal hyphae resembling mucormycosis. At this point we decided to re-evaluate the patient. On examination, he had a 3×1 cm linear non tender ulcer with surrounding induration on the left thigh (Figure 1C). His complete blood count showed total leukocyte count – 7400 (Neutrophils -50 %, Lymphocytes-34%, Eosinophils-4%, Monocytes-7%), ESR – 24 mm in 1 hour. His blood glucose, renal function test and liver function test were within normal limits. Human Immunodeficiency virus 1 and 2 were non-reactive. Since the history and clinical picture didn't fit with a diagnosis of mucormycosis (the morphology of the lesion, duration of the ulcer), a second opinion of the slide was sought. The histopathology description (Figure 2A, 2B, 2C) included the presence of granulomas in dermis and subcutis associated with the presence of numerous eosinophils. There were also scattered abscesses and eosinophilic material surrounding the fungal hyphae resembling Splendore–Hoeppli phenomenon. A probable diagnosis of subcutaneous phycomycosis was suggested with a comment that fungal culture was required for confirmation. Additional biopsy specimen was collected aseptically for fungal culture from the edge of the lesion. On Sabouraud's Dextrose Agar, furrowed creamy brown, heaped up, radially folded colonies grew after 3 days of incubation (Figure 3). Lactophenol cotton blue wet mount showed aseptate hyphae and smooth walled zygospores with characteristic conjugation beaks which confirmed the fungus to be *Basidiobolus ranarum* (Figure 4). After the diagnosis of basidiobolomycosis was confirmed, the patient was started on oral Itraconazole 200 mg once daily for 3 months. The ulcer healed slowly and complete resolution of the lesion (Figure 1D) was seen after 3 months.

Discussion

Basidiobolomycosis is caused by *Basidiobolus ranarum*, a saprophytic fungus present in soil, decaying fruit and vegetable matter as well as in the gut of amphibians and reptiles.[2] It can cause a variety of clinical manifestations including subcutaneous zygomycosis, gastrointestinal zygomycosis and occasionally an acute systemic illness. The subcutaneous form is a granulomatous infection of the skin and subcutaneous tissues characterized by the formation of firm, painless, disciform nodule generally on the

thighs and buttocks in a "bathing suit" distribution.[1] It mainly affects young, male and immunocompetent persons. It is usually transmitted by minor trauma which may be through insect bite, intravenous catheter, or even intramuscular injection. Clinically it starts as small hardened swelling over the extremities and progressively increases in size to form a painless, non tender swelling. Macroscopically it closely mimics a soft tissue tumor, synovial sarcoma, Burkitt's lymphoma or histopathologically mimics mucormycosis. The other differential diagnosis would be atypical mycobacterial infections, sporotrichosis and parasitic infections like oncocerciais.[3]

In our patient also it started as a small painless swelling and progressively increased in size. Even though the histopathology was reported as mucormycosis, the possibility of mucormycosis could be ruled out by the absence of features such as angio/tissue invasion and necrosis; and slow growing nature of the lesion. Laboratory diagnosis is mainly based on histopathological features and culture of the organism which is the "gold standard". Histologically, basidiobolomycosis is associated with eosinophilic infiltration; with short broad aseptate hyphae.[4] Some may be surrounded by an eosinophilic material which is called as 'Splendore – Hoeppli' phenomenon.[5]

Most patients with basidiobolomycosis respond well to

Fig. 3: Growth of basidiobolus ranarum on Sabouraud's dextrose agar appearing yellowish grey rugose and smooth colonies with a waxy texture on the obverse end

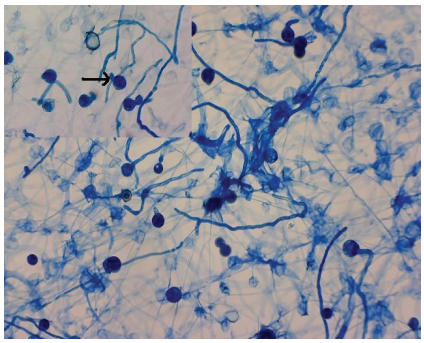

Fig. 4: Lacto phenol cotton blue staining of basidiobolus ranarum. Non septate broad hyphae and zygospores with conjugation beaks seen (Insert - arrow) X 400 magnification

oral itraconazole. The other treatment options are potassium iodide, trimethoprim-sulfamethoxazole. Some strains do not respond to amphotericin B. In the present case also the patient responded well to itraconazole and the ulcer got completely resolved after three months of treatment.

Conclusion

This case is presented to insist on the importance of clinical correlation of histopathology reports along with proper sampling and appropriate microbiological test while treating rare infections.

Abstract

Kikuchi Fujimoto Disease (KFD) is a rare clinical syndrome. Classically, KFD presents with fever and cervical lymphadenopathy. In most cases, it is a benign self limiting syndrome lasting around one to four months. It has been documented in all ethnic groups but is more prevalent in the Asian population. The diagnosis of KFD can be difficult as its clinical features can be similar to malignant lymphoma and Systemic Lupus Erythematosus (SLE) associated lymphadenitis. A strong association with SLE and sometimes other autoimmune diseases has been noted. Severe extranodal involvement can occur very rarely. A case of severe KFD presenting with features similar to secondary sepsis is unusual. In this report, we discuss a case of atypical Kikuchi's disease which presents with generalized serositis mimicking sepsis. Severe KFD has been known to resolve with corticosteroid administration. Patients with severe disease may need long term monitoring for development of autoimmune disorders.

Keywords

Kikuchi Fujimoto Disease (KFD); lymphadenopathy; sepsis

KFD: Kikuchi Fujimoto Disease; SLE: Systemic Lupus Erythematosus; ESR: Erythrocyte Sedimentation Rate; INR: International Normalized Ratio; HIV: Human Immunodeficiency Virus; HCV: Hepatitis C Virus; ADA: Adenosine Deaminase; FNAC: Fine Needle Aspiration Cytology; AFB: Acid Fast bacilli; ANA: Anti-nuclear Antibody; ANCA: Anti-neutrophil Cytoplasmic Antibodies; CD: Cluster of Differentiation; FDG-PET: Fluorodeoxyglucose Positron Emission Tomography

Introduction

Kikuchi Fujimoto disease (KFD) is a rare benign self limiting syndrome, classically described as cervical lymphadenopathy with low grade fever. At times, it presents with extranodal involvement which can even be life threatening. Varied presentations have been reported, emphasizing the need for accurate diagnosis and treatment [1-4]. This report aims to discuss a case of atypical Kikuchi's disease which presented with generalized serositis mimicking sepsis.

Case Presentation

A 40 year old male presented with low grade fever for one week followed by abdominal distension

and pain along with vomiting and breathlessness two days prior to admission. He also had bilateral neck swellings for the past one month. He was admitted elsewhere for his complaints and the investigations showed leucopenia, thrombocytopenia, minimally elevated liver enzymes and positive Dengue IgM antibody. Based on these investigations he was treated for dengue fever and also underwent cervical lymphnode excision biopsy. As he worsened clinically with the development of abdominal pain, vomiting and breathlessness he was referred to our center.

On examination he was febrile, tachycardic (PR- 140/min), normotensive (BP- 120/70 mm Hg), room air saturation was only 88% and kept on 4L oxygen support. The abdomen was soft but distended, bowel sounds were sluggish, clinically free fluid was appreciated. Ryle's tube aspiration produced 700 ml bilious aspirate.

Protein	4 g/dL
Albumin	2.45g/dL
ADA	9.6 U/L

Initial investigation (Table 1) revealed a severe thrombocytopenia, with a normal total and differential count. Urea and creatinine levels were mildly elevated. Liver function tests showed a slight elevation of serum total bilirubin levels. Amylase and lipase levels were normal. Serology was negative for hepatitis B antigen (HBsAg), Anti HCV and HIV antibodies. Dengue serology was positive for IgG antibody but negative for IgM antibody. Chest radiograph showed minimal pleural effusion. No air fluid levels seen in erect abdomen radiograph. Ultrasound abdomen showed moderate ascitis and minimal pleural effusion. Ascitic fluid total counts were elevated with atypical monocytic predominance (Table 2). It was a high protein low serum ascitic albumin gradient type of ascitis suggestive of peritoneal involvement. Pleural fluid total counts were elevated with monocytosis and presence of mesothelial cells (Table 3). Pleural fluid ADA level was normal. Pleural fluid cytology showed inflammatory cells composed of neutrophils, lymphocytes and anthracotic pigment laden macrophages, consistent with suppuration. Sinus tachycardia with low voltage complexes were seen in ECG but echocardiogram and Troponin T were normal. Serum procalcitonin was not elevated. Blood cultures, ascitic and pleural fluid cultures were sterile. AFB staining for tubercular bacilli and Gene Xpert MTB-RIF was negative ruling out tubercular cause. On further evaluation, abdominal Computed Tomography (CT) scan showed left mild to moderate pleural effusion, bilateral atelectasis and moderate fatty liver, omental fat stranding was seen and edematous wall in the distal ileal loops showing luminal narrowing.

Patient continued to have fever spikes and tachycardia was persistent throughout the hospital stay. On the 4th day of admission his clinical condition went for decompensation requiring mechanical

ventilation. He was treated with antibiotics for secondary infection and other supportive measures. Repeat procalcitonin level (Table 1) was normal, cultures continued to be sterile. This suggested a possible autoimmune cause but on further investigation ANA – immunofluorescence, ANA profile and ANCA profiles were negative, RA factor was negative. At this time the histopathology report of the lymph node biopsy showed a typical histology of Kikuchi's disease. A pulse therapy of high dose intravenous steroids was started following which patient showed a remarkable response. He was extubated and continued on nasal oxygen within two days of initiation of therapy. Platelet counts, total counts, kidney function, tachypnea and tachycardia improved and fever spikes settled. The patient was switched to oral steroid therapy and did well.

Discussion

Kikuchi Fujimoto disease (KFD) was first described by Kikuchi [1] et al and Fujimoto [2] et al independently in 1972, Japan. KFD is a perplexing disease due to its wide range of clinical manifestations and no definitive etiology. Typically, it is described as a sub-acute lymph node enlargement in association with low grade fever. It is also known as Histiocytic Necrotising Lymphadenitis for its defining histopathological features, a mononuclear hypercellular response with variable necrosis [3,4].

KFD is very rare typically said to occur in young females of Asian descent. Although more frequent in Asians, it has been reported in all population groups. The age at presentation usually is less than 40 years. There is a female predominance among adults, anywhere from 1:4 to 1:1 male to female ratio has been reported. A male predominance among children is noted in the pediatric age group [5,6,7].

In the retrospective analysis done by Dumas et al and In Young Joung et al, patients more frequently present with unilateral cervical lymphadenopathy involving the posterior cervical triangle [6,7]. Fever, myalgias, arthalgia are the most common presenting symptoms. Patients also had associated cutaneous rash, night sweats, and weight loss. Tender lymphadenopathy and autoimmune associations are more frequent in womenand severe presentations are seen more in men. Cutaneous rash, weight loss, arthalgia are associated with SLE. The syndrome in classical cases is benign, self limiting, lasting for around one to four months and requiring no more than supportive therapy alone. Recurrence is rare anywhere from 20%- 3% [5,7].

Various theories have been proposed to explain the etio-pathogenesis of the disease. It is thought to be a self limiting hyper-immune response to agents like viruses or physio-chemical agents. Viruses like Epstein Barr Virus (EBV), Herpes-viruses 6 and 8, Herpes simplex virus, Human immunodeficiency virus and other infectious agents like Yersenia pestis and Toxoplasma have been suggested as the etiology. A viral etiology has been justified based on the clinical prodrome, atypical blood picture and poor response to antibiotics but no consistent evidence has been put forth. Other theories suggest that KFD may be an incomplete autoimmune phenomenon which may or may not evolve into a full blown autoimmune disease. The association of SLE with KFD supports this theory. KFD has also been associated with some HLA (Human Leukocyte Antigen) phenotypes, which can explain a familial predisposition in rare cases and its higher frequency in some ethnic groups. Though many points support these theorized none have been established as the cause for the disease [4,5].

There is no pathognomonic feature of KFD in blood investigations, but studies have noted

leucopenia, elevated serum Lactate Dehydrogenase and thrombocytopenia in these patients [5-7]. Only definitive investigation for diagnosis is lymph node biopsy and histopathology. The typical histopathological feature in case of KFD is effacement of architecture of the lymph node, paracortical apoptotic necrosis with presence of histiocytes, plasmacytoid cells interspersed by karyorrhectic debris and without formation of granulomas. Crescentic histiocytes are present in the necrotic foci with clustering of the plasmacytoid dendritic cells at the margins of the necrotic foci. There may be a mix of lymphocytes present some of them may be large with tingible body macrophages giving a false appearance of lymphoma. Kuo et al have divided the histopathological findings in KFD into proliferative, necrotizing and xanthomatous types [3]. Immunohistochemistry is used along with histopathology for diagnosis and for differentiation from malignant lymphomas [3-5]. The predominance of CD8 positive lymphocytes, myeloperoxidase, lysozyme, CD68 and CD4 in histiocytes is considered a marker for KFD along with absence of neutrophils. FNAC can show approximately 50% accuracy in selected cases of lymphadenopathy and sometimes can be useful independently as a means of diagnosis if typical clinical features are present [5]. Imaging studies like ultrasonography, computed tomography and FDG-PET scans find their use in evaluation of lymphadenopathy especially in generalized disease. Studies to determine the characteristic imaging patterns of KFD induced lymphadenopathy have been published but have yet to be accepted as a reliable means of diagnosis [5,6].

The diagnosis of Kikuchi's disease can be confounding due to its varied presentations. The possibility of misdiagnosis is high, as other more common disease present similarly. Moreover, the only definitive means of diagnosis is lymph node biopsy. The main differentials are Tuberculosis, Malignant lymphoma and SLE lymphadenitis. Cases of KFD mimicking acute appendicitis, malignant papillary carcinoma of thyroid have been published. There have also been reports of high rates of misdiagnosis in the past. One such article reports a 40% chance of misdiagnosis, a false diagnosis of malignant lymphoma was made [8]. With greater awareness of the disease and improving imaging studies misdiagnosis may have reduced. KFD may also be under-diagnosed as a mild episode can be attributed to probable infectious or reactive cause without further evaluation.

Accurate diagnosis becomes challenging especially when the presentation is atypical. Varied atypical manifestations of KFD have been reported. Extra-nodal involvement of KFD is associated with greater severity and duration of disease. There have been reports of Kikuchi-Fujimoto disease causing pleural effusion and interstitial lung disease, cryptogenic organizing pneumonia, autoimmune hepatitis, panuveitis and aseptic meningitis [6,9]. There is a strong association of KFD with Systemic Lupus Erythematosis, 13-25% of patients with KFD also developed SLE [6]. Kikuchi's disease can occur before, during and after the onset of SLE [5]. KFD has also been reported in association with autoimmune diseases like Rheumatoid arthritis, Sjogren's syndrome, Anti-phospolipid antibody syndrome, relapsing polychondritis multiple connective tissue disorder and others [9].

In contrary to the classical, benign cases of KFD, there are reports of fatal disease. In these extremely rare cases, death occurred due to disseminated intravascular coagulopathy, pulmonary hemorrhage and hemophagocytic syndrome [10].

In this case for discussion, the main working diagnosis was sepsis of probable gastrointestinal origin. A severe case of Kikuchi's disease mimicking sepsis with generalized serositis without an

autoimmune association is unheard of. This may suggest that KFD can occur independently without an autoimmune trigger. A case was reported of a female patient with histopathology suggesting KFD developed ascitis and plural effusion which progressed into a case of SLE [11]. In another report two cases with mixed connective tissue disorder develop KFD presenting similar to sepsis [12]. This also emphasizes the need for long term follow up for this patient to review autoimmune status.

Accurate diagnosis is essential in choosing the line management, as this is hugely different from that of its differentials. Hence, a diagnosis of KFD in any case with fever and lymphadenopathy should always be kept in mind.

The treatment of KFD is mostly symptomatic. Till present no guideline has been established for treatment of Kikuchi- Fujimoto disease. Good results have been documented with use of steroids in case of severe KFD. Others such as hydroxychloroquine, intravenous immunoglobulin and a combination therapy have been tried in cases of refractory or recurrent disease [6,12]. Although, a good response to treatment and prognosis is seen, a case refractory to treatment has been reported. A quick improvement in the general condition was seen in our patient after administration of steroids and he remains sero-negative in follow-up for 6 months following remission.

Conclusion

In conclusion, Kikuchi Fujimoto disease though rare, should always be on the list of differentials for any case of fever with lymphadenopathy. Despite being benign, KFD can present with severe manifestations. So, accurate diagnosis is indispensible in treatment of such patients.

Characterization of cardiac autonomic function in COVID-19 using heart rate variability: a hospital based preliminary observational study

https://doi.org/10.1515/jbcpp-2020-0378
Received November 13, 2020; accepted February 18, 2021;
published online March 12, 2021

Abstract

Objectives: The novel corona virus disease, which was initially reported in China in late 2019, has become a global pandemic affecting 330 million cases. COVID-19 affects predominantly the respiratory system, in addition to other organ systems, mainly the cardiovascular system. One of the hypotheses is that virus entering the target cells by binding to angiotensin converting enzyme 2 affecting hypothalamic pituitary axis could lead to dysautonomia which is measured by heart rate variability (HRV). HRV is a non-invasive measure of autonomic function that facilitates identification of COVID-19 patients at the risk of developing cardiovascular complications. So, we aimed to assess HRV in COVID patients and compare between COVID patients and normal controls.

Methods: In a case control design, we compared 63 COVID-19 infected patients with 43 healthy controls matched for age and gender. Along with clinical characterization, heart rate variability was evaluated using ambulatory 5 min ECG in lead II and expressed in frequency and time domain measures. Statistical analysis was performed using SPSS 17.0.

Results: Mean age of the study population was 49.1 ± 14.2 years and 71 (66.9%) were males. Frequency domain measures high (HF) and low (LF) frequency powers were significantly decreased in COVID-19 patients compared to controls. HF/LF and LF/HF ratios were not different between groups. Time domain measures rMSSD (root mean square of successive RR interval differences) and SDNN (standard deviation of NN intervals) were significantly increased among COVID-19 subjects. COVID-19 infection was associated with increased parasympathetic activity as defined by rMSSD>40 {adjusted odds ratio 7.609 (95% CI 1.61–35.94); p=0.01} and SDNN>60 {adjusted odds ratio 2.620 (95% CI 1.070–6.44); p=0.035} after adjusting for age, gender and comorbidities.

Conclusions: Our study results showed increased parasympathetic tone in COVID patients. Early diagnosis of autonomic imbalance in COVID patients is needed to plan management and limit progression of disease.

Keywords: heart failure; pulmonary hypertension; right heart.

Introduction

In December 2019, a novel coronavirus disease (nCoV) epidemic emerged in Wuhan City, Hubei Province, China. Owing to its high transmissibility and infectivity rate it spread across the world and WHO declared it as a pandemic on March 11, 2020 [1, 2]. As this virus predominantly affects the respiratory system it has been renamed as severe acute respiratory syndrome coronavirus 2 (SARS CoV-2) and the disease caused by this virus has been named as corona virus disease 19 (COVID-19) [3].

COVID-19 shows wide range of clinical presentations ranging from asymptomatic/mild symptoms (fever, cough, dyspnea, myalgia, fatigue, anosmia, dysgeusia and diarrhea) to severe illness like acute respiratory distress syndrome (ARDS), arterial and venous thrombosis, myocarditis and varieties of neurological manifestations [4–7]. A report from WHO says that “80% of infections are mild or asymptomatic, 15% are severe infections and 5% are critical infections” [8]. Co-morbid conditions like obesity, type 2 diabetes mellitus, coronary artery disease, chronic liver disease, chronic kidney disease and chronic respiratory disease are known to be risk factors for developing severe disease [9–11]. Wide spectrum of manifestations is explained by SARS CoV-2 having target cells in multiple organs and systems like respiratory tract including lung parenchyma,

ileum, bladder, esophagus, heart, kidney, hypothalamus, pituitary, adrenal glands etc. These target cells have angiotensin converting enzyme-2 (ACE2) receptors in their cell wall. ACE2 binding affinity of the SARS CoV-2 spike protein ectodomain is one of possible mechanisms by which entry to these cells is facilitated [1, 12]. Histopathological and immune histochemical studies have clearly demonstrated a direct assault on these organs/systems by the SARS CoV-2 virus [13].

Though main portal of entry is respiratory system and hence the dominantly affected one, SARS CoV-2 reaches other systems through mechanism yet unknown. Neuroinvasive potential of SARS CoV-2 has been discussed in recent literature in the context of plausible explanation for variety of neurological manifestations of COVID-19 [14–16]. Earlier studies have demonstrated that SARS CoV-1 and MERS CoV (Middle east respiratory syndrome CoV) have the potential to enter and invade central nervous system, dominantly in brainstem structures [12, 17, 18]. Owing to the similarities in viral structure and receptor binding domain, neurotropism of SARS CoV-2 can be speculated from the evidence found from SARS CoV-1. Though sparse, direct evidence of neurotropism of SARS CoV-2 is emerging in literature. A recent report by Paniz–Mondolfi et al. [19], demonstrated by electron microscopy, presence of viral particles in postmortem brain tissues of a COVID-19 patient. Another report by Moriguchi et al. [20], evidenced the presence of SARS CoV-2 in cerebrospinal fluid. It has been postulated that SARS CoV-2 can enter the central nervous system by several mechanisms such as invasion through olfactory epithelium [21], synapse-connected route from terminal nerve endings [22] and transmission across blood-brain barrier by endothelial damage [19]. Clinical implications of neuropropensity of SARS CoV-2 range from mild symptoms like headache, dizziness etc., to severe manifestations like seizures, encephalitis, Guillain-Barre syndrome and cerebrovascular events. Involvement of autonomic nervous system (brainstem and hypothalamus) can lead to dysfunction of vital organs including cardiovascular system, thereby significantly influencing the outcome in COVID-19 patients. Cardiovascular system is also affected by the virus leading to manifestations like acute myocardial infarction, myocarditis and arterial & venous thrombosis. Monitoring the cardiac autonomic function of patients with COVID-19 can help us identify the individuals who are at risk of developing adverse cardiovascular outcomes.

Autonomic dysfunction has been reported in viral infections like retrovirus (human immunodeficiency virus, human T-lymphotropic virus), herpes viruses, flavivirus, arbovirus, enterovirus 71 and lyssavirus [23]. Current literature on autonomic dysfunction in COVID-19 patients is very sparse, barring a few case reports [24, 25]. Though various other methods were employed in these clinical settings to elicit dysautonomia, heart rate variability (HRV) measurement was seldom used for this purpose. During last two decades, HRV is considered most objective, reproducible and validated tool for demonstration of autonomic dysfunction [26]. Frequency and time domain measures of HRV have emerged as the most promising markers of balance between parasympathetic and sympathetic activity of autonomic nervous system that controls homeostasis of all vital organs.

Eliciting an association between autonomic dysfunction and COVID-19 could clarify the genesis of many clinical manifestations and importantly the unpredictable natural course of the illness. In this study, we intended to evaluate for autonomic imbalance and the direction of its deviation in COVID-19 subjects by measuring HRV and comparing the differences in HRV metrics between SARS CoV-2 positive and negative individuals.

Methods

This was an analytical cross-sectional study involving adult COVID-19 patients admitted for treatment in PSG Institute of Medical Sciences, Coimbatore, a specialized COVID-19 treating center in South India during March to June 2020. Sample frame during this period was approximately 500 inpatients whose COVID-19 status was confirmed by reverse transcription-polymerase chain reaction (RT-PCR) test of nasopharyngeal and oropharyngeal swab. Eligible inpatients (test group) of both genders, aged between 25 and 60 years were recruited from the sample frame by convenient sampling method. Patients with uncontrolled hypertension, coronary artery disease, cerebrovascular accident, family history of young myocardial infarction were excluded. Similarly, those patients on treatment with beta-blockers, inhaled or oral beta-mimetics, theophylline and other drugs with potential chronotropic effects were excluded. Patients with severe disease (those requiring oxygen support and/or intensive care) were also excluded. The comparison group included age and gender-matched healthy individuals from among the employees of medical school who tested negative for SARS CoV-2 by RT-PCR of their nasopharyngeal and oropharyngeal swab and fulfilled above mentioned selection criteria. This study was cleared by the institutional human ethics committee, and all study participants gave written informed consent. All such subjects recruited for the study underwent a detailed clinical examination.

Assessment of HRV

Study participants in both the groups were instructed to refrain from smoking, caffeine intake for 2 h and alcohol intake for 36 h. They should have had adequate rest, at

least 8 h of uninterrupted sleep on the night before the assessment of HRV and normal breakfast on the day of assessment. They were made to lie quietly in a couch in supine position for 5 min to alleviate the anxiety in a sound attenuated room with dim lighting and the temperature ranging from 20 to 25 °C.

After explaining the procedure to the subject, HRV, a quantitative marker of the autonomic activity was assessed using an ambulatory ECG system (INCO digital NIVIQURE, Bangalore, India) in lead II for 5 min. It is a multichannel digital data acquisition system which enables to acquire, analyze and store ECG data. ECG data was obtained at a sampling rate of 1,024 Hz in standard lead II configuration. The interface RS232C-compatible module was used to transfer data from the recording unit to the computer. The transferred data was analyzed using inbuilt software system. The series of RR intervals obtained were subjected to frequency and time domain analysis. Time domain indices of HRV indicate the amount of variability in measurements of interbeat interval (IBI), which represent time period between successive heartbeats. Time domain measures include standard deviation of NN intervals (SDNN), root mean square of successive RR interval differences (rMSSD) and percentage of successive RR intervals (pNN50). Frequency domain measurements estimate the distribution of absolute or relative power into frequency bands. Frequency domain measures include low frequency (LF) and high frequency (HF) [26]. HF component indicates the parasympathetic activity, whereas LF represents both sympathetic and vagal activity, and SDNN, rMSSD and pNN50 measure parasympathetic activity [26, 27].

Statistical analysis

The data were examined initially for normality of distribution and homogeneity of variance and expressed in terms of mean ± SD or percentage. Data with wide dispersion were expressed in log transformed values. Data from continuous variables were compared between study groups using Student's *t*-test whereas categorical variables were compared using Chi-Square test. Mann–Whitney *U* test was performed for variables that were not normally distributed. HRV variables that were significantly different between the groups were used as dependent variables for logistic regression analysis. For this purpose, HRV measures were dichotomized to categorical variable (artificial categorization using median split [28]) using an arbitrary cut-off value that was close to the median as reported by Nunan et al. [27] in their systematic review of studies involving normal subjects. Stepwise logistic regression analysis was employed to identify significant covariates and to evaluate association between HRV measures and SARS CoV-2 status after adjusting for important confounders like age, gender and comorbidity. Subgroup analysis was performed to characterize clinical and HRV profiles of SARS CoV-2 infected subjects based on symptom status. A p value of <0.05 was considered significant. All statistical analyses were carried out using SPSS version 17 software.

Results

In total, 106 participants were recruited for the study, which included 63 (59.4%) COVID-19 subjects and 43 (40.6%) healthy individuals who tested negative for SARS CoV-2. Among COVID-19 patients 33 (52.3%) had mild to moderate symptoms and 30 (47.6%) were asymptomatic. Mean age of the study population was 49.09 ± 14.21 years with 71 (67%) male subjects and 35 (33%) female subjects (Figure 1).

Comparing COVID-19 patients and healthy subjects, both groups were age and gender matched. Vital parameters like heart rate, SPO_2 at room air, systolic and diastolic blood pressure showed no difference between the study groups. Among frequency domain HRV parameters, HF and LF powers were significantly decreased among COVID-19 patients as compared to healthy individuals. HF/LF ratio and LF/HF ratio were not different between the groups (Table 1). Among time domain parameters, mean rMSSD was significantly higher in the COVID-19 group compared to healthy individuals (Figure 2). Mean SDNN value was higher among COVID-19 subjects with a trend toward statistical significance.

In the above graphical representation, the box spans the interquartile range, ends of the box represent upper and lower quartiles, bold horizontal line within the box represents the median value and the whiskers show the

Table 2: Stepwise logistic regression analysis of association between COVID-19 infection and parasympathetic overtone as defined by rMSSD>40 or SDNN>60.

Parasympathetic overtone	Odds ratio (95% CI)	p-Value
rMSSD>40		
Unadjusted	9.058 (1.98–41.35)	0.004
Adjusted for age and gender	8.670 (1.86–40.30)	0.006
Adjusted for age, gender and diabetes mellitus type 2	8.174 (1.75–38.22)	0.008
Adjusted for age, gender and presence of comorbidities	7.609 (1.61–35.94)	0.01
SDNN>60		
Unadjusted	2.380 (1.014–5.58)	0.046
Adjusted for age and gender	2.427 (1.020–5.77)	0.045
Adjusted for age, gender and diabetes mellitus type 2	2.417 (1.002–5.83)	0.049
Adjusted for age, gender and presence of comorbidities	2.620 (1.070–6.44)	0.035

minimum and maximum values. The circles with numericals are outliers.

Based on the published data on range of observations and median value of normal subjects, we defined parasympathetic overtone when subjects had rMSSD more than 40 and SDNN more than 60 [27]. These dichotomous variables indicated that COVID-19 patients had higher parasympathetic overtone than the healthy subjects (Table 1). Stepwise logistic regression analysis revealed a significant association between SARS CoV-2 infection status and parasympathetic overtone after adjusting for age, gender, T2DM or the presence of one or more comorbidities (Table 2).

Subgroup analysis was performed comparing the characteristics between symptomatic and asymptomatic subjects with COVID-19 (Table 3). Symptomatic COVID-19 patients were elderly and predominantly males as compared to asymptomatic patients. Symptomatic patients more frequently had at least one co-morbidity. Common

SDNN[a]	1.87 ± 0.36	1.91 ± 0.3	0.135

SPO_2, oxygen saturation; BP, blood pressure; HR, heart rate; SDNN, standard deviation of NN intervals; rMSSD, root mean square of successive RR interval differences; pNN50, percentage of successive RR intervals; LF, low frequency power; HF, high frequency power. *Mann–Whitney *U* test, level of significance 0.05. [a]Log transformed values. [b]Chi square test, level of significance 0.05. [c]Student's *t*-test, level of significance 0.05.

co-morbidities among symptomatics were DM type 2 (36.7%), Systemic hypertension (33.3%), obesity (10%), hypothyroidism (13.3%) and psychomorbidity (10%). Both frequency and time domain HRV parameters showed no difference between the subgroups.

Discussion

Our study clearly demonstrated an increased parasympathetic activity in COVID-19 patients, independent of important confounders like age, gender and comorbidities including diabetes mellitus. Autonomic dysfunction in COVID-19 subjects in our study was best demonstrated by time domain measures of HRV namely rMSSD and SDNN with predefined cut-off values. HF and LF powers in frequency domain were significantly decreased in COVID-19 subjects, though their ratios were not significantly different when compared to the healthy uninfected subjects. In a subgroup analysis of COVID-19 subjects, HRV measures were not different between asymptomatics and mild to moderate symptomatic. To our knowledge, our study was the first to demonstrate higher rate of autonomic imbalance among COVID-19 patients as compared to uninfected healthy group.

Our search through literature yielded scanty reports on autonomic dysfunction among COVID-19 patients. Ritwik Ghosh et al. [24] reported in one case of COVID-19, clinical features of autonomic dysfunction in the form of sinus arrhythmia, postural hypotension, intermittent profuse sweating, constipation, erectile dysfunction and squeezing sensation in the chest. Cardiac dysautonomia was not studied in this report. In another case report, Reiner Buchhorn et al. [25], studied a 58-year-old COVID-19 patient with 24 h ECG monitoring and found a significant decrease in heart rate and a paradoxical decline in HRV. But for these two case reports suggesting a possible autonomic dysfunction, no studies have yet, evaluated the presence of this important physiological disharmony in COVID-19 patients.

Though scanty in the context of COVID-19, plethora of evidence available in the literature demonstrating autonomic dysfunction in other infectious diseases like human immunodeficiency virus [29–31] human T Cell lymphotropic virus [32], Epstein Barr virus [33], cytomegalovirus [34], West Nile virus [35], Chagas disease [36, 37], diphtheria [38], leprosy [39], dengue[40], tetanus [41] and botulism [42]. Methodological differences in evaluating autonomic function as well as variations in study design do not allow head-to-head comparison of these studies with our findings in COVID-19 patients**.** In our search through literature, we found only two reports using HRV to link autonomic dysfunction with infection. Jeevagan Vijayabala et al. [43] postulated sympathetic dysfunction as one of the pathogenetic mechanisms in Dengue shock syndrome . Robert Carter et al. [40] examined HRV of 27 children during defervescence in dengue viral infection and found that cardiac parasympathetic activity was the major cause for reduction in heart rate during this period of illness. Their observations were mainly based on frequency domain measures of HRV after correcting for baseline changes in heart rate. Contradictory to the above observations, La-Orkhun et al. [44] found no significant changes in various time and frequency domain metrics of HRV at least 24 h after defervescence, and follow-up conducted at least 14 days after defervescence. Our findings are consistent with Jeevagan Vijayabala et al. and Robert Carter et al., that we too found an increased parasympathetic activity in COVID-19 patients as demonstrated by the increase in time domain variables of HRV. This study further substantiates

two cases as cited above that reported autonomic dysfunction due to COVID-19. Proposed mechanisms of viral infection induced autonomic dysfunction include invasion of the central nervous system and the direct viral, toxin-mediated or immune-mediated involvement of the peripheral and autonomic nervous system [45].

Unlike the time domain variables, we found that frequency domains of HRV, specifically the LF/HF ratio were not different between the COVID-19 subjects and the healthy subjects. Traditionally LF/HF ratio was considered a marker of sympatho-vagal balance in cardiovascular system. However recent evidence this ratio merely indicates one part of complex non-linear interaction between sympathetic and parasympathetic nervous systems confounded by multiple physiological and mechanical factors [46]. Some of these confounders may have been missed in our study protocol. Also, smaller sample size may explain our inability to detect subtle difference in LF/HF ratio between the groups.

Our study involved a standardized measurement of heart rate variability using an ambulatory 5 min ECG recording in lead II. Precision of our evaluation was further augmented by stringent selection of subjects and optimal conditions for HRV measurement during conduct of the study. Our study is limited by participation of only asymptomatics and mild to moderate symptomatic patients with SARS CoV-2 infection. Severely ill COVID-19 patients were excluded from the study because we believed that factors like stress, cytokine storm, drugs like steroids, vasopressors etc., positive pressure ventilation, prolonged hospitalization and related psychomorbidity that typically characterize these patients may have a confounding effect on our observations. None of our study subjects had any of these factors that could have possibly altered our findings. Sample size of the study was not adequate to provide enough statistical power to our findings. But we believe that this preliminary report can serve a stimulus for future research in this direction. A larger sample size could have facilitated further evaluation of association between symptoms and autonomic function in our subjects.

In conclusion, this study has found that COVID-19 is associated with autonomic dysfunction whose mechanism and prognostic implications need to be evaluated further. HRV measurement, being a simple, noninvasive, inexpensive tool, its utility in clinical practice as a possible rapid diagnostic and prognostic marker needs to be assessed in future research.

Abstract

Secondary infections are commonly identified in viral respiratory infections and are an important cause of mortality and morbidity. Post Coronavirus disease 19 (COVID 19) infections significantly change the long-term outcome of COVID 19. The complexities of post COVID 19 infections are the diversity of pathogens encountered and high index of suspicion is needed to diagnose & manage these infections. But the significance of bacterial and fungal infection following COVID 19 has not been adequately elucidated in literature. We report five interesting cases of secondary infections in post COVID 19 patients which include *Pneumocystis Jirovecii* pneumonia; Mucormycosis; Pulmonary Tuberculosis; Pulmonary Nocardiosis and Pseudomonal lung abscess. We have highlighted the challenges imposed and management of such patients.

Keywords

post coronavirus disease 19; nocardia; tuberculosis; mucormycosis, *pneumocystis jirovecii*.

Introduction

Coronavirus disease 19 (COVID19) is an ongoing pandemic caused by the Severe Acute Respiratory Syndrome CoronaVirus 2 (SARS CoV 2). This virus commonly affects the lungs causing pneumonia with acute respiratory distress syndrome, type 1 respiratory failure, pulmonary thromboembolism and other organ systems. Severe complications include respiratory failure, sepsis, acute coronary syndrome, acute renal failure and secondary infections. Those who had COVID 19 develop two types of complications. First one is post-COVID 19 sequelae where in the patients have persisting hypoxia requiring oxygen support. The second one is the post COVID 19 infections. Risk factors for secondary infections included the use of broad-spectrum antimicrobials, glucocorticoids, severe pulmonary involvement and patients on immunosuppressant drugs for other conditions [1,2]. Review of literature has revealed reports of co-infection with various microorganisms during active COVID 19. There were no reports of infections following remission

of COVID 19. Here we report 5 such cases of post COVID 19 infection with different pathogens all occurring after remission from COVID 19.

Case I

A 63-year-old male known case of ischemic heart disease was treated for COVID 19. High resolution computerized tomography of (HRCT) lungs revealed CT severity index 14/25. He was treated with Remdesivir, Low molecular weight Heparin (LMWH), glucocorticosteroid. He improved and was discharged. One month after discharge, he presented with fever, breathlessness and cough for 10 days. On examination, he maintained 90% saturation in room air and had bilateral wheeze and crepitations. Complete Blood Count (CBC) showed white blood cell (WBC) count of 12,900 with 78% neutrophils and 10% lymphocytes. His renal function test (RFT) and liver function tests (LFT) were within normal limits. HRCT chest showed evidence of resolving atypical pneumonia. Bronchoalveolar Lavage (BAL) tested positive for Pneumocystis. jirovecii by Gomori Methenamine Silver (GMS) stain (Figure 1) and PCR. He was treated with Cotrimoxazole and prednisolone. He completely recovered after the treatment.

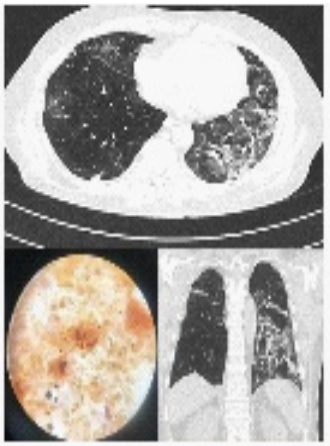

Figure 1: HRCT coronal and axial section of lung showing subtle ground glass densities with predominant interlobular septal thickening within with adjacent parenchymal strands and thin atelectasis in both lungs, predominantly in the peripheries, peri hilar regions and lower lobes. BAL- Gomori Methenamine silver staining shows cysts of *Pneumocystis Jirovecii.*

Case II

A 56-year-old male a known case of Type 2 Diabetes mellitus/ Systemic Hypertension who was treated for COVID 19 and discharged home 2 months back, presented with fever for more than 2 weeks. His vitals were stable and systemic examination showed bilateral crepitations. CBC showed a WBC count of 1,700 cells/cmm with 75% neutrophils, 19% lymphocytes and 5% monocytes. His RFT and LFT were within normal limits. Positron Emission Tomography (PET) scan showed features suggestive of COVID 19 sequelae in lungs and low metabolic activity at lymph nodes. BAL sample tested positive for *Mycobacterium Tuberculosis* (MTB) by XPERT MTB-Rifampicin (RIF) assay. He was started on Anti-Tubercular Therapy (ATT) with Rifampicin, Isoniazid, Pyrazinamide and Ethambutol. The patient gradually improved and was then discharged with ATT. On review, he had no further fever spikes and was symptomatically better.

Case III

A 61-year-old male, a known case of Type 2 Diabetes Mellitus/ Dyslipidemia, treated for COVID 19

one month back, presented with pain on the left half of the face with blurring of vision and protrusion of the left eye. On examination, he had proptosis of the left eye with left III, IV, V2, VI, VII cranial nerve palsies. CBC showed a WBC count of 8,500 with 56% neutrophils and 34% lymphocytes. RFT and LFT were within normal limits. MRI showed evidence of fungal sinusitis and orbital cellulitis. Diagnostic nasal endoscopy showed large posterior septal perforation with the involvement of the left maxillary sinus. He underwent left maxillary sinus debridement. He was started on intravenous Liposomal amphotericin B for 4 weeks and was switched to oral Isavuconazole. His tissue culture on Sabouraud dextrose agar and Lactophenol Cotton Blue stain revealed growth *Rhyzopus sp* (Figure 2). He was doing well on follow up.

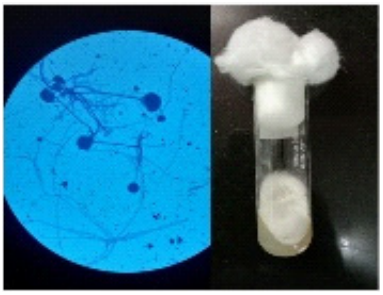

Figure 2: Tissue culture on Sabouraud dextrose agar showing black to grey tan cottony growth with salt and pepper appearance. Lactophenol Cotton Blue staining showed broad pauciseptate hyaline hyphae with right angled branching.

Case IV

A 54-year-old male known case of Type 2 diabetes mellitus had COVID 19 a month back, presented with non-productive cough and high-grade fever for 2 days. On examination, his vitals were stable and had reduced breath sounds in the left interscapular area. CBC showed a WBC count of 9,800 per cmm with 82% neutrophils and 12% lymphocytes. His RFT, LFT were within normal limits. Blood cultures were sterile. Chest x-ray showed a thick-walled cavity with an air-fluid level in the left middle and lower zone. BAL sample grew *Pseudomonas aeruginosa* (inducible AMPC). He was started on intravenous Meropenem. During the course of his stay, he developed proximal muscle weakness of all four limbs. Nerve conduction study showed demyelinating Polyradiculoneuropathy due to Guillain Barre syndrome. He was started on IV immunoglobulin and showed gradual improvement. On review, he was afebrile and chest X-ray showed complete resolution of the abscess.

Case V

A 58-year-old male with no co-morbidities admitted and treated for COVID 19 presented 2 weeks post-discharge with fever, dry cough and breathlessness for a week. On examination, he was afebrile and vitals stable. Systemic examination revealed bilateral basal crepitations. CBC showed a WBC count of 10,800 cells/cmm with 78% neutrophils and 12% lymphocytes. RFT and LFT were within normal limits. HRCT showed consolidation of the left lower lobe. BAL for modified Ziehl Neelsen stain for Nocardia was positive (Figure 3). He was started on Trimethioprim-Sulfamethoxazole. On review, the patient had no fever and was symptomatically better.

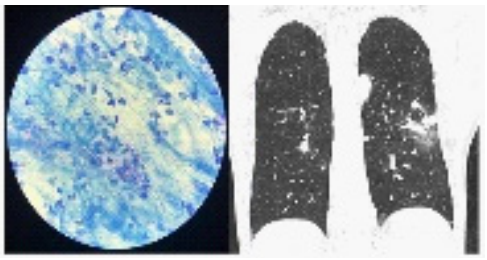

Figure 3: HRCT coronal section of lung showing consolidation in the left lower lobe. BAL – Modified Acid Fast Bacilli (AFB) stain showing the partially acid-fast beaded filamentous appearance of Nocardia.

Discussion

We report five cases of post COVID 19 sequelae that developed different secondary infections in a time span of two weeks to three months after active COVID 19 infection. All five patients were aged above 55 years and had similar severity of COVID 19 infection and treatment for the same. Four of these five patients had co morbidities.

Experiences from SARS, MERS and influenza outbreaks have evidenced co infection with other microorganisms in a subset of patients that frequently determines the morbidity and mortality [3,4]. A similar clinical pattern has been reported in COVID 19 pandemic, with concurrent secondary infections occurring during acute phase of COVID 19 infection. Lansbury L et al in their metaanalysis reviewed thirty studies and reported a pooled prevalence of 7% of co infections; most of them were of bacterial etiology [5]. Various other pathogens like invasive aspergillosis [6], Pneumocystis jirovecii [7], Mycobacterium tuberculosis [8] and mucormycosis [9] have also been implicated.

In our search through literature, we found no publications on secondary infections during the recovery phase of COVID 19 infection, similar to our report. More recently, studies have emerged in literature on the so called “Post COVID 19 syndromes” which elaborates on the clinical course after the acute phase of COVID 19 infection [10,11]. Even these studies have not commented on the incidence or characteristics of secondary infections occurring during the recovery phase of COVID 19 infection. In this context, indirect evidence comes from a study by Donnelly JP et al, who found that sepsis (8.5%) and pneumonia (3.1%) were common causes for readmission of COVID 19 patients within 60 days of discharge from initial hospitalization [12]. This study along with our report reiterates the importance of early diagnosis and management of post COVID 19 secondary infections.

Propensity for developing secondary infections ‘de novo” in late phases of COVID 19 infection could be explained by several factors like COVID 19 related damage to the lungs, immunomodulatory drugs, comorbidities etc. It is also possible that concurrent infections during acute phase of COVID 19 infection, might have remained undetected due to hesitancy for thorough microbiological evaluation using invasive “aerosol generating” procedures like bronchoscopy. Such undiagnosed concurrent infections potentiated by aforesaid factors, may have emerged in later course of recovery from COVID 19 infection.

Going by the potential impact of post COVID 19 secondary infections on morbidity and mortality, we strongly recommend future research in this subject. In an attempt to synchronize our efforts to understand this important entity we also recommend data repositories or registries to profile post COVID 19 infections. We believe that these efforts will help us evolve strategies towards better management of COVID 19.

ABSTRACT

Background: Metabolic syndrome (MS) is associated with premature coronary artery disease (CAD). The aim of this study was to evaluate the prevalence of MS and its association with severity of CAD proven by coronary angiogram (CAG) in young patients.
Methods: We included patients, aged 45 years or less, admitted with acute coronary syndrome (ACS), who had CAD confirmed by coronary angiography. They were divided into two groups according to the presence or absence of MS based on International Diabetes Federation (IDF) criteria. CAD was classified into single, double and triple vessel disease (TVD). The prevalence of MS and its individual parameters was calculated.
Results: Among 90 young patients who presented with ACS, MS was present in 67 patients (74.44%). Among those with MS, the prevalence of each individual criterion was statistically significant in MS group (P <0.05). Prevalence of pre-existing hypertension and diabetes was significantly higher in MS group (p <0.01). Smoking, alcohol consumption and family history of CAD were not statistically significant in patients with and without MS. Fifteen out of 90 patients (14 in MS group) who presented with ACS had TVD in CAG, but this was not statistically significant (p 0.06).
Conclusions: This study confirms a very high prevalence of MS in young Indian patients with premature CAD. MS was more prevalent than the conventional risk factor smoking in young CAD patients. We could not find significant difference in severity of CAD based on CAG between MS and non-MS group.

Keywords: Coronary angiogram, Coronary artery disease, Metabolic syndrome, Young patients

INTRODUCTION

Coronary artery disease (CAD) affecting younger individuals has reached enormous proportions. There is no doubt that it will become a major public health problem in the future unless we concentrate on reversible causes and prevention, through research studies. CAD is increasing in developing and transitional countries because of urbanization, demographic and lifestyle changes, whereas it is decreasing in many developed countries.[1] Studies have suggested that the risk of myocardial infarction is mostly due to modifiable risk factors like smoking, physical inactivity, poor diet, psychosocial stress, hypertension ,diabetes mellitus, dyslipidemia and increased waist-hip ratio.[2,3] Many of these risk factors are grouped or are seen at the onset of metabolic syndrome (MS).

Metabolic syndrome, a cluster of glucose intolerance, hypertension, dyslipidemia and abdominal obesity, has

been recognized as a major predeterminant of type 2 diabetes mellitus and CAD.[4,5] MS was associated with a 1.5 fold increase in all-cause mortality and a two fold increase in cardiovascular outcomes in a recent metaanalysis.[6] Presence of MS with or without diabetes was found to be an independent determinant of premature CAD.[7] CAD in younger population is an area of increasing interest because of its potential for long-term disability and premature death.

Few studies have reported MS and its association with CAD in the young.[7-9] We found only very limited studies in an Indian setting analyzing the association of MS with premature CAD.[10] The prevalence of MS in young patients with angiographically proven premature CAD has not been studied in Indians, to our knowledge. Understanding the impact of MS on CAD in younger age group is important for developing public health policy towards prevention and management. Hence this study was undertaken to know the prevalence of metabolic syndrome using International Diabetes Federation (IDF) criteria in patients with premature coronary artery disease proven by coronary angiogram (CAG). We also tried to evaluate any association between the presence of metabolic syndrome and severity of CAD.

METHODS

This cross-sectional study was conducted at our centre, a large tertiary care teaching hospital in South India. The study was done after obtaining institutional ethical committee clearance and informed consent. All patients, aged 45 years or less, admitted with acute coronary syndrome (ACS) [ST-elevation myocardial infarction (STEMI)/non-ST-elevation myocardial infarction (NSTEMI) and unstable Angina as per standard definition], in our hospital during the period March 2014-August 2014 were included in the study. We excluded patients younger than 18 years or older than 45 years of age and patients who did not undergo coronary angiogram for various reasons.

ACS was diagnosed in patients with symptoms compatible with myocardial infarction (MI), based on electrocardiogram (ECG) changes and cardiac enzymes. Ejection fraction (EF) and left ventricular systolic dysfunction (LVD) was assessed by echocardiography. CAG was done in all subjects either at admission for primary Percutaneous Coronary Intervention (PCI) or electively after initial medical stabilization with thrombolysis or conservative treatment, depending on the clinical circumstances and consent from the patient. CAD was diagnosed as a 50% or greater stenosis in one of the three major coronary arteries and classified as single vessel disease (SVD), double vessel disease (DVD) and triple vessel disease (TVD) based on the number of arteries involved. The IDF criteria were used for a diagnosis of MS, which is suitable for Indian population.[4] MS was defined as the presence of abdominal obesity (defined by waist circumference ≥ 90 cm for men and ≥ 80 cm for women) plus two or more of the following factors

- Triglycerides ≥150 mg/dL or specific treatment for this lipid abnormality,
- High density lipoprotein (HDL) cholesterol <40 mg/dL for men or <50 mg/dL for women or specific treatment for this lipid abnormality,
- Blood pressure ≥130/85 mm Hg or treatment of previously diagnosed hypertension,
- Fasting plasma glucose ≥ 100 mg/d L or previously diagnosed type 2 diabetes.

Detailed history was taken including presenting symptoms, history of diabetes/systemic hypertension/ history of CAD in the family/usage of alcohol and smoking. A careful physical examination was done with reference to waist circumference (WC) and blood pressure. About ≥3 measurements of BP at the time of entry with values greater than or equal to 130/85mmHg on an average or any medications for hypertension was considered significant. WC was recorded according to the national health and nutritional survey. Peripheral venous blood samples were drawn at the time of admission, the following morning after an overnight fast for lipid profile (total cholesterol, high density lipoprotein cholesterol (HDL-C), low density lipoprotein cholesterol (LDL-C) and triglycerides) and at day 5 for fasting plasma glucose.

Statistical analysis

The data were analyzed using Statistical Package for Social Science (SPSS) Version 19.0, and Microsoft Excel 2010. Continuous variables were expressed as mean/SD and compared with independent sample t-test. Categorical variables were expressed as percentage and compared with chi-square test. A predictive value of less than 0.05 was taken as statistically significant.

RESULTS

A total of 90 young patients with ACS, who underwent CAG were studied. The key demographics of the study group are summarized in Table 1. Patients ranged from 26 to 45yrs. The mean age of the patients was 39.7 yrs. Among 90 patients, 82 were male and eight were female. Out of 90 cases, 67 (74.44%) had MS according to IDF criteria and 23 (25.55%) did not. Of these 67 patients with MS, 29 (43.28%) met three, 24 (35.82%) met four and 14 (20.89%) met all five criteria for MS. MS was found in 60 men out of 82 (73.17%) and seven women out of eight (87.5%), thus a greater percentage of young women had MS than men, but this was not statistically significant.

The distribution of MS criteria as defined by IDF in those 67 patients was as follows (Figure 1).

Table 1: Baseline demographic characteristics.

Variable value	Ms		P
	Yes (n=67)	No (n=23)	
Blood pressure ≥130/85mmhg	44 (65.67%)	6 (26.08)	<0.01
Fasting blood glucose ≥100mg/dl	43 (64.17%)	9 (39.13%)	<0.05
Triglycerides (mg/dl)	179.14	115.86	<0.01
HDL-C (mg/dl)	32.36	36.78	<0.05
WC (in cms)	95.64	87.23	<0.001
Age	40.49	37.39	<0.01
Sex			
Male	60	22	0.674
Female	7	1	
Diabetes mellitus	37 (55.22%)	5 (21.73%)	<0.01
Pre-existing hypertension	31 (46.26%)	3 (13.04%)	<0.01
Family history of CAD	10 (14.92%)	2 (8.69%)	0.448
Smoking	42 (62.68%)	15 (65.21%)	0.825
Alcohol consumption	32 (47.76%)	13 (56.52%)	0.468
Dyslipidemia	15 (22.3%)	2 (8.69%)	0.148
STEMI	36 (53.7%)	18 (78.26%)	<0.05
LVD	23 (34.32%)	11 (47.82%)	0.24

MS: Metabolic syndrome, HDL-C: High density lipoprotein cholesterol, WC: Waist circumference, CAD: Coronary artery disease, STEMI: ST-elevation myocardial infarction, LVD: Left ventricular systolic dysfunction.

All (100%) had abdominal obesity, 60 (89.55%) had low HDL or treatment for lipid abnormality, 45 (67.16%) had BP≥130/85 mmHg or treatment for hypertension, 43 (64.17%) had elevated triglycerides or treatment for lipid abnormality and 43 (64.17%) had raised FBS or DM. All these criteria were statistically significant in MS group.

Table 2: Angiography results in MS/non- MS.

Angiogram result	MS		Non-MS		P value
	N= 67	%	N=23	%	
SVD	39	58.2	16	69.56	0.335
DVD	14	20.89	6	26.08	0.605
TVD	14	20.89	1	4.34	0.066

MS: Metabolic syndrome, SVD: Single vessel disease, DVD: Double vessel disease, TVD: Triple vessel disease.

MS patients had significantly higher prevalence of pre-existing hypertension and diabetes (p<0.01). Alcohol consumption, smoking status, patients receiving treatment for dyslipidemia and family history of CAD were not statistically significant in patients with and without MS (Table 1).

Thirty-six patients (53.7%) out of 67 in MS and 18(78.26%) out of 23 in non-MS cohort presented with ST elevation MI, which was statistically significant (p <0.05). Twenty-three patients (34.32%) in MS and 11(47.82%) in non-MS group had LVD with the p value of 0.24, which was not significant.

Majority of patients in both MS and non-MS groups had SVD, 58.2 % and 69.56 % respectively; it was not significant (p 0.33). Fifteen out of 90 patients who presented with ACS had TVD. Fourteen patients with TVD had MS, whereas only one patient in non-MS group had TVD, even though TVD was more common in MS, it was not statistically significant (p 0.06) (Table 2).

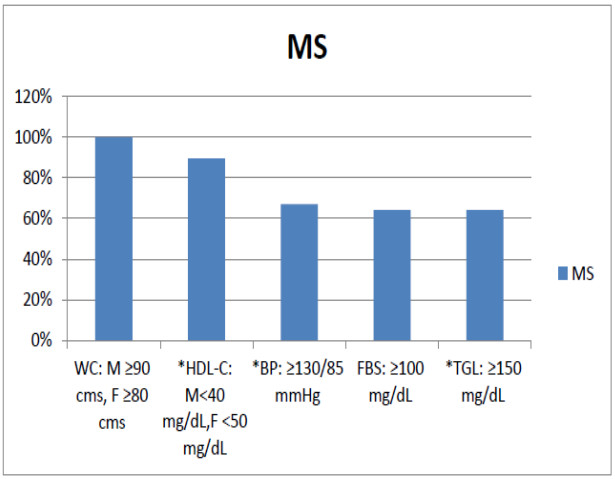

Figure 1: Prevalence of each criterion in MS group. MS: metabolic syndrome, WC: waist circumference, HDL-C: high density lipoprotein cholesterol, BP: blood pressure, FBS: fasting blood glucose or known type 2 diabetic, TGL: triglycerides. M: male, f: female, * or on treatment.

DISCUSSION

MS is characterized by a constellation of risk factors such as raised triglyceride, low HDL, glucose intolerance, hypertension and abdominal obesity that may lead to the development of CAD. Asian Indians are more prone to

diabetes and premature CAD, which is attributed to increased insulin resistance and characteristic abdominal obesity. Asian Indians have a different distribution of body fat, with abdominal obesity or a higher body fat content, even in the presence of normal body mass index.[11] Increased visceral fat is a dependable indicator of hyperinsulinemia and insulin resistance, which are risk factors for diabetes, dyslipidemia, hypertension and CAD.[12]

Hence, we have applied IDF criteria which has lower ethnic-specific waist circumference cut-offs for obesity, in our study.

We found that the prevalence of MS among patients presenting with young CAD was alarmingly high (74.44%). The prevalence of MS in young patients with CAD was similarly high in studies done by Hassanin et al. (66.39%) and Ranjith et al. (57%).[9,13] However, other studies have shown lower prevalence of MS in similar groups of patients ranging from 26% to 37%.[8,10,14]

Various studies in young CAD patients have shown a higher prevalence of MS in young women than in men.[9,10,14] In our study too the prevalence of MS was more common in women than men (87.5% versus 73.17%), but the difference was not statistically significant. This is important because Morraquin et al. have shown that women with CAD and MS have significantly higher risk of cardiovascular events and decreased survival than women without MS.[15]

Cigarette smoking was found to be the most common risk factor for premature CAD in earlier studies.[9,10,14,16] This was in contrast to our study, where we found MS was dominating with 74.44% versus smoking (63.33%), as a risk factor for premature CAD. This finding could suggest that MS may play a significantly more important role than smoking in the development of cardiovascular disease in younger age group.

While assessing the various components of MS in patients with the syndrome, we found that all patients had abdominal obesity, low HDL was the next most frequently seen risk factor (89.55%). A similar pattern of the individual components of MS in young patients with CAD was seen in a study done by Sadeghian et al.[17] Another study done in young Indians also showed a higher prevalence of low HDL (78.8%) in MS patients.[10] Higher percentage of low HDL in Indians was seen in a study conducted by Goswami et al. in MS patients with CAD.[18]

Studies have shown the predominance of dysfunctional HDL in MS patients and this proinflammatory HDL can further worsen metabolic dysfunction and hence increase the cardiovascular risk.[19] We also noted in our study that all eight women with premature CAD had low HDL. Hence, our study confirms higher prevalence of abdominal obesity and low HDL, which are well recognized risk factors for CAD.[20-23]

We also found a higher incidence of STEMI in non-MS group (78.26%) than MS (53.7%). This was unlike the results of Danciu et al. and Chung et al., where MS patients had more STEMI.[8,24] Danciu et al. found that STEMI in MS patients was statistically significant, whereas Chung et al. did not.

Although TVD was more common in the MS cohort than non-MS (14 patients versus one patient), this was not statistically significant. Thus, no significant difference in disease severity in terms of number of vessels stenosed, based on CAG, was found in our study. Goswami et al. in an Indian study found that the prevalence of MS increased significantly in patients with TVD, but they had included patients of all age groups.[18] Marroquin et al. showed that women with MS had increased risk of cardiovascular events in angiographically significant CAD patients, but again patients ranged from 21 to 86 years.[15]

There are a few limitations to our study. Those patients who met four out of five criteria for MS without the principal criteria (waist circumference more than 80 in women and more than 90 in men) were excluded from the MS group. We had only few female patients in our study. The strength of our study is that we describe the prevalence of MS in angiographically proven premature CAD, which is the gold standard to diagnose CAD.

CONCLUSION

To conclude, this study clearly indicates a very high prevalence of MS in Indian patients with premature CAD. Our study is important because we found that MS was more prevalent than the conventional risk factor of smoking in young patients with CAD. We could not find significant difference in severity of CAD between MS and non-MS group in young patients, but larger and more studies in a similar age group are required to confirm this finding.

Family physicians have an important role in identifying MS in young healthy individuals and thus, may help find people at risk for premature CAD. Healthcare professionals should routinely measure waist circumference and screen for low HDL, which is usually ignored in practice. The presence of MS or any of its components in young people should trigger an aggressive approach toward patient education and implementation of primary and secondary measures to help reduce the prevalence of premature CAD.

ABSTRACT

Clinical human brucellosis is quite rare in India, that too in an non susceptible host. This report describes a case of clinical human brucellosis in India. This case involved a 36 years old male, a professor in an Engineering college. He presented with complaints of fever for 4 months with myalgia, generalized tiredness, loss of weight and loss of appetite. On evaluation, total counts and ESR was elevated and all other investigations were normal. Based on history, common causes like occult tuberculosis or autoimmune diseases were considered. But, blood cultures grew *Brucella melitensis* in all 2 samples and a diagnosis of brucellosis was made. He was treated with Rifampicin and Doxycycline. Suspicion of brucellosis in this patient is low because the patient has no history of contact with animals, consumption of unpasteurized milk or occupational exposure. So, the health care practitioners should be aware of this possibility of this zoonotic infection as a differential diagnosis in patients with nonspecific symptoms and unexplained prolonged fever.

Keywords: Brucellosis, Non-susceptible host, Prolonged fever

INTRODUCTION

Burcellosis is a multisystem disease with a broad spectrum of nonspecific symptoms that usually occurs within 2 weeks but up to 3 months after inoculation. It is usually due to consumption of unpasteurized contaminated goat's milk or soft cheese that had been infected with *Brucella melitensis*.[1] They are small non-motile, nonsporing, non-capsulated gram-negative coccobacilli that usually infects goats and sheep.[2] The principal organizsm causing worldwide brucellosis is *Brucella melitensis*. It is the most pathogenic and invasive one, followed by *Brucella suis*, *Brucella abortus*, *Brucella canis*, *Brucella pinnipediae* and *Brucella cetaceae*.[3]

Human brucellosis is commonly found in countries with rural communities that live with close association with animals and its prevalence in a region depends on factors such as methods of processing milk and milk products, food habits, social economic status, hygiene and climate.[4] Both human and animal brucellosis are still endemic in some parts of the world such as Pakistan, China and Srilanka.[5-7]

The clinical features of brucellosis are nonspecific and depends upon the stage of the disease and the organs and systems involved. The most commonly reported symptoms are undulating fever, fatigue, malaise, chills, sweats which may be characterized by a peculiar odour at night, insomnia, headache, myalgia, arthralgia, anorexia, weight loss, hepatomegaly and splenomegaly. Brucellosis can also manifest as a localized disease affecting the central and peripheral nervous system, gastrointestinal tract, genitourinary tract and heart.[8]

Without the critical epidemiological clue to exposure to animals or consumption of unpasteurized dairy products,

this disease can pose a great diagnostic challenge to the clinician. Authors report a case of human brucellosis in a non- susceptible host.

CASE REPORT

36 years old male presented with complaints of fever for 4 months, which was associated with myalgia, generalized tiredness, loss of weight and loss of appetite. There was no history of contact with animals, consumption of unpasteurized milk or occupational exposure. General examination was unremarkable. Abdominal palpation revealed hepatosplenomegaly. His hemoglobin and platelet levels were within normal limits, while total counts showed leucopenia with monocytosis. Erythrocyte sedimentation rate was also elevated. Other basic biochemical tests were within normal limits, except for mild transaminitis.

At this moment, either occult tuberculosis or autoimmune diseases were suspected based on the history, clinical and laboratory findings. However, blood cultures were taken, and broad-spectrum antibiotics were started. CECT chest and CECT abdomen were not suggestive of occult TB infection. Autoimmune workup was negative. As a part of workup for fever of longer duration, Brucella agglutination test and scrub IgM serology were sent. Brucella agglutination test turned out to be positive. Simultaneously, blood culture grew *Brucella melitensis* in all 2 samples.

Based on his serological test and blood cultures, a diagnosis of brucellosis was made. He was eventually prescribed Rifampicin once daily and Doxycycline BD for 6 consecutive weeks.

DISCUSSION

In this case, the patient did not have any history of living in close association with animals or consumption of unpasteurized milk. He also did not have any occupational risk of exposure to brucella. Nevertheless, human brucellosis is quite rare in South India, making the suspicion level among clinicians to be quiet low.

There was a long interval between onset of symptoms and diagnosis in our patient. A lot of health care practitioners do not consider the possibility of brucellosis, especially in patients with prolonged fever. Delay or misdiagnosis can lead to treatment failure, relapses, focal complications and high case fatality rate.[9]

This patient showed many of the symptoms of brucellosis which included undulating fever, myalgia and other clinical features such as hepatomegaly and splenomegaly.[10]

Infective endocarditis is a rare devastating complication from systemic brucellosis and could require surgical intervention. Splenic, hepatic or pulmonary abscess can also develop. Other rare complications include deep vein thrombosis, arthritis, spondylitis, meningitis and nephritis. Ocular manifestations include optic neuritis and uveitis.[11] Common hematological manifestations include leucopenia, anemia and thrombocytopenia.[12]

The standard treatment for human brucellosis is doxycycline, 100mg BD and rifampicin 600-900mg once a day for 6 consecutive weeks. A combination of doxycycline and gentamycin is also preferred. However, the standard treatment varies depending on the patients' age, pregnancy status, CNS involvement and cardiovascular involvement.[13] For children less than 8 years of age, a combination of TMP-SMX and aminoglycoside or a combination of rifampicin and TMP-SMX for 45 days is needed.[14,15]

CONCLUSION

Diagnosis of brucellosis is generally not considered in a non-endemic country. Health care practitioners should be aware of this possibility of this zoonotic infection as a differential diagnosis in patients with nonspecific symptoms and unexplained prolonged fever.

ABSTRACT

Eosinophilic gastroenteritis is a rare disease that is characterized by Eosinophil infiltration in one or multiple segments of the gastrointestinal tract. The etiology of this condition remains unknown. Eosinophilic gastroenteritis has heterogeneous clinical manifestations that depend upon the location and depth of infiltration in the gastrointestinal tract, and eosinophilia may or may not be present. This article reports a case of Eosinophilic Gastroenteritis in a 57 years old retroviral male patient, who presented with chronic diarrhea, bilateral pedal edema and eosinophilia. Ultimately, the diagnosis of eosinophilic gastroenteritis was clinched. The rare character of eosinophilic gastroenteritis and its varied clinical presentations often lead to delayed diagnosis and complications. Case reports may help to disseminate knowledge about the disease, thereby increasing the likelihood of early diagnosis and intervention to prevent complications.

Keywords: Chronic diarrhea, Eosinophilic gastroenteritis

INTRODUCTION

Eosinophilic gastroenteritis (EG) is classified in a group of diseases known as eosinophilic gastrointestinal disorders (EGIDs). The primary EGIDs are defined as diseases that selectively affect the gastrointestinal tract with the presence of inflammatory infiltrate that is rich in eosinophils in the absence of other causes of eosinophilia, such as drug reactions, parasitic infections, or malignancies. This group of diseases, the incidence of which has increased over the last few decades, includes eosinophilic esophagitis, eosinophilic gastritis, eosinophilic enteritis, eosinophilic colitis, and EG.[1] All of these conditions exhibit significant infiltration of eosinophils in the gastrointestinal tract and a very strong association with allergies.[2] In 1970, Klein classified the disease according to the predominance of eosinophilic infiltration in different layers of the intestinal wall, namely, the mucosal, muscle, and sub serosal layers.[3]

The involvement of different layers usually gives rise to different clinical manifestations. Mucosal disease generally presents with bleeding, protein-losing enteropathy, or malabsorption. Involvement of the muscle layer may cause bowel wall thickening and subsequent intestinal obstruction. The sub serosal form usually presents with eosinophilic ascites. The diagnosis for EGIDs is established after ruling out other causes of an eosinophilic disease, particularly atopy, parasitic infestations, vasculitis, and hyper eosinophilic syndrome (HES). Authors report a typical case of widespread EG with associated involvement of colonic mucosa in which symptoms dramatically responded to a course of steroids, as evidenced by careful follow up.

CASE REPORT

57 years old male, diagnosed with HIV 1 infection 2 months back, started on anti-retroviral drugs (Tenofovir,

Lamivudine, Efavirenz) presented with complaints of loose stools (3-4 episodes/day) for 2 months and B/L swelling of legs for 4 days. He also had history of loss of weight and appetite. He had no history of atopy/ food or drug allergies. He was treated with nitazoxanide but without any improvement. His CD_4 count was 751 cells and HIV viral load was 880IU/L. HBsAg, anti HCV and TPHA were negative.

On examination he was thin built and had pitting pedal edema. Systemic examination revealed no abnormalities. Investigations showed anaemia (Hb-9.8 g%) and eosinophilia (67.1%) (Absolute eosinophil count 8,700 cells/cu.mm). Liver function test showed hypoproteinemia, elevated alkaline phosphatase and GGT levels. serum LDH, uric acid were within normal limits. Since he was an immunosuppressed host, opportunistic infections were first considered. Stool examination with modified ZN stain for microsporidium, isospora and cryptosporidium were negative.

Stool examination for other ova and parasites were also negative. Radio allegro sorbent test (RAST) for a battery of allergens including common foods were negative. As he had granulomatous hepatitis picture, CECT abdomen was done to look for intraabdominal lymphadenopathy which showed transmural thickening in caecum, ascending colon and proximal transverse colon, with few enlarged mesenteric lymph nodes. Upper GIscopy and deep duodenal biopsies were normal. Colonoscopy showed ileal nodularity, biopsies were taken from multiple sites of colon.

As a part of workup for granulomatous hepatitis, liver biopsy was done. Histopathological examination of liver biopsy showed lobular inflammation with many eosinophils, heavy inflammatory infiltrate including many eosinophils. Ileal biopsy also demonstrated tissue eosinophilia. He was started on T. prednisolone 60 mg (1mg/kg/day). Complete remission of the diarrhea occurred in about one week. One month later, the patient's bowel habits were normal, and he had gained 4 kg.

DISCUSSION

Eosinophilic gastroenteritis can involve any part of gastrointestinal tract from the esophagus down to the rectum. The stomach and duodenum are the most common sites of involvement.[4-7] Four criteria are required for the diagnosis of EG: the presence of gastrointestinal symptoms, eosinophilic infiltration of the gastrointestinal tract, exclusion of parasitic disease or other identifiable cause of eosinophilia and the absence of other systemic involvement.[8-10]

Eosinophils are normal constituents of the mucosa of the gastrointestinal tract; however, the number of eosinophils that can be defined as normal in a biopsy specimen has not been clearly defined.[10] Peripheral eosinophilia is not necessary to make a diagnosis, but it is present in approximately two-thirds of patients and is more prevalent in the serosal than in the mucosal and muscular disease forms.[11,12] The presence of peripheral eosinophilia, abundant eosinophils in the gastrointestinal tract, and a dramatic response to corticosteroid provide some support that the disease is mediated by a hypersensitivity-type reaction. Moreover, a study at Mayo Clinic showed that 50% of patients with EG give a history of allergy such as asthma, allergic rhinitis, urticaria, drug allergy, and eczema.[13]

It must be emphasized that in the mucosal form of the disease, multiple biopsies must be taken during endoscopy, because mucosal involvement is often patchy in nature. Treatment with a steroid is the mainstay in the management of EG. Dramatic clinical improvement is seen after treatment with a low dose of steroid. The duration of treatment is controversial, however. This patient was started with prednisolone 60 mg daily, then tapered over (a period of 6 weeks) and responded favourably.

Due to the positive retroviral status in present patient, authors at first, ruled out opportunistic infections. Not many cases of EG in immunosuppressed patients are reported in literature. Bacterial infections (*Helicobacter pylori*, etc) and parasitic infestations (Ascaridosis, Anisakiasis, Enterobiasis, Anchylostomiasis, Trichina, Teniasis, etc) are a well-known cause of EG, but in present patient neither bacteria in gastric biopsies or stool culture nor ova and parasites were found in the stools.[14-16]

Hypereosinophilic syndrome (HES) may be associated with gastroenteritis but was ruled out because it is an idiopathic condition characterized by marked peripheral eosinophilia exceeding 1500 cells/ml for six consecutive months and its major targets are the heart, lung, brain and kidneys, with>55% of patients presenting with a complication in≥ 1 of these sites.[17] Celiac disease was excluded since deep duodenal biopsy showed normal histologic pattern. In present case, no positive food allergen could be demonstrated, and the colonic involvement makes it similar to the pure form of EG, in which a positive RAST test is rarely found.[3]

CONCLUSION

Eosinophilic gastroenteritis is an uncommon disease with signs and symptoms similar to many other diseases. It is quite rare in immunosuppressed patients, which is why it is often not considered in the differential diagnosis. Histology is essential for the diagnosis of EG and should be considered. Making the correct diagnosis early may result in effective treatment, thereby achieving quicker remission.

Association of N-terminal-Pro-B-type Natriuretic Peptide with Localization of Thrombus and Clinical Outcome in Acute Pulmonary Embolism

Santni Manickam[1], Yoganathan Chidambaram[2], Jayachandran Kuppusamy[3], Clement Jenil Dhas[4], Sujith Kumar[5]

ABSTRACT

Introduction: Pulmonary Embolism is a major health problem which is associated with significant mortality and morbidity. It is a common and lethal condition. This study was undertaken to find the association between NT-Pro-BNP levels and the localisation of thrombus in acute Pulmonary Embolism and to prognosticate the patients.

Material and methods: Prospective study conducted at a tertiary care hospital.Thirty patients with Pulmonary Embolism of various etiologies, confirmed with clinical features, laboratory investigations and imaging and fulfilling the inclusion and exclusion criteria were included. After getting informed consent, Blood samples for assessment of NT-Pro-BNP levels were collected within 24 hours of admission.

Results: In 19 patients, the thrombus was located centrally (in main pulmonary artery) whereas in 11 patients, the thrombus was located in the peripherally (in segmental and subsegmental pulmonary arteries). 22 participants of the study had normal clinical outcome. 5 patients were morbid (oxygen dependant/ heart failure) whereas 3 patients died. Patients with central pulmonary embolus had higher NT-Pro-BNP levels whereas patients with pulmonary embolus in the segmental or subsegmental pulmonary arteries had relatively less NTPro-BNP levels. Patients with high NT-Pro-BNP levels had complicated in-hospital course/ mortality whereas, patients with relatively lower NT-Pro-BNP had uncomplicated in-hospital course.

Conclusion: This study shows that higher NT-Pro-BNP levels indicate higher probability of a more central location of thrombus in pulmonary embolism and also right ventricular overload. Also patients with higher NT-Pro-BNP levels had a complicated in hospital course.

Key words: Pulmonary Embolism, Pulmonary Arteries, Right Heart Failure, NT Pro-BNP

INTRODUCTION

Pulmonary Embolism (PE) is a major health problem which is associated with significant mortality and morbidity. It is a common and lethal condition. Pulmonary Thrombo Embolism (PTE) and deep vein thrombosis (DVT) collectively known as venous thromboembolism (VTE) encompass one disease entity. Among cardiovascular diseases, VTE along with stroke and myocardial infarction rank as three big cardiovascular killers. PTE implies partial or complete occlusion of pulmonary arterial circulation by the clot formed elsewhere usually in deep veins of the leg. Less than 5% of venous thrombosis occurs in other sites. The incidence of PE in non-hospitalised patients is 3.5 per 10,000 person years while the incidence rate in hospitalised in-patients can be above 500 per 10,000 person years.[1] In India, VTE is a common cause of mortality and morbidity in patients hospitalized for medical or surgical illnesses. It is often misdiagnosed and not intervened in time. Though the exact magnitude of problem is not known in India, the clinical relevance and incidence is not expected to be different from Western countries. Acute PE has high early mortality rates. Despite the advances in diagnosis and treatment, the early mortality rates have not changed significantly. Due to the embolus obstructing the pulmonary bed, PE can result in a life threatening condition, acute right ventricular (RV) failure.[2] Early diagnosis is of paramount importance since most patients die within the first hours of presentation. Timely management is usually highly effective in reversing RV failure. The diagnosis of acute PE is based on the assessment of clinical likelihood, ECG, CXR, echocardiography, laboratory investigations, mainly D-dimer and cardiac biomarkers and imaging techniques (CT pulmonary angiogram). Several cardiac biomarkers have emerged as indicator of right ventricular dysfunction and clinical outcome predictor in patients with acute PE. Brain type natiuretic peptide (BNP) is a marker of ventricular dysfunction. Following cardiac myocyte stretch, this compound is released into the circulation. It is synthesized as an inactive pro hormone (Pro-BNP) which is split into active hormone BNP and an inactive N-terminal fragment (NT-Pro-BNP).[3] This study was undertaken to find the association between NT-Pro-BNP levels and the localisation

BY-NC-ND

of thrombus in acute PE, to monitor and prognosticate the patients closely.

Primary objectives of the study were to study the association of N-terminal-Pro-B-Type Natriuretic Peptide with localisation of thrombus in Acute Pulmonary Embolism and to study the association between NT-Pro-BNP levels and clinical outcome in patients with Acute Pulmonary Embolism and secondary objectives were to study on the various risk factors in patients diagnosed with acute pulmonary thrombo embolism and to follow up the patients at the end of 1 month to know the clinical outcome.

MATERIAL AND METHODS

Prospective study was conducted at a tertiary care hospital, PSG Hospitals, Coimbatore. Thirty consecutive patients diagnosed to have pulmonary embolism were included in this study with the following criteria.

Inclusion criteria

All patients of age more than 18 years with clinical and radiological evidence of acute PE will be included in the study.

1) Clinical evidence

Patients presenting with dyspnoea, hemoptysis and chest pain with no acute ischemic changes in ECG and with normal Ejection fraction. ECG in acute pulmonary embolism will shows S1Q3T3 pattern.

2) Radiological evidence

CT pulmonary angiogram showing filling defects within the pulmonary vasculature.

Exclusion criteria

Patients with COPD, known case of Congestive cardiac failure and chronic kidney disease are excluded from this study.

After getting informed consent, Blood samples for assessment of NT-Pro-BNP levels were collected within 24 hours of admission. Risk factors for pulmonary thrombo embolism were noted such as prolonged bed rest, hypertension, malignancy etc. Thrombi located in main/ right/left pulmonary artery were classified as central while the others at segmental/sub-segmental levels were classified as peripheral. Echocardiographic findings such as ejection fraction, functions of right and left ventricle, pulmonary artery pressure were noted. Clinical course of the patient and clinical outcome were also noted. Clinical outcome of the patient at the end of one month was recorded by following up. Then descriptive and statistical analysis of location of thrombus and clinical outcome in relation with NT-Pro-BNP levels was done.

Risk factors	Frequency (n)	Percent (%)
Prolonged immobilization	13	43.3
Carcinoma	4	13.3
Unprovoked	13	43.3
Total	30	100.0

Table-1: Risk factors of the study participants

Clinical Outcome	Frequency (n)	Percent (%)
Normal	22	73.3
Morbid	5	16.7
Death	3	10.0
Total	30	100.0

Table-2: Clinical Outcome after 30 Days

STATISTICAL ANALYSIS

The data collected from the patients was tabulated using Microsoft excel. The data are reported as mean +/- SD depending on their distribution. Risk factors will be described in numbers and percentage. Any association will be analysed using chi-square test. Correlation will be analysed by Pearsman correlation. A p value of <0.05 using two tailed test was taken as being significant for all statistical tests. All data were analysed with statistical software package (SPSS version 24.0)

RESULTS

In our study, we included 30 patients diagnosed with acute pulmonary thromboembolism. The mean age of study population is 57.6 years. 11 patients belonged to the group of 51 to 60 years. Only 2 patients were younger adults and 2 patients were old adults. Among the study group 17 patients were male (56.7%) and 13 patients were female (43.3%).In our study population following were the risk factors noted. Thirteen patients had prolonged immobilisation following road traffic accident or following major orthopaedic surgeries. 4 patients had underlying malignancy such as Ca lung or Ca breast. 13 patients had unprovoked PTE.(Table 1) The thrombus was located unilaterally in 19 patients whereas 11 patients have bilateral thrombus. In 19 patients, the thrombus was located centrally (that is, in main pulmonary artery) whereas in 11 patients, the thrombus is located in the peripherally (segmental and sub segmental pulmonary arteries).22 participants of the study had normal clinical outcome. 5 patients were morbid (oxygen dependant/ heart failure) whereas 3 patients died.(Table 2)

Patients with central pulmonary embolus have higher NT-Pro-BNP levels whereas patients with pulmonary embolus in the segmental or subsegmental pulmonary arteries have relatively less NT-Pro-BNP levels. And the difference between the two was statistically significant. (P= 0.02)(Table 3)

Patients with high NT-Pro-BNP levels had complicated in-hospital course/mortality whereas, patients with relatively

	Localisation	N	Mean	Std. Deviation	P value
PROBNP	Central	19	6196.27	4377.75	.02*
	Peripheral	11	1529.10	2636.40	

Table-3: Association of PROBNP with localization

	Clinical Outcome	N	Mean	Std. Deviation	P value
PROBNP	Normal	22	3814.15	3860.52	.005*
	Morbid	5	3009.16	4033.77	
	Death	3	11864.00	1417.83	

Table-4: Association of PROBNP with Clinical Outcome

lower NT-Pro-BNP had uncomplicated in-hospital course. (P = 0.005)(Table 4)

DISCUSSION

Acute PE shows wide variations in clinical presentation from asymptomatic course to a massive pulmonary embolism that may be fatal. When planning treatment for this condition, risk stratification is important. In this study 30 patients diagnosed with pulmonary embolism were included. The mean age of study population is 57.6 years.17 patients were male(56.7%) and 13 patients were female (43.3%). The thrombus was located unilaterally in 19 patients whereas 11 patients had bilateral thrombus. In 19 patients, the thrombus was located centrally (main pulmonary artery) whereas in 11 patients the thrombus was located in the peripheral pulmonary artery (segmental and subsegmental pulmonary arteries). 22 participants of the study had normal clinical outcome. 5 patients were morbid (oxygen dependant/ heart failure) whereas 3 patients died. Patients with central pulmonary embolus have higher NT-Pro-BNP levels whereas patients with pulmonary embolus in the segmental or subsegmental pulmonary arteries have relatively less NTPro-BNP levels. And the difference between the two is statistically significant. (P= 0.02).

Patients with high NT-Pro-BNP levels had complicated in-hospital course/ mortality whereas, patients with relatively lower NT-Pro-BNP had uncomplicated in hospital course. (P = 0.005).From this study, it is evident that patients with higher NT-Pro-BNP levels have more central thrombus, have complicated in-hospital course and also cause morbidity and mortality. Whereas patients with comparatively lower NT-Pro-BNP levels have thrombus in segmental or subsegmental pulmonary arteries and they have an uncomplicated course.

The findings of our study were consistent with many other similar studies.

In a prospective study conducted by Akpinar et.al in turkey in Forty-nine patients concluded that higher pro bnp levels indicate higher probability of a more central location of thrombus in pulmonary embolism, resulting a more adverse clinical course and also leading to right ventricular overload..

In a prospective study done by Pruszcyk et.al in Poland in 79 patients found NT-Pro-BNP to be a prognostic marker in acute pulmonary embolism.[5]

An Egyptian prospective study by A.Selem et al conducted in 64 patients concluded elevated NT pro-BNP in PE was associated with worse short term prognosis in terms of higher morbidity and mortality.[6] Another study, Heleder Dores et al a retrospective study also had similar results as that of our study which concluded that elevated NT pro-BNP in PE identified worse short term prognosis and also had excellent power to predict 30 day all cause mortality.[7]

In a meta analysis conducted by Frederikus et.al, in the Netherlands, they found that higher concentrations of NT-Pro-BNP distinguish patients with pulmonary embolism at higher risk of complicated in-hospital course and death from those with low NT-Pro-BNP levels.[8] In another meta analysis conducted by Cavallazzi et.al in USA, they found that NT-Pro-BNP levels are significant predictors of all cause in hospital or short term mortality.[9] A meta analysis by Guillaume Coutance et al concluded while elevated BNP levels can help to identify high risk of death and adverse outcome, the high negative predictive value of normal BNP levels is certainly more useful.[10]

From our study it is evident that NT-Pro-BNP levels are significant predictor of all cause in- hospital mortality in patients with acute PE. The potential outcome of our study is that patients with normal levels of NT-Pro-BNP have a high negative predictive value for unfavourable outcome. Patients with normal NT-Pro-BNP levels have low risk of death as well as for hemodynamic collapse.This was consistant with a study conducted by Nils Kucher in 73 patients which predicted that lower the pro-BNP levels, lower would be the hospital stay.[11]

Our study have a few limitations. First, the sample size is limited. Further studies including larger number of patients are necessary to clarify this point. Secondly, NT-pro-BNP is a precursor of BNP. The conversion of BNP to NT-Pro-BNP may take several minutes after myocardial stretch which may lead to false negative results in patients who present early. Serial monitoring of NT-Pro-BNP (eg. At admission and 6 hours later) may overcome this limitation.

CONCLUSION

This study shows that higher NT-Pro-BNP levels indicate higher probability of a more central location of thrombus in pulmonary embolism and also leading to right ventricular overload.Also patients with higher NT-Pro-BNP levels had a complicated in-hospital course.Further studies with large number of patients were undertaken to determine the exact cut off levels of NT-Pro-BNP to help in treatment decisions.

ABSTRACT

Background: The causes of megaloblastic anemia may vary in different geographical regions. The aim of the present study is to evaluate the utilization of bone marrow examination and upper gastrointestinal endoscopy (UGIE) in megaloblastic anemia.
Methods: This was a cross-sectional descriptive study done on 50 patients (age ≥15years) of macrocytic anemia after applying inclusion and exclusion criteria. A bone marrow aspiration with biopsy and an UGIE with duodenal biopsy were performed in consented patients with evidence of megaloblastic anemia in the peripheral smear or Vitamin B12 deficiency or folate deficiency or both.
Results: Out of 50 cases, 38 patients had pure Vitamin B12 deficiency, 2 patients had pure folate deficiency and 5 patients had combined deficiency. Among 43 patients with vitamin B12 deficiency, only four (9.3%) were vegetarians and remaining 39 (90.7%) were having non-vegetarian diet. Bone marrow study was done in 29 patients (out of 50) and all of them were found to have megaloblastic erythropoiesis in the bone marrow. Thirty three out of 50 consented for UGIE and duodenal biopsy. Out of 33, 17 patients (51.5%) had features of tropical sprue in biopsy.
Conclusions: We found a high prevalence of tropical sprue in megaloblastic anemia due to Vitamin B12 and/or folate deficiency. We recommend that UGIE with deep duodenal biopsy should be considered in all patients with megaloblastic anemia to rule out tropical sprue in India.

Keywords: Bone marrow study, Duodenal biopsy, Megaloblastic anemia, Tropical sprue, Upper gastrointestinal endoscopy

INTRODUCTION

Megaloblastic anemia is characterized by macrocytic anemia and abnormally large erythrocyte precursor cells (megaloblasts) in the bone marrow. Disorders that affect the synthesis of DNA in the precursors of erythrocytes in the bone marrow lead to megaloblastic anemia. Vitamin B12 and folate deficiencies are the most common causes of megaloblastic anemia.

The causes of megaloblastic anemia may vary in different geographical areas. Pernicious anemia is a major cause of megaloblastic anemia in western countries, but nutritional deficiencies and malabsorption could be the leading cause of megaloblastic anemia in India.[1] Studies have shown that vitamin B12 deficiency is more common in vegetarians.[2,3]

The main cause of folate deficiency is less intake of green leafy vegetables and legumes. There have been hardly any studies on the role of bone marrow and upper gastrointestinal endoscopy (UGIE) in the evaluation of megaloblastic anemia. The objective of the present study is to evaluate the utilization of bone marrow examination and UGIE in megaloblastic anemia.

METHODS

This was a cross-sectional descriptive study carried over a period of 12 months from July 2013 to June 2014 on 50 patients (age ≥15years) of macrocytic anemia treated in a tertiary care hospital of South India. Macrocytic anemia was identified when:

- A mean red blood corpuscular volume >95 fL
- Anemia with hemoglobin of
  a) <13 g/dL in male
  b) <12 g/dL in female.

Inclusion criteria

Patients above the age of 15 years with macrocytic anemia.

Exclusion criteria

Patients with liver disease, chronic kidney disease, hypothyroidism, hemolytic anemia, hemorrhagic disease, post splenectomy and pregnant patients.

The history was taken in detail; a complete and thorough physical examination was carried out in all patients. Detailed information was sought on alcohol consumption, drug intake, thyroid disorder and other comorbid illness. All patients were investigated with a hemogram that included estimation of hemoglobin level, red cell indices (MCV, MCH and MCHC), red cell distribution width, total leucocyte count, differential leucocyte count, platelet count, reticulocyte count, and peripheral smear examination.

All patients were subjected to fasting serum Vitamin B12, fasting serum folic acid, serum TSH, creatinine, liver function test and lactate dehydrogenase. A bone marrow aspiration with biopsy and an UGIE with deep duodenal biopsy were performed in patients with evidence of megaloblastic anemia in the peripheral smear or Vitamin B12 deficiency or folate deficiency or both, who gave consent for the same.

Statistical analysis

The data were analyzed using Microsoft Excel 2010 and Statistical Package for Social Science (SPSS) Version 19.0. Continuous variables were expressed as mean/SD and categorical variables were expressed as percentage. Independent student T test and Anova tests were used as described below. A predictive value of less than 0.05 was taken as statistically significant.

RESULTS

In current study population of fifty patients presenting with macrocytic anemia, 34 were male comprising about 68% and 16 were female comprising about 32%. The mean age of male and female were 53.15±15.89 and 54.37±16.58 respectively. Majority of the population belong to the age group above 40 years, both in males and females. Six patients in this study group were vegetarians. Five patients gave history of consuming alcohol. Three patients gave history of drug exposure and were on phenytoin/ sodium valproate.

The major symptom at presentation was fatigability (58%, n=29), 16% (n=8) presented with chronic diarrhea and 26% (n=13) with other symptoms like short pyrexia etc. No patient had bleeding tendencies or features of nervous system involvement.

On clinical examination, pallor was noticed in all patients in various degrees from mild to severe. Icterus was seen in 10 patients, hyperpigmentation of the knuckles in 7 patients. Organomegaly was noticed in 2 patients, among them one had hepato-splenomegaly and one had splenomegaly.

Out of 50 cases, 38 patients had low Vitamin B12, 5 patients had low levels of both folate and Vitamin B12 and 2 patients had low folate level alone. Vitamin B12 and folate levels were normal in the remaining five patients (Table1). Among 43 patients with Vitamin B12 deficiency, only four (9.3%) were vegetarians and remaining 39 (90.7%) were having non- vegetarian diet.

Table 1: Vitamin B12 and folate status in the study group.

Vitamin status	n=50	Percentage (%)
Pure vitamin B12 deficiency	38	76
Pure folate deficiency	2	4
Combined deficiency	5	10
Both normal	5	10

Table 2 shows hematological parameters of our patients. Out of 50 patients, 24 patients presented with anemia alone, 6 patients with bicytopenia (low hemoglobin and low platelets) and the remaining 20 patients with pancytopenia.

Table 2: Hematological parameters.

Hematological parameter	Mean ± SD
Hemoglobin (g%)	7.1 ± 2.5
MCV (fL)	115.1 ± 10.3
Red cell distribution width	22.71 ± 6.2
Total WBC count	4775 ± 2643
Platelet count	123686 ± 100097

Table 3: Comparison of severity of anemia with macrocytosis.

Hemoglobin (g%)	MCV(fL) Mean ± SD	n =50	P value
< 6	113.56 ± 7.83	18	>0.05
> 6	115.96 ± 11.39	32	

Study found no statistical significance (p=0.4) between the severity of anemia and the degree of macrocytosis, when the values of MCV were compared with the degree of anemia using independent student T test (Table 3). There was no statistical significance (p=>0.5) between the mean of MCV and levels of serum Vitamin B12 using Anova test (Table 4).

Table 4: Comparison of serum Vitamin B12 level and MCV.

Vitamin B12 level (pg/mL)	n=50	MCV (fL) Mean ± SD	P value
< 100	n = 28	116.69±10.89	>0.05
101-190	n = 15	112.20±6.83	
> 190	n = 7	114.92±12.50	

Out of 24 patients with anemia, 21 had low serum Vitamin B12 and 16 of 20 patients with pancytopenia had low serum Vitamin B12. All 6 patients with bicytopenia had low serum Vitamin B12. When the various levels of low serum Vitamin B12 were compared with presentation of patient with anemia, bicytopenia or pancytopenia using Anova test there was no significance (p=>0.5) (Table 5).

Table 5: Comparison of serum Vitamin B12 level and hematological presentation.

Presentation	n=50	Vitamin B-12 level (pg/mL) Mean ± SD	P value
Pancytopenia	20	64.37±31.41	>0.05
Bicytopenia	6	76.83±33.36	
Anemia	24	98.24±44.88	

The peripheral smear examination showed neutrophilic hyper segmentation and / or macro-ovalocytosis in 25 patients suggesting megaloblastic erythropoiesis. These patients and another four (Vitamin B12/folate/or both deficient) who gave consent were subjected to a bone marrow examination. Among 50 patients, bone marrow examination was done in 29 and all of them were found to have megaloblastic erythropoiesis in the bone marrow.

Thirty three out of 50 consented for UGIE and deep duodenal biopsy. Twenty-six of them showed duodenal finding of either scalloped duodenal folds or folded duodenal margins. Others showed features of erosive gastritis, atrophic gastritis or antral gastritis. One had external gastric impression and the other had gastric polyp (Table 6).

Among twenty-six patients who had abnormal duodenal features in endoscopy, fifteen showed features suggestive of tropical sprue in duodenal biopsy (Table 6). Two patients who had normal duodenal findings also had features of tropical sprue in biopsy. Hence 17 patients out of 33 (51.5%), who gave consent for endoscopy and biopsy had tropical sprue. Among 17 patients with tropical sprue, 15 had low Vitamin B12 level, one had both low vitamin B12 and folate levels and one had both normal.

Table 6: Upper gastrointestinal endoscopy and duodenal biopsy findings.

Endoscopy findings	n =33
Scalloped duodenal folds / flattened duodenal margins	26
Erosive gastritis	2
Atrophic gastritis	2
Antral gastritis	1
Others	2

Non-specific	3
Brunner's gland hyperplasia	3
Peptic duodenitis	1
No specific pathology	7

DISCUSSION

Megaloblastic anemia has variable etiological factors. In current study population 76% had Vitamin B12 deficiency, 10% had deficiency of both Vitamin B12 and folate and 4% had pure folate deficiency. Our findings were consistent with a study by Khanduri and Sharma, who have reported Vitamin B12 deficiency to be 65% in 120 patients of megaloblastic anemia, combined Vitamin B12 and folate deficiency in 12% and folate deficiency in 6% .[4] A similar high prevalence of Vitamin B12 deficiency was reported by Sarode et al, in 102 cases (76%) of nutritional megaloblastic anaemia.[5] In contrast to this finding, Haq et al, found that folic acid deficiency was the commonest cause (62.5%) of megaloblastic anemia in her patients.[6]

The predominant symptoms in this study were fatigability (58%) and chronic diarrhea (16%). No patient presented with bleeding manifestation or had neurological symptoms. Unnikrishnan et al, found 91.7% of their patients presenting with fatigability, but in contrast to present study, 36.7% had bleeding manifestation and 10% presented with neurological symptoms.[7] In another study by Haq et al, in a population of 80 patients, 84% had fatigability and 27.5% had bleeding tendency.[6] Bleeding manifestations in thrombocytopenia due to Vitamin B12 or folate deficiency are typically mild and this may be the reason why no patient presented with bleeding tendency in the study.

In the present study, clinical examination revealed pallor in 100%, icterus in 20%, skin hyperpigmentation in 14% and organomegaly in 4%. Haq et al, found pallor in 84% and splenomegaly in 48%.[6] In a study by Unnikrishnan et al, 35% had jaundice, 31.7% had splenomegaly, 28.3% had hepatomegaly and 23.3% had skin changes.[7] Thus

when compared to the above studies we found lesser percentage of patients with organomegaly and skin changes.

Among 43 patients with Vitamin B12 deficiency, only four (9.3%) were vegetarians and remaining 39 (90.7%) were having non-vegetarian diet. 39 out of 44 (88.6%) non-vegetarians had Vitamin B12 deficiency in present study group. In concordance with present study, Unnikrishnan et al, and Iqbal et al, also reported a higher proportion of non-vegetarians having megaloblastic anemia and Vitamin B12 deficiency.[7,8] In contrast to our finding, Liggy et al and Kankonkar et al, showed Vitamin B12 deficiency higher in vegetarians than non-vegetarian. But the study cohort was different, Liggy et al, included all the patients and not only anemic patients, Kankonkar studied B12 deficiency in different diseases.[9,10] In current study 40% of patients had pancytopenia. Other studies have also found that megaloblastic anemia can present with pancytopenia.[5,11]

Bone marrow study was done in 29 out of 50 patients by us. All patients had megaloblastic erythropoiesis in the bone marrow. Khanduri and Sharma have suggested that bone marrow study should be done in selected patients when myelodysplasia is a differential diagnosis.[4] We also agree with them that bone marrow examination need not be done in all patients initially with megaloblastic anemia or Vitamin B12/folate deficiency, as it did not contribute to identifying a different etiology. In present study population of 50 patients, 33 (66%) underwent endoscopy and biopsy. 17 patients out of 33 (51.5%) had tropical sprue (TS). Among 17 patients with TS, 15 had low Vitamin B12 level, one had both low Vitamin B12 and folate levels and one had both normal.

An interesting observation in this study was that tropical sprue was more prevalent in megaloblastic anemia due to Vitamin B12 and/or folate deficiency. This may be because of endemic nature of TS in India. We found that Vitamin B12 deficiency was more in non-vegetarians and this may be due to underlying TS associated malabsorption.

TS is a malabsorption syndrome of unknown etiology or due to a probable persistent infection. TS cause malabsorption of folic acid and Vitamin B12 leading to megaloblastic anemia. A study done in West India in 1968 has reported that majority of patients with TS have Vitamin B12 deficiency.[12] After extensive literature search, we could not find many studies of endoscopic biopsy in megaloblastic anemia. There are few studies in malabsorption syndrome. Dutta et al. in a south Indian study and Ranjan et al. in a north Indian study found that TS was the commonest cause of malabsorption syndrome.[13,14]

There are a few limitations to current study. The sample size was small and we could not do complete work up for megaloblastic anemia and malabsorption due to cost factor.

CONCLUSION

To conclude, we found a high prevalence of TS in megaloblastic anemia due to Vitamin B12 and/or folate deficiency. We observed in thisstudy that being a non-vegetarian does not protect against Vitamin B12 deficiency, hence we recommend that all patients with megaloblastic anemia (including vegetarians) in India should be subjected to UGIE with deep duodenal biopsy to rule out TS, as the prevalence is high and treatment is different.

Study also found that bone marrow study did not yield added information and hence need not be considered in all patients with megaloblastic anemia or Vitamin B12/folate deficiency at the time of presentation, unless clinically indicated. We need larger and more studies to confirm our finding.

Abstract

Background: Rheumatoid arthritis (RA) and Fibromyalgia (FM) are chronic illnesses with pain as the common component. Hand grip function is limited in both RA and FM patients, the assessment of which might help in important decision making.

Methods and findings: We analyzed the hand grip strength in RA and FM patients with simple inexpensive hand dynamometer and compared it with age and sex matched healthy controls. Our study had 16 RA and 14 FM patients. The mean hand grip force in dominant right hand was 87.8 ± 22.7 kilograms in fibromyalgia while in RA it was 60.3 ± 21.0 kilograms. Non-dominant hand grip was 72.5 ± 25.7 kilograms in fibromyalgia while in RA it was 52.2 ± 29.3 kilograms. On comparison of the hand grip strength between RA and FM patients, we found that RA patients had a significantly lower dominant and non -dominant hand grip strength than FM patients ($p=0.002$ and $p=0.055$ respectively). When compared with age and sex matched healthy controls both dominant and non-dominant hand grip was significantly lower in RA group ($p<0.001$) while non-dominant hand grip strength in FM was significantly lower than controls ($p<0.001$).

Conclusion: Rheumatoid arthritis patients have poor handgrip than Fibromyalgia and both have poor hand grip than age matched controls.

Introduction

Rheumatoid arthritis (RA) is a chronic inflammatory systemic disorder of autoimmune etiology which causes progressive joint inflammation, destruction and limitation of joint function if left untreated. Hand and wrist joint involvement is noticed in 80 to 90% of RA patients [1] leading to hand deformities and limitation of the hand function. The most commonly affected hand joints are the metacarpophalangeal (MCP), proximal interphalangeal (ICP) and wrist joints. Reduced flexion or extension of PCP and MCP joints affect the fine movements of the hand and grasp function [2] causing functional disability which in turn affects the activities of daily living (ADL).

Impairment of hand function in RA is due to multiple factors. Apart from hand pain, deformities and loss of range of joint movements, the decreased muscle strength or fatigue also plays an important role in the limitation of joint function. Most of the patients with RA have reduced handgrip strength and impaired hand function [3-7] which has implications on the overall morbidity and mortality.

The effect of handgrip strength on total locomotion [8] was studied by Jonsson et al. and found it to be highly significant. Also one of the predictors of mortality in RA was reduced handgrip [9] as noted by Pincus et al. All these indicate that it is all the more important to assess the hand function in RA patients and initiate appropriate early treatment strategies to preserve the hand function.

Another rheumatological disease which causes chronic widespread pain, fatigue, limitation of physical activities, functional and emotional impairment is Fibromyalgia syndrome [10-14]. Chronic pain seen in fibromyalgia is non-inflammatory.

Alteration in the central processing of pain input and defect in endogenous inhibition of pain is responsible for the chronic widespread pain and increased pain sensitivity [15]. Difficulty in performing the daily routine tasks such as walking, reaching for high shelves, lifting objects and washing own hair is due to decrease in the muscle strength and flexibility. Numerous studies have shown reduced handgrip in patients with FM [16-20].

In fact RA and FM are two commonly encountered rheumatological diseases which can cause limitation of hand

function. Both can co-exist in the same patient and can have masking clinical features. In view of increased pain sensitivity seen in FM patients, they might exhibit tenderness on palpation which can be mistaken for hand involvement in RA. This necessitates the objective measurement of hand function by using a valid tool to assess the hand function.

Assessment of handgrip by dynamometer is a well-established measure to assess the hand function in both the diseases [16,21]. With this background, we intended to assess the handgrip strength in RA and FM patients and to compare it with the healthy subjects to find out the degree of impairment of hand strength in both the study groups.

Aim

The aim of the study is to assess the handgrip strength in RA and FM patients and to compare it with the age and sex matched controls.

Patients and Methods

The study included a total of 30 study subjects, out of which 16 had Rheumatoid arthritis diagnosed as per 2010 ACR classification criteria; 14 had Fibromyalgia diagnosed according to ACR revised diagnostic criteria 2016.

A group of 30 age and sex matched controls were chosen in the study. Subjects more than 17 years were included in the study. Patients with hand deformities or anomalies, blindness, neurological or muscular diseases which affect the performance of the test were excluded from the study.

Methodology

This is a cross sectional observational study conducted in patients attending Rheumatology OP during June 2013-March 2014 in a tertiary care center in Coimbatore, South India. The study design was approved by the Ethics committee and informed consent obtained from all the participants. The handgrip strength of the dominant and non–dominant hand was assessed in both the study and control groups by the same examiner to avoid the inter-observer error.

The hand grip power assessment was done by using a country made handheld plastic dynamometer with the readings from 0 to 110 kilograms. This hand held dynamometer has the advantage of easy availability and reduced cost. The assessment was done with the subjects seated in a chair, shoulders adducted and neutrally rotated, elbows flexed at 90 degrees, forearm in neutral position; wrist between 0 to 30 degrees dorsiflexion and 0 to 15 degrees ulnar deviation. After an initial demonstration of the test, the subjects were asked to squeeze the instrument gradually and continuously for a period of at least two seconds; two recordings were taken in each hand and the mean score was calculated.

Statistical Analysis

Descriptive statistics were reported using mean and SD, median with 25^{th}, 75^{th} percentiles. Handgrip strength of right and left sides were compared between FM and RA group using independent t test. Handgrip strength between FM, RA and control group was compared using ANOVA. Bonferroni correction test was done for multiple comparisons. Paired t test was used to compare the right and left side handgrip strength in each group separately. p value less than 5% was considered as statistically significant.

Results

Among 30 patients, 16 had RA with a mean age of 53.19 ± 6.12 years; 14 had FM with a mean age of 45.36 ± 13.48 years.

The mean age of the control group was 48.03 ± 11.07 years. There were 13 females each in the RA and FM groups; while there were 3 males in RA and 1 male in FM group. There were 4 male and 26 females in the control group.

The results of mean, median with 25^{th} and 75^{th} percentiles of hand grip in RA, FM and control groups were listed in **Table 1**. The mean hand grip in dominant hand was 87.8 ± 22.7 kilograms in fibromyalgia while in RA it was 60.3 ± 21.0 kilograms. Non-dominant hand grip was 72.5 ± 25.7 kilograms in fibromyalgia while in RA it was 52.2 ± 29.3 kilograms. In healthy controls the grip strength was 89.4 ± 11.7 in dominant hand and 81.2 ± 14.1 kilograms in non-dominant hand.

On comparison of the hand grip strength between RA and FM patients **(Table 1)**, we found that RA patients had a significantly lower hand grip in both dominant and non-dominant hands than FM patients (p=0.002 and p=0.055 respectively).

Table 1: Comparison of hand grip in rheumatoid arthritis (RA) and fibromyalgia (FM) patients.

Variables		FM	RA	P-value
Dominant Hand	Mean	87.8 ± 22.7	60.3 ± 21.0	0.002*
	Median with 25^{th} and 75^{th} percentiles	90 (70, 110)	70 (40, 77)	
Non-dominant Hand	Mean	72.5 ± 25.7	52.2 ± 29.2	0.055*
	Median with 25^{th} and 75^{th} percentiles	70 (53.7, 92.5)	45 (31, 70)	

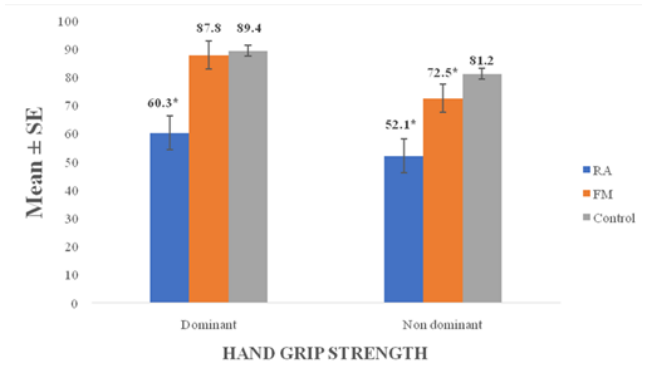

Figure 1: Graphical comparison.

When compared with healthy age and gender matched controls **(Figure 1)**, results showed that RA group had significantly lower dominant hand grip than FM and healthy controls ($p<0.001$). While comparing the non-dominant handgrip strength, it was observed that both FM and RA groups had significantly lower strength as compared to health control groups **(Table 2)**.

Within group comparison of dominant and non-dominant hand grip, results showed that in FM group, hand grip strength was significantly higher in dominant hand ($p=0.003$) but there was no significant difference in RA group **(Table 3)**.

Table 2: Comparison of hand grip in rheumatoid arthritis (RA), fibromyalgia (FM) and healthy controls.

Variables		FM	RA	Control	P-value
Dominant Hand	Mean	87.8 ± 22.6	60.3 ± 21.0*	89.4 ± 11.7	<0.001
	Median with 25th and 75th percentiles	90 (70, 110)	70 (40, 78)	85 (80, 100)	
Non-dominant Hand	Mean	72.50 ± 25.70*	52.1 ± 29.2*	81.2 ± 14.1	<0.001
	Median with 25th and 75th percentiles	70 (54, 93)	45 (31, 70)	80 (70, 90)	
*Significantly lower than control group.					

Table 3: Comparison of dominant and non-dominant handgrip in rheumatoid arthritis (RA) and fibromyalgia (FM) patients.

Variables	Dominant Hand	Non-dominant Hand	P-value
FM	87.8 ± 22.6	72.5 ± 25.7	0.003*
RA	60. 3 ± 21.0	52.1 ± 29.2	0.403

Discussion

While there are various studies on RA and FM separately which had compared the hand grip strength with that of healthy controls, the literature is sparse regarding head-on comparison of handgrip in FM and RA patients. Our study is one of its kinds which assessed the handgrip force in RA and FM patients and compared it with the healthy controls. The present study showed that both the dominant and non-dominant hand grip was less in RA group when compared with the FM and healthy controls. Our observation of reduced hand grip in RA patients when compared with the healthy controls was similar to that observed in other studies [17,22,23].

Our results concur with the other studies which had reported lower hand grip in FM patients when compared with the healthy women [17,18]. Nordenskiold et al. [17] reported 40% reduction in the handgrip in FM patients than healthy adults. Sahin et al. [18] compared the handgrip of 41 fibromyalgia patients with 40 years of age and BMI matched healthy women and noted lower grip force in FM patients. Similar observation of reduced grip force in FM patients than healthy controls was noted in other studies as well [19,20]. Also patients with severe FM had lower grip force than those with moderate FM [16,24] which we have not analyzed in our study.

In the present study we noted that the dominant hand grip is significantly higher than the non-dominant hand in FM group while we did not observe any significant difference in RA group. This might possibly be due to symmetrical hand involvement limiting the hand grip function equally in Rheumatoid arthritis. The data from the literature is conflicting regarding the influence of dominance on hand grip in RA patients. Iop et al. [25] did not observe a significant difference in hand grip between the right and left hand in the Rheumatoid arthritis group which was similar to our observation. Fraser et al. [26] observed that dominant hand in RA patients was on average 20% weaker than the non-dominant hand while another study [27] reported greater hand grip in the dominant hands of RA patients.

To the best of our knowledge, we found only one study which had assessed the hand grip strength in RA and FM patients and compared it with the healthy controls. Our observation of reduced grip force in both the study groups was similar to that observed by Nordenskjold [17] who had studied 19 RA, 14 FM and 18 healthy subjects. The hand grip was assessed by Grippit instrument and compared with the normative data from 169 healthy subjects.

We used a simple, easily available, non-expensive hand held dynamometer to assess the hand grip while most of the reported studies worldwide had used Jamar dynamometer, a standard instrument to measure the hand grip. The need for assessment of chronic diseases through simple means is more important in the follow up of patients; having expensive and

© Under License of Creative Commons Attribution 3.0 License

complicated assessment tools may not be always feasible in routine clinical practice. One such kind of instrument is the simple country made hand held dynamometer which is widely available but lacks the reliability. Also the normative data of hand grip as measured by Jamar dynamometer is available across a wide range of population [28]. There is one Indian study with normative data for hand grip in young adults [29] while the data across various age groups is lacking. Hence we compared our study results with the age and sex matched controls.

We have not taken into account the physique and the work pattern of the study population which might have an influence in the assessment of hand grip strength. Manual workers and labors which require lot of muscular action may have a greater hand grip strength than people who are not used to do such activities. The disease activity assessment was not done in our study patients which can have an influence of the hand function. Ours is a small observational study but worth mentioning which can stimulate further research in this field.

Conclusion

RA patients have poor hand grip than fibromyalgia and both RA and FM have low hand grip when compared to controls.

DPP-4 Inhibitors

ABSTRACT

There were about 65 million diabetic population in 2016 in India. There were studies which concluded that the Dipeptidyl Peptidase-4 Inhibitors and Sodium Glucose Co-Transportor 2 Inhibitor were providing non-glycaemic control and cardiovascular benefits. Hence, it is important to find out the effect of those drugs on various parameters among the Indian Type 2 Diabetes Mellitus population. The aim is to evaluate and compare the effects of SGLT-2 inhibitors and DPP-4 inhibitors in Type 2 DM patients. The objective is to find out &compare the effects of both class of drugs on the physical profile [Body Weight (BW), Body Mass Index (BMI), Hip-Waist ratio), Diabetic Profile [Fasting Blood Sugar] (FBS), Glycated Haemoglobin (HbA1C)] & Side Effect Profile. The patients were categorized into two Group 1 & 2. Both groups were containing 50 patients, each based on the inclusion &exclusion criteria. The collection of demographics and history were done. Group 1 patients were initiated with DPP-4 Inhibitor, Group 2 patients with SGLT-2 Inhibitors, respectively. At baseline and during follow-up, the parameters like the physical profile, Diabetic Profile were noted. In Body Weight, the mean difference between the groups was found to be 2.9 $\pm$0.79 ($p<0.05$). Similarly, for BMI, it was 2.9$\pm$1.36 ($p<0.04$). For the Hip-Waist ratio, it was 0.07 ($p<0.05$). For FBS, it was 22.08 mg/dl (0.0001), for HbA1c it was 1.09 ($p<0.0043$). On the Side effect profile, SGLT-2 Inhibitors were showing higher incidence for the occurrence of Urinary Tract Infection (UTI) while comparing with DPP-4 Inhibitors. This can be overcome by proper patient counseling. This study concluded that SGLT-2 inhibitors may serves as the best medication choice for add on therapy in Type 2 DM patients.

INTRODUCTION

Diabetes mellitus is one of the most common chronic diseases which is present in almost all nations. It is the most common non-communicable disease (Shaw *et al.*, 2010). About 65 million diabetic population in 2016 in India, whereas it was 26 million in 1990. In India, the prevalence of Diabetes Mellitus among adults aged 20 years or older was increased from 5.5% to 7.7% between the years of 1990 to 2016, respectively. In 2016, the highest prevalence is seen in the states of Tamil Nadu

& Kerala, which were stated as High Epidemiological Transition Level (High ETL) & Delhi as Higher-Middle ETL, which is followed by Goa, Punjab & Karnataka (Tandon *et al.*, 2018). The micro and macro vascular complications will be reduced by obtaining fair glycaemia control (Alfeena Mary PS *et al.*, 2018). Early initiation of pharmacologic therapy is associated with improved glycaemic control and reduced long-term complications in type 2 DM. In the case of uncontrolled type 2 DM, the drug classes like SGLT-2 inhibitors and DPP-4 inhibitors are used as add on therapy, sometimes as monotherapy also.

DPP-4 inhibitors (Sitagliptin, Teneligliptin, Evo gliptin) produce its effect by activating incretin, which is released by the intestinal cells after food intake. It is usually given as a once-daily dose. DPP-4 is an enzyme that degrades various biologically active peptides, including the GLP-1 and GIP. GLP-1 is playing a major part in releasing insulin (Aschner *et al.*, 2010). Along with glucose control, these drugs were found to have cardiovascular benefits due to its pharmacological augmentation of GLP-1R (Dicker, 2011).

SGLT-2 inhibitors (Dapagliflozin, Canagliflozin, Empagliflozin, Remogliflozin, Ertugliflozin) are a newer class of OHAs (Oral Hypoglycaemic Agents) which are approved to be used as monotherapy or in combination with metformin, sulfonylurea, or insulin. Work by preventing the reabsorption of glucose in PCT and by facilitating its excretion in urine. Hence, the glycaemic control is achieved along with the glucose excretion. The mechanism of action of these drugs is dependent on blood glucose levels and independent of the actions of insulin. So, there are minimum incidences for the occurrence of hypoglycaemia, and there is no risk of overstimulation or fatigue of the beta cells. (Alfeena Mary PS *et al.*, 2018).

Since both classes of drugs are being used either as monotherapy or as part of dual and triple therapy in type 2 diabetes patients, it is important to compare the effects of those drugs in the Indian type 2 diabetes population. This study involves the comparison of Physical (weight, BMI, Hip-waist ratio), Diabetic (FBS, HbA1C) & Side effect profiles of both classes of drugs.

MATERIALS AND METHODS

The study was conducted in the Department of General Medicine in PSG Hospital, Coimbatore. It was approved by the Institutional Human Ethics Committee, PSG Institute of Medical Sciences and Research (Proposal no: 19/072). It is an observational study which included a total of 100 subjects who were divided into two treatment groups. Both groups contain 50 patients each. Group 1 (G1) contains 28 Males & 22 Females whereas Group 2 (G2) contains 30 Males & 20 Females.

The inclusion criteria include Type 2 DM patient of age above 18 years with poor diabetic control and on regular follow up, Patients who are going to be initiated respectively with SGLT 2 Inhibitors & DPP-4 inhibitors as add on therapy for controlling DM and the patients with normal liver function, renal function. Exclusion criteria include patients with Type 1 DM, renal failure, psychiatric, paediatric, gestational diabetes mellitus, history of diabetic ketoacidosis & primary renal glucosuria, and patients who are unwilling to participate.

Group 1 patients were initiated with DPP-4 Inhibitor, Group 2 patients with SGLT-2 Inhibitors, respectively. At baseline and during follow-up after 3 months of drug initiation, the parameters like the physical profile, Diabetic Profile, and side effects were noted and statistically compared. The effect of drugs within a group was compared by using Paired *t*-Test and between groups were by using Independent *t*-Test.

RESULTS AND DISCUSSION

Effects of DPP-4 Inhibitors

The total of 50 G1 patients who were initiated with DPP-4 inhibitors, drugs given were Teneligliptin 20mg (14 patients), Evo gliptin 5mg (07 patients), DPP-4 Inhibitor +Metformin 500mg (16 patients), DPP-4 Inhibitor +Repaglinide 0.5 mg (06 patients), DPP-4 Inhibitor +Glimepiride 1mg (07 patients).

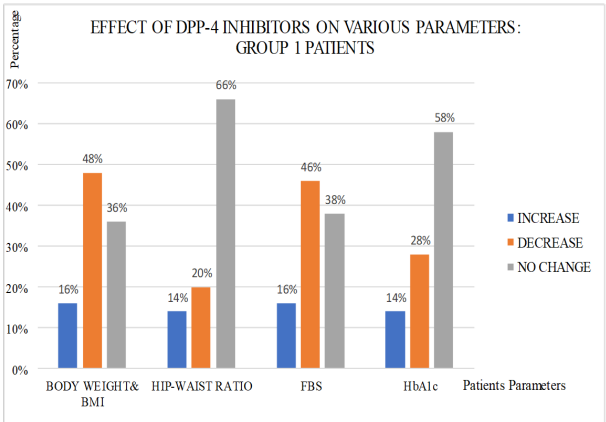

Figure 1: Cluster chart showing the effect of DPP-4 inhibitors on various parameters among Group 1 patients [BMI-Body Mass Index FBS-Fasting Blood Sugar HbA1c-Glycated Haemoglobin]

Once after the drug initiation, the patients were

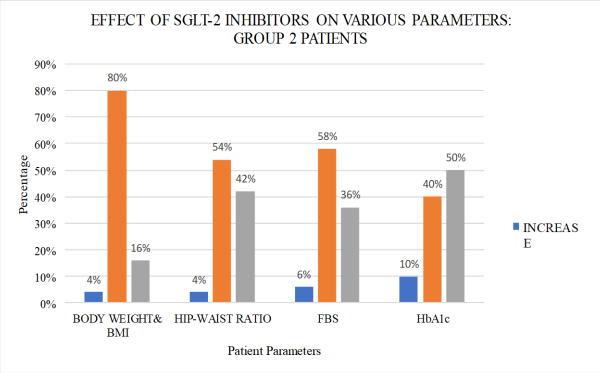

Figure 2: Cluster chart showing the effect of SGLT-2 inhibitors on various parameters among Group2 patients [BMI-Body Mass Index FBS-Fasting Blood Sugar HbA1c-Glycated Haemoglobin]

followed up for three months, and their physical and diabetic profile are monitored, and the changes were noted. According to the effect of drugs on individuals, their parameters get varied. They were depicted in Figure 1

Figure 1 showing the effect of DPP-4 Inhibitors on various parameters among G1 patients. The mean baseline weight (68.44±3.81) was reduced to 64.45±1.71) (p=0.04), the mean baseline BMI (26.73±1.31) was reduced to (25±1.38) (p=0.05), the mean difference between Hip-Waist ratio was 0.13 (p=0.05), the mean difference between FBS was 59.87 mg/dl (p=0.03), the mean difference between HbA1c was 1.2% (p=0.04).

A retrospective sub-analyzed study of sitagliptin effect on glucose and lipid metabolism, blood pressure, body weight and renal function in type 2 DM patients for a period of 6 months by dividing 173 patients of Type 2 DM into obese group (BMI $\geq$ 25) and non-obese group (BMI < 25), concluded that the body weight was significantly reduced in obese patients from the baseline values despite the ages and HbA1c also decreased in both the groups significantly (Katsuyama *et al.*, 2014)

A review of sitagliptin brought a conclusion that on the addition of sitagliptin (100mg/d) to already existing oral antidiabetic treatment produce a significant reduction of HbA1c. After 24 weeks of the addition of sitagliptin (100mg/d) to metformin produced a significant reduction of HbA1c (0.65%), FBS (25.4 mg/dl), Post Prandial Glucose (2h) (50.6 mg/dl) (Gallwitz, 2007)

GLP-1 also found have cardioprotective action in experimental models of heart failure and myocardial infarction. DPP-4 inhibitors may have cardiovascular effects either by depending or independent of GLP-1 (Jose and Inzucchi, 2012)

An Indian study reported the results of a 16-week, multicentric, double-blind, placebo-controlled, Phase 3 studies of teneligliptin 20 mg daily in drug-naive T2DM patients. This study (N = 237) reported a significant −0.55% glycated hemoglobin (HbA1c) reduction (placebo-subtracted) in teneligliptin arm (P = 0.0043) compared to control. While a significant reduction in 2 hours postprandial glucose (PPG) (−25.8 mg/dl, P = 0.0070) versus placebo was observed, an insignificant reduction in fasting plasma glucose (FPG) was seen (−8.8 mg/dl, P = 0.18) in teneligliptin 20 mg arm. Similarly, a higher percentage of patient achieved the target HbA1c of <7% in teneligliptin arm (43.4% vs. 27.3%, P = 0.026) compared to the control and "overall" the drug was well tolerated (Suryawanshi *et al.*, 2016)

Effects of SGLT-2 Inhibitors

The effects of SGLT-2 Inhibitors among various parameter of G2 patients were depicted in Figure 2

Figure 2 showing the effect of SGLT-2 Inhibitors on various parameters among G2 patients. The mean baseline weight (71.34±3.28) was reduced to 64.45±1.97) (p=0.02), the mean baseline BMI (29.93±4.32) was reduced to (27.03±2.96) (p=0.04), the mean difference between Hip-Waist ratio was 0.27 (p=0.04), the mean difference between FBS was 81.95 mg/dl (p=0.01), the mean difference between HbA1c was 2.29% (p=0.02)

A retrospective study which involves 61 patients who received 12 months of dapagliflozin concluded that After the 12 months intake of drug the body weight was -3.4±2.6 kg reduced significantly from the baseline value, the drug reduces the hyperglycemia and body weight by inhibiting the renal glucose reabsorption in a safe manner in Type 2 DM patients. (Cho *et al.*, 2017)

The study of "Efficacy and Safety of SGLT-2 Inhibitors" in Emirati patients which included 307 patients concluded that at 6 months of drug administration the baseline HbA1c was decreased from the baseline value, from 8.9±1.7% to 8±1.5% & at 1 year the mean HbA1c was 8±1.4% (p=0.0001). Likely, the bodyweight also reduced from the baseline at the sixth month, from 85.7±17.8 kg to 84±12.2 kg (p=0.0001). (Bashier *et al.*, 2017)

Comparision between the effects of DPP-4 inhibitors & SGLT-2 inhibitors

Since both categories of the drugs is used as add on therapy in the treatment of Type 2 DM, it's important to find out the effect of those drugs on various parameters among the Indian Type 2 DM population. This result may help to wisely choose the add

on therapy drugs for the treatment of Type 2 DM.

Effects of drugs on

Body weight and BMI

Table 1: DPP-4 Inhibitors Vs SGLT-2 Inhibitors on Body Weight and BMI

Body Weight& BMI	DPP-4 Inhibitors	SGLT-2 Inhibitors
Increase (%)	16	4
Decrease (%)	48	80
No Change (%)	36	16

BMI-Body Mass Index

Hip-waist ratio

Table 2: DPP-4 Inhibitors Vs SGLT-2 Inhibitors on Hip-Waist Ratio

Hip-waist ratio	DPP-4 inhibitors	SGLT-2 Inhibitors
Increase (%)	14	4
Decrease (%)	20	54
No change (%)	66	42

The comparison of the effect of both the drugs over the patient's body weight and Hip-Waist Ratio were depicted in Table 1 &Table 2 respectively. In Body Weight, the mean difference between the groups was found to be 2.9 ±0.79 ($p<0.05$). Similarly, for BMI, it was 2.9±1.36 ($p<0.04$). For the Hip-Waist ratio, it was 0.07 ($p<0.05$). SGLT-2 Inhibitors were showing significant reduction while comparing with DPP-4 Inhibitors.

In 2017, Min SH et al. conducted a meta-analysis study titled "Comparison between SGLT2 inhibitors and DPP4 inhibitors added to insulin therapy in type 2 diabetes: a systematic review with indirect comparison meta-analysis". Covariate-adjusted indirect comparison using meta-regression analyses revealed that SGLT2i/INS achieved greater reduction in HbA1c [weighted mean difference (WMD) -0.24%, 95% confidence interval (CI) -0.43 to -0.05%], fasting plasma glucose (WMD -18.0 mg/dL, 95% CI -28.5 to -7.6 mg/dL) and body weight (WMD -2.38 kg, 95% CI -3.18 to -1.58 kg) from baseline than DPP4i/INS without increasing the risk of hypoglycemia. (Min *et al.*, 2017)

FBS

HbA1c

The comparison of the effect of both the drugs over the patient's FBS & HbA1c were depicted in Table 3 &Table 4 respectively. The mean difference between the groups over FBS was 22.08 mg/dl (0.0001), for HbA1c it was 1.09 ($p<0.0043$). SGLT-2 Inhibitors were showing significant reduction while comparing with DPP-4 Inhibitors.

Table 3: DPP-4 Inhibitors Vs SGLT-2 Inhibitors on FBS

FBS	DPP-4 Inhibitors	SGLT-2 Inhibitors
Increase(%)	16	6
Decrease (%)	46	58
No Change (%)	38	36

FBS- Fasting Blood Sugar

Table 4: DPP-4 Inhibitors Vs SGLT-2 Inhibitors on HbA1c

HbA1c	DPP-4 Inhibitors	SGLT-2 Inhibitors
Increase (%)	14	10
Decrease (%)	28	40
No Change (%)	58	50

HbA1c-Glycated Haemoglobin

Table 5: Side Effect Frequency of the Drugs

Drugs Category	Side Effects (%)
DPP-4 Inhibitors	10
SGLT-2 Inhibitors	14

An observational study on "Safety and Efficacy of Sodium-glucose Cotransporter-2 Inhibitors as Adjuvant to Insulin Add-on Therapy in Uncontrolled Type 2 Diabetic Patients" concluded that the SGLT-2 Inhibitors were more effective in both glycemic control (FBS, HbA1c) and non-glycemic control (Body Weight, BMI, Blood Pressure) and acts as a well-tolerated therapy in patients. This put forth the overall reduction in cardiovascular risks (Alfeena Mary PS *et al.*, 2018)

Side effect profile of the drugs

Since 50 patients were enrolled in each group like DPP-4 Inhibitors and SGLT-2 Inhibitors, respectively, along with the effects of two categories of drugs on various patient's parameters, their Side effects are also monitored during the follow-up period of 3 months. It was given in Table 5.

Side effects of DPP-4 Inhibitors: Nausea, Diarrhoea, Stomach pain, Flu-like symptoms, Nasopharyngitis and HSR (Amori *et al.*, 2007)

Side effects of SGLT-2 Inhibitors: UTI, Hyperkalaemia, Hypotension, Hypoglycaemia and Dia-

betic Ketoacidosis (Hsia *et al.*, 2017)

On Side effect profile, SGLT-2 Inhibitors were showing higher incidence for the occurrence of UTI while comparing with DPP-4 Inhibitors

CONCLUSIONS

Both DPP-4 Inhibitors and SGLT-2 Inhibitors were producing significant impact over the Physical and Diabetic profile of Type 2 DM patients. Though while comparing with DPP-4 Inhibitors, SGLT-2 Inhibitors were producing a more prominent effect over patient's parameters, and apart from producing a significant effect on the Physical and Diabetic profile, SGLT-2 inhibitors were also found to have cardiovascular benefits. Side effects like UTI can be overcome by proper patient counseling. On an overall consideration of the effects produced by both the class of drugs, this study concluded that SGLT-2 inhibitors may serves as the best medication choice for add on therapy in Type 2 DM patients.

A prospective study on the clinical profile and outcome of meningoencephalitis in adults in a South Indian tertiary care centre

Velammal Petchiappan[1], Divya Pedireddy[2], Santni Manickam[3], Jayachandran Kuppusamy[4]

Abstract

Background Although there are numerous studies on meningitis and encephalitis separately, literature on meningoencephalitis is sparse. In this study we analysed the clinical profile of meningoencephalitis and its clinical outcome.

Methods Fifty adults diagnosed with meningoencephalitis from July 2014 to July 2015 in a tertiary care hospital in South India were studied prospectively and their clinical presentation, aetiology and outcome were analysed.

Results Among 50 patients, 33 (66%) were male; 39 (78%) were <50 years of age. Fever was the most common presenting symptom in 41 out of 50 patients (82%), followed by headache (74%) and altered sensorium (62%); only 18 patients (36%) had all three classical symptoms. Twenty-eight out of 50 patients (56%) did not have neck stiffness. A majority of patients had acute-to-subacute clinical presentation. *Mycobacterium tuberculosis* was identified in 58% (29 out of 50). Forty-seven patients (94%) recovered completely.

Conclusion Tuberculosis was the most common cause of meningoencephalitis in the studied population, often with subacute presentation, and outcome was good with early institution of antituberculous therapy.

Introduction

Meningitis is a clinical syndrome characterised by inflammation of the meninges surrounding the brain and the spinal cord. The classic triad of meningitis consists of fever, headache and neck stiffness.[1] Meningitis can be of infective or noninfective aetiology, occurring in any age group, with extremes of age being the most severely affected. The immune-compromised state also has high mortality and morbidity. The overall case fatality rate of bacterial meningitis in adult patients is around 30%.[2–4]

Although encephalitis by definition involves the brain parenchyma, it may also involve the meninges as well, which is termed as 'meningoencephalitis'. From an epidemiologic and pathophysiologic perspective, encephalitis is distinct from meningitis, though on clinical evaluation both can coexist. The clinical presentation is encephalopathy with diffuse or focal neurological symptoms, including behavioural and personality changes, decreased level of consciousness, neck pain/stiffness, photophobia, lethargy, generalised or focal seizures, acute confusion or amnesic states, and flaccid paralysis.[5]

Organisms responsible for bacterial meningitis are *Streptococcus pneumoniae*, *Neisseria meningitis*, Group B streptococci, *Listeria monocytogens* and *Haemophilus influenza* type b. Most patients recover completely if appropriate antibiotic therapy is instituted promptly. *Mycobacterium tuberculosis* is another major cause, especially in developing countries. Tuberculous meningitis is a critical disease in terms of fatal outcome and permanent sequelae, requiring rapid diagnosis and treatment.[6]

The term aseptic meningitis is used for all types of inflammation of the brain meninges not caused by pus-producing bacteria. It is usually a benign syndrome. Viral and aseptic meningitis are terms used interchangeably as, not only viruses are a major cause, other noninfective causes are equally attributable to the development of meningitis. Worldwide causes of viral meningitis include enterovirus, herpes, mumps, measles and HIV, with enterovirus being the most common cause of viral meningitis.

In the emergency setting differentiating bacterial meningitis from other causes, such as fungal, tuberculous, viral,

Table 1 Age-wise distribution of the study subjects

Age (years)	Male	Female	Total
18–30	12	5	17
31–50	17	5	22
51–60	2	7	9
>60	2	0	2
Total	33	17	50

neoplastic, toxic or autoimmune causes, is extremely difficult. If a diagnosis of meningitis is made, it is prudent to start the patient on empirical antibiotics until the cultures and other results are awaited.[7] Whereas plenty of literature is available on meningitis, the clinico-aetiological profile and outcome in patients with meningoencephalitis remains not that well studied, except for in the paediatric population.[8] The present study was carried out to assess the causes, clinical profile and outcome in adults diagnosed with meningoencephalitis in a tertiary care hospital.

Methods

Patients

The study was based on prospective collection of data in adults aged 18 years and above who were diagnosed with meningoencephalitis of various aetiologies, confirmed with laboratory investigations and brain imaging. The study was conducted in a tertiary care centre, Coimbatore, South India, from July 2014 to July 2015.

Inclusion and exclusion criteria

Patients with community-acquired meningoencephalitis, those who underwent lumbar puncture for the diagnosis and those with both positive and negative cerebrospinal fluid cultures were included in the study. Patients with hospital-acquired meningitis, patients with myelitis, neurosurgical devices or a recent history of neurosurgery were excluded.

Assessments

Data were extracted using a proforma that included detailed history, clinical examination details and requisite investigations. History and clinical findings attributable to the meningitis and meningoencephalitis were collected in detail, which included fever, headache, vomiting, neck stiffness, seizures, altered sensorium, cerebrospinal fluid (CSF) rhinorrhoea and focal neurological deficits. In addition to basic investigations (which included complete blood count, blood sugar, renal and liver function tests, and chest X-ray), blood culture was also taken for all patients. All underwent lumbar puncture and CSF analysis was carried out that included sugar, protein, total count, differential count, Gram stain, bacterial culture, Ziehl Neelsen stain for acid-fast bacilli (AFB), India ink stain for *Cryptococcus,* cryptococcal antigen test and automated culture for AFB. Neuroimaging (CT or MRI brain) was carried out on all patients. CSF polymerase chain reaction (PCR) was carried out in selected patients. Herpes simplex virus (HSV) PCR was carried out in selected patients with suspected HSV encephalitis based on clinical, CSF and neuroimaging findings.

Table 2 Clinical presentation of the study subjects

Clinical variables	Number of patients	%

Tuberculous meningitis	29	58
Acute pyogenic meningitis	8	16
Viral meningoencephalitis	8	16
Cryptococcal meningitis	2	4
Cerebral toxoplasmosis	2	4
Aspergillus meningitis	1	2
Total	50	100

Based on the duration of illness, patients were classified into acute (<1 week), subacute (1–4 weeks) and chronic (>4 weeks) and also grouped based on aetiology. To assess the clinical outcome of the patients the Barthel index was used.[9] Barthel index is an ordinal scale used to measure the performance in 10 activities of daily living with the score ranging between 0 and 20; functional evaluation was carried out at the end of the first month. A score of <12 is taken as a poor outcome and >12 as a good outcome; death is included in the poor outcome category. The results were analysed to assess the clinical presentation, aetiology and clinical outcome.

Ethical clearance

The study was approved by the Institutional Human Ethics Committee (Approval Number 14/193).

Results

The study included 50 consecutive patients with acute meningoencephalitis. Among 50 patients, 33 (66%) were male, 17 (34%) were female. The majority of them (78%) were <50 years of age (Table 1).

Clinical presentation

The common initial presenting symptoms were fever, headache and altered sensorium (Table 2). Among 50

Aetiology	Acute	Subacute	Chronic	Total
Tuberculous meningitis	4	21	4	29
Acute pyogenic meningitis	8	0	0	8

Total	23	23	4	50

Acute: clinical presentation <1 week; Subacute: clinical presentation between 1–4 weeks; Chronic: >4 weeks duration

Table 4 Mode of onset of symptoms in various aetiologies of meningoencephalitis

patients, 32 (64%) had both fever and headache; only 18 (36%) had all the three classical signs of meningitis – headache, fever and altered sensorium. Twenty-eight patients (56%) did not have neck stiffness, even though there was meningeal involvement as noted in neuroimaging. Six patients (12%) had seizures; five had generalised tonic–clonic seizures, while focal motor seizures was noted in one. Among those six patients, one had a parenchymal lesion in the MRI (granuloma), meningeal enhancement was noted in three and MRI was normal in two.

Altered sensorium was observed in 31 patients; of which 10 had significant deterioration in consciousness (Glasgow coma scale <10). Among those with poor Glasgow coma scale, one had pyogenic meningitis with extensive vasculitic infarcts in the bilateral cerebral hemisphere and brainstem; seven had abnormal findings in MRI like meningeal enhancement, granuloma or hydrocephalus; MRI was normal in the remaining two. All of these 10 patients with altered sensorium required ventilatory support in intensive care unit. See online for Supplementary Tables 1–4.

Aetiology and mode of onset

The aetiological profile of meningoencephalitis is listed in Table 3. The most common cause found in the present study was *M. tuberculosis*. Among eight patients with acute pyogenic meningitis, the microbiological diagnosis was confirmed in five; three had pneumococcal growth in CSF analysis, while blood culture was positive in two (*S. aureus*; pneumococci). The remaining three patients with acute pyogenic meningitis had sterile cultures due to prior antibiotic exposure. However, very high neutrophil count in the CSF suggested the diagnosis of acute pyogenic meningitis.

Acute and subacute clinical presentation was seen in 23 each while the remaining four presented with chronic symptoms. The mode of onset of symptoms in various aetiologies is listed in Table 4.

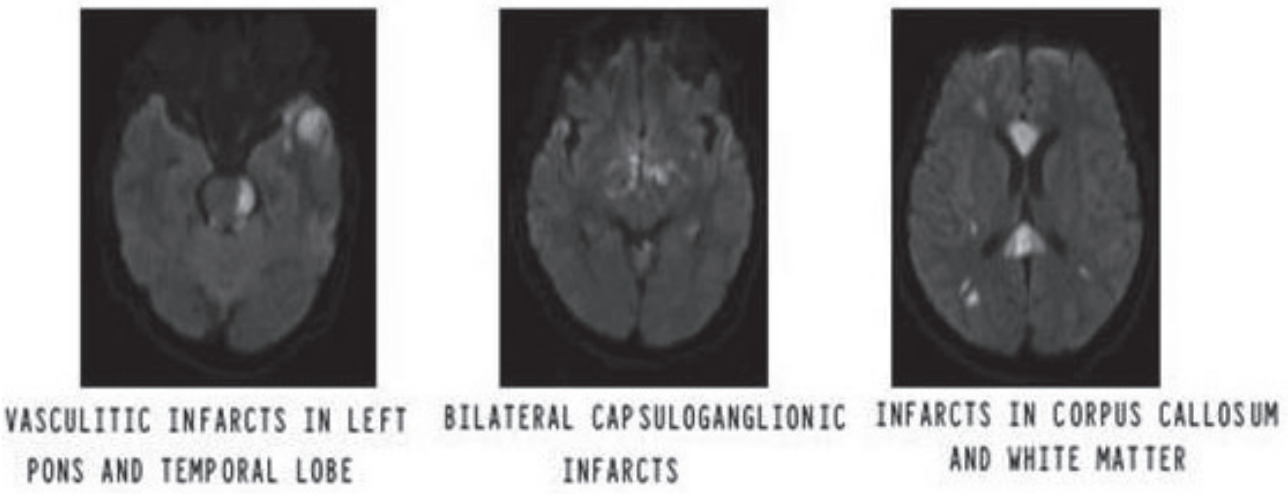
Outcome

Clinical outcome was assessed at the end of 1 month using the Barthel index. Among 50 patients, 47 (94%) recovered completely without any deficits; two had fulminant course and succumbed to the illness by the end of 1 month; one had Barthel index score of 0 (Table 5).

Discussion

The present study included 50 adult patients with meningoencephalitis, *M. tuberculosis* was the most common agent. Tuberculosis still poses a huge health threat in developing countries like India despite advances in the detection and management of the disease.

The common presenting symptoms were fever, headache and altered sensorium. This was similar to other studies with acute bacterial meningitis.[2,10,11] In the present study, nine did not have fever (five had tuberculous aetiology, two had cryptococcal meningitis, cerebral toxoplasmosis and *Aspergillus* meningitis in one each). All patients with acute pyogenic and viral meningoencephalitis presented with fever. Only 18 out of 50 patients (36%) had all the three symptoms – fever, headache and neck stiffness; a similar observation (41%) was noted in a prospective cohort study of community-acquired bacterial meningitis in adults in the Netherlands.[11] Neck stiffness was absent in 28 patients (56%), which indicates that absence of fever or neck stiffness does not exclude the possibility of infectious meningoencephalitis.



Diagnosis of pyogenic meningitis was made based on typical CSF findings (Supplementary Table 1) that showed high protein, low sugar and very high neutrophil count in the CSF (>1,000 cells/mm^3 in most of the patients). In five out of these eight patients with acute pyogenic meningitis, organisms could be isolated either in the blood or CSF. For the remaining three, the cultures were sterile possibly due to prior antibiotic exposure. In a retrospective study of 305 patients with acute bacterial meningitis, 53 (17.4%) had

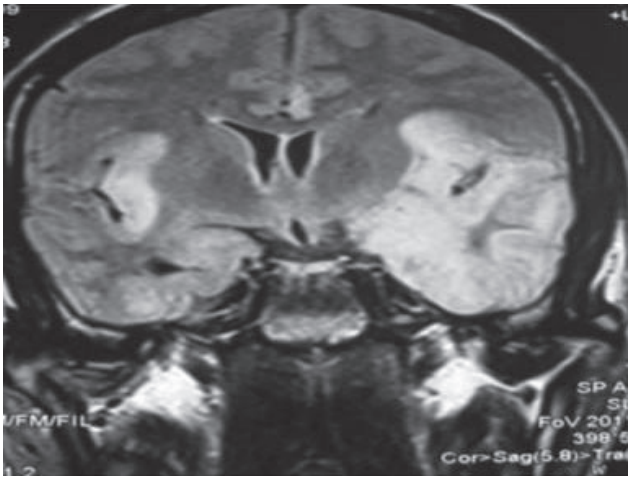
Outcome	TM	APM	VME	CM	CT	AM	Total
Good (n = 47)	29	6	8	1	2	1	47
Poor (n = 3)	0	2	0	1	0	0	3
Total	29	8	8	2	2	1	50

AM: *Aspergillus* meningitis; APM: acute pyogenic meningitis; CM: cryptococcal meningitis; CT: cerebral toxoplasmosis; TM: tuberculous meningitis; VME: viral meningoencephalitis

Table 5 Clinical outcome in various aetiologies of meningoencephalitis

Figure 1 Fulminant pneumococcal meningitis with extensive vasculitic infarcts in bilateral cerebral hemisphere and brainstem

received antibiotics before admission and among these, death occurred only in one. The death rate was high (12%) in the remaining 252 patients who had not received antibiotics before admission. This study indicates the importance of the early institution of antibiotic therapy.[12,13]



Surprisingly, four out of eight patients (50%) with acute pyogenic meningitis had a history of CSF rhinorrhoea before the onset of illness. Of these, three had a head injury in the past. MRI brain in one patient revealed a defect in the anterior cranial fossa that was the cause of CSF leak. One of them had recurrent episodes of pyogenic meningitis due to persistent CSF leak through the nose. After recovery from meningitis, he underwent a neurosurgical procedure for the correction of bony defects. This highlights the importance of elicitation of history for CSF rhinorrhoea in subjects with recurrent meningitis so that the underlying cause can be corrected. Six out of eight acute meningoencephalitis patients recovered completely without residual deficits; however, two had fulminant pneumococcal meningitis, of which one succumbed to the illness although treatment was initiated appropriately, the other survived with severe neurological disability, i.e. bilateral conjugate gaze paralysis of eyeballs and quadriparesis due to multiple infarcts (Figure 1). These outcomes highlight the fact that despite early diagnosis and appropriate treatment some patients with acute pyogenic meningitis may have a fulminant course with a severe neurological disability that can impair the quality of life.

Eight patients had acute viral meningoencephalitis, diagnosed based on CSF analysis and brain imaging features. A viral aetiology was considered when CSF had slightly elevated protein, low-to-normal blood sugar and moderately elevated lymphocyte count. Bacterial cultures, Gram stain, AFB stain and India ink stain were negative in these patients. Out of these eight patients, microbiological confirmation (positive HSV PCR in CSF) was possible in only two; both had temporal cortex hyperintense signals in MRI brain (Figure 2). All recovered completely with acyclovir and were asymptomatic during follow up. In many cases of presumed viral encephalitis (32–75%), the responsible organism could not be pin-pointed despite detailed diagnostic testing. In the California Encephalitis Project, 334 patients with encephalitis were studied from 1998 to 2000; aetiology could not be identified in 208 (62%), despite extensive testing and evaluation.[14]

Although commonly tuberculous and cryptococcal meningitis presents with subacute courses, four patients with tuberculous meningitis and one with cryptococcal meningitis presented with acute onset illness. Two patients presented with central nervous system toxoplasmosis and these patients were found to be HIV positive; they presented with hemiparesis; CSF serology for toxoplasma immunoglobulin G was positive; both the patients recovered well with treatment.

In the present study 15 had basal meningeal exudates on brain imaging. Hydrocephalus was present in five; of which two had significantly larger hydrocephalus, which progressively increased in size and both underwent ventriculoperitoneal shunt. In two large community-based series, hydrocephalus was seen in approximately 75% of

Figure 2 Herpes simplex encephalitis – T2-weighted MRI shows left temporal and right insular hyperintensity

patients, basilar meningeal enhancement in 38%, cerebral infarcts in 15–30% and tuberculomas in 5–10%.[15,16] With early appropriate antituberculous therapy and steroids, all patients with tuberculous meningitis in the present study recovered well without neurological deficits.

The present study had several limitations: PCR studies in all CSF culture-negative samples could not be performed and the study was conducted in a single centre with a limited number of patients. Further larger studies on meningoencephalitis would throw more light on the clinical profile and outcome.

In conclusion, the present study underscores the fact that the absence of fever or neck stiffness does not exclude the possibility of infectious meningoencephalitis. The focus in all cases should be on early diagnosis and appropriate treatment, though in some patients the outcome may not be uniformly good.

Is Serum Uric Acid an Added Risk Factor for Micro-Vascular Complications of Diabetes Mellitus? – A Prospective Study

Santni Manickam[1], Prashanth Arun[2], Velammal Petchiappan[3], Sujaya Menon[4]

ABSTRACT

Introduction: Diabetes is the leading cause of adult blindness due to retinopathy, end stage renal disease due to nephropathy and foot ulcers and lower limb amputation due to neuropathy. Serum uric acid levels independently predict the development of micro vascular complications. In this study, we analyse the association of serum uric acid with the micro vascular complications of diabetes.

Material and methods: In this hospital based observational study, hundred diabetic patients were included; of which fifty had micro vascular complications, the remaining fifty had no complications. Blood investigations including fasting(FBS) and post prandial blood sugars(PPBS), glycosylated haemoglobin (HbA1C), and serum creatinine and serum uric acid were done in all patients. All the parameters were compared between the two groups.

Results: Females presented with significantly higher complications as compared to males. The mean age of the patients presented with and without complications was 56.4 ± 9.3 and 59.9 ± 10.3 respectively. HbA1C had a positive correlation with the serum uric acid (SUA) (r=0.327, *P* = 0.001). Mean uric acid levels were higher among patients with complications (5.96 ± 2.16) compared to patients without complications (4.95 ± 2.04) which was statistically significant (*P* value =0.021). Patients with nephropathy and neuropathy had significant elevation in serum uric acid levels than those without; however this significance was not noted in those with retinopathy.

Conclusion: Patients with micro vascular complications had higher levels of serum uric acid compared to those without complications. Also there was positive correlation between HbA1C and serum uric acid levels.

Keywords: Serum Uric Acid, Micro Vascular Complications, Diabetic Retinopathy, Diabetic Neuropathy, Diabetic Nephropathy, Glycosylated Haemoglobin.

INTRODUCTION

Diabetes mellitus is the most challenging health problem in this century. Diabetes is the leading cause of adult blindness due to retinopathy, end stage renal disease due to nephropathy and foot ulcers and lower limb amputation due to neuropathy.[1]

Uric acid (UA) is primarily a purine metabolic waste product. About 70% of it gets excreted by the kidneys. Hyperuricemia has gained importance as many studies have reported that it not only has an important role in the development of metabolic syndrome but also micro vascular risk factor.[2-5] Elevated serum uric acid is a feature of hyperinsulinemia or insulin resistance.[6]

Many studies have suggested that inflammation and oxidative stress results from the metabolism of uric acid, leading to vascular injury. The rate limiting step of uric acid production is an enzymatic reaction of the xanthine oxidase (XO) enzyme that oxidises hypoxanthine – xanthine into uric acid. UA synthesis is accompanied by the generation of reactive oxygen species (ROS). XO in the vascular endothelium is associated with ischemia reperfusion injury. It has also been suggested that XO inhibitors improve endothelium-dependent vascular relaxation in blood vessels of hyperlipidemic rabbits.[7] XO as the source of ROS in ischemia/reperfusion injury has been discovered 30 years ago.[8,9]

In recent years there has been a debate regarding the association of hyperuricemia with diabetic complications. If this association is conclusively established, therapeutic interventions aiming to reduce uric acid synthesis might help to retard the progression of micro vascular complications of diabetes. Hence this study was conducted aiming to show the association of uric acid levels with diabetic complications.

MATERIAL AND METHODS

This is a hospital based observational study conducted in a tertiary care centre at Coimbatore from April 2015 to April 2016. Patients with Type 2 Diabetes Mellitus of the age group of 20 to 80 years admitted in the medical wards were included in the study. Patients admitted with acute complications like diabetic ketoacidosis and hyperosmolar coma and patients with gestational diabetes were excluded

How to cite this article: Santni Manickam, Prashanth Arun, Velammal Petchiappan, Sujaya Menon. Is serum uric acid an added risk factor for micro-vascular complications of diabetes mellitus? – a prospective study. International Journal of Contemporary Medical Research 2019;6(7):G30-G34.

DOI: http://dx.doi.org/10.21276/ijcmr.2019.6.7.20

from the study. Informed consent was obtained from the patients. Before commencement of the study, approval was obtained from the Institutional Ethics Committee.

A detailed history and physical examination was done. Baseline investigations including fasting and post prandial blood sugars, HbA1c and serum creatinine were done. The diagnosis of diabetes was based on American Diabetic Association criteria. The presence of micro vascular complications was established by fundus examination by an ophthalmologist to assess retinopathy, Urine spot Protein/ creatinine ratio (PCR) to assess nephropathy and nylon monofilament test to assess neuropathy. Serum uric acid was done in all patients. Hyperuricemia was defined as serum uric acid greater than 7 mg/dl.

The study population was divided into two groups: group I patients with diabetes and without any vascular complications; group II patients with diabetes and any one or more of vascular complications.

STATISTICAL ANALYSIS

Descriptive statistics were reported as mean and standard deviation; categorical variables were presented with number and percentages. Chi-square test was used to test the association between the variables. Independent t test was used to compare the blood parameters between diabetes with complications and without complications. P value less than 0.05 was considered statistically significant.

RESULTS

Among the 100 diabetic patients studied, there were 62 males and 28 females; 50 had presented with complications and 50 had no complications in the study group. Out of 50 with diabetes related micro-vascular complications, there were 24 males and 26 females. There was a significant difference in the presence of complications and sex; Females presented with significantly higher complications as compared to males (P= 0.004). The mean age of the patients presented with and without complications was 56.4 ± 9.3 and 59.9 ± 10.3 years respectively; although not significant (P= 0.084), patients who presented with complications were younger than those without complications.

	Present (%)	Absent (%)
Diabetic Retinopathy	19(38)	31(62)
Diabetic Neuropathy	16(32)	34(68)
Diabetic Nephropathy	19(38)	31(62)

Table-1: Distribution of Micro vascular complications

	Diabetes with complications	Diabetes without complications	P value
Sex Male Female	 24 (39) 26 (68)	 38 (61) 12 (32)	0.004*
Age	56.4 ± 9.3	59.9 ± 10.3	0.084
HbA1c	8.28 ± 2.00	7.55 ± 1.50	0.044*
FBS	137.8 ± 44.5	133.5 ± 46.6	0.644
PPBS	210.1 ± 60.3	187.7± 52.7	0.028*
Uric acid	5.96 ± 2.16	4.95 ± 2.04	0.021*

Table-2: Comparison of age, sex, HbA1c and uric acid levels in diabetic patients with and without micro-vascular complications.

Microvascular complication		Serum uric acid level (mg/dL)	P value
Diabetic retinopathy	Present	5.97 ± 2.14	0.97
	Absent	5.95 ±2.20	
Diabetic neuropathy	Present	6.56 ± 2.30	0.004
	Absent	4.73 ± 1.10	
Diabetic nephropathy	Present	7.05 ± 2.13	0.006
	Absent	5.33 ± 1.94	

Table-3: Serum uric acid levels in micro vascular complications

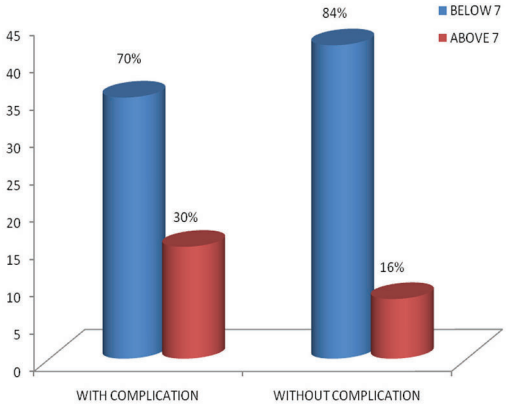

Figure-1: Frequency distribution of serm uric acid(mg/dl) in Diabetes mellitus with and without complications.

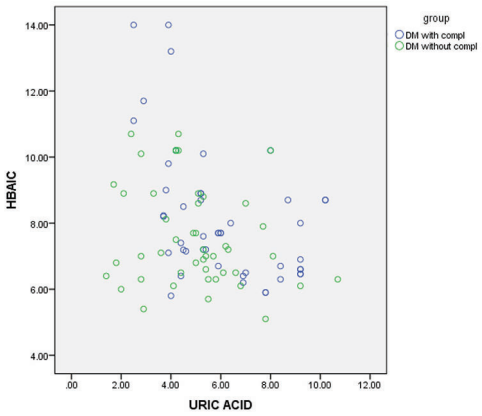

Figure-2: Co-relation of HbA1C with the Serum uric acid levels

The distribution of micro vascular complications is shown in Table 1. Both retinopathy and nephropathy were equally prevalent and slightly more than neuropathy.

Hyperuricemia (Serum uric acid >7 mg/dl) was more prevalent among patients with complications (30%) compared to patients without complications (Fig 1). As shown in Table 2, mean uric acid levels were higher among patients with complications (5.96 ± 2.16 mg/dl) compared to patients without complications (4.95 ± 2.04 mg/dl) which was statistically significant (*P* value = 0.021). HbA1C had a positive correlation with the serum uric acid levels (r=0.327, *P* = 0.001) as shown in Fig 2.

Table 3 represents the prevalence of hyperuricemia in patients with retinopathy, neuropathy and nephropathy, as compared to those without these complications. It can be seen that nephropathy and neuropathy patients had significantly more hyperuricemia than those without. However there was no statistically significant difference seen in the group with retinopathy. This suggests that high uric acid levels are associated with microangiopathies in Type 2 Diabetes.

DISCUSSION

Increasing amounts of uric acid in the serum causes Gout and this is the most significant cause of lifestyle-related disorder. Uric acid is primarily a product of purine metabolism. Serum uric acid (UA) levels are determined by a balance between Uric acid production and excretion. The rate-limiting step of UA production is an enzymatic reaction of the xanthine dehydrogenase/xanthine oxidase (XDH/XO) enzyme that oxidizes hypoxanthine-xanthine into UA. It is expressed in the liver and small intestine of XDH/XO-rich parenchyma cells[10] and is thought to be the major source for UA. The enzyme is also expressed in adipose tissue, the vascular endothelium, and macrophages, all of which are implicated in lifestyle-related diseases.[11] The UA production rate is based on the amount of substrate and/or XO activity. Since the generation of reactive oxygen species (ROS) depends on XO activity, XO is one of the major sources of oxidative stress in cells along with nicotinamide adenine dinucleotide phosphate oxidase, myeloperoxidase, lipoxygenase, and nitric oxide synthase.[12]

The kidney is an important regulator of circulating UA levels and is responsible for 60%-70% of total body UA excretion.[13] The remaining UA is secreted into the intestine, followed by bacterial uricolysis.[13] UA excretion in the kidney consists of urate secretion and reabsorption, and earlier research suggests the involvement of hyperfiltration.[6] Ninety percent of UA filtered by the kidney is reabsorbed.[13]

In patients with diabetes, the SUA level is low due to increased urate clearance.[14] In these patients, hypouricemia is associated with glycosuria[15], decreased metabolic control, hyperfiltration, and a late onset of disease, while elevated SUA is a feature of hyperinsulinemia or insulin resistance.[6]

Development of vascular complications was predicted independently by serum uric acid.[16] In a study conducted by Poonam Agrawal et al., it was concluded that the Uric acid levels are raised in patients with diabetic retinopathy when compared to those without retinopathy.[17] A study conducted by Ching-Chao Liang et al., concluded that there were increased serum uric acid levels which correlated with the severity of diabetic Retinopathy in patients with type 2 DM.[18] Vitreous UA and glucose concentrations were higher in proliferative than in non-proliferative DR. Focal UA production in the vitreous is thought to be involved in the pathogenesis and progression of DR.[19]

UA is lowered in Diabetes mellitus (DM) due to hyperfiltration[20], but decreased UA excretion during renal dysfunction raises SUA levels. Nazir Shah et al.[21] conducted a study in 2013 in 163 patients of diabetes mellitus (type 2) and proposed that elevation in the levels of uric acid was more in the diabetic patients with nephropathy (50%). In a study conducted in 60 diabetic patients by Nasri et al.[22], it was proved that there was a significant association between diabetic nephropathy and the levels of uric acid in the patient's serum. Petter Bjornstadet al[23] stated that there is a relation between the uric acid level elevation and development of diabetic nephropathy. Su-Mi Kim et al.[24] demonstrated that high UA contributes to the development of nephropathy in diabetic patients.

Several recent studies have been investigating therapeutic interventions to delay nephropathy progression.[25-27] Allopurinol therapy significantly decreases serum UA levels in hyperuricemic patients with mild to moderate CKD. Its use is safe and has been shown to help preserve kidney function when used for a duration of 12 months.[25] Febuxostat has a higher renoprotective effect than allopurinol, inhibits oxidative stress, has anti-atherogenic activity, reduces blood pressure, and decreases pulse wave velocity and left ventricular mass index, most likely due to a strong serum UA lowering effect.[27] In animal diabetic nephropathy model, allopurinol attenuated transforming growth factor-beta1-induced Smad pathway activation in tubular cells.[28]

The prevalence of diabetic peripheral neuropathy shows a significant correlation with increased UA levels.[29] Several studies demonstrated that, when controlled for confounding factors such as age, gender, BMI, renal function, and/or diabetic duration, Serum UA levels were high in patients with diabetic polyneuropathy and sudomotor dysfunction.[30,32]

The pathophysiology of diabetic neuropathy is not completely understood, and multiple metabolic imbalances underlie the development of diabetic neuropathy.[33] Hyperglycemia, dyslipidemia, and cardiovascular dysfunction are all independent risk factors for neuropathy. Probable etiologic factors include the polyol pathway, non-enzymatic glycation, free radicals, oxidative stress, and inflammation. Oxidative stress and inflammation are involved in XDH/XO activity. It is therefore speculated that UA generation by XDH/XO plays a role in diabetic neuropathy.

In a study conducted by Yili Xu et al., it was concluded that the patients with vascular complications had increased serum uric acid levels. He also said that this could be an independent predictor of vascular complications.[34] We found similar results in our study.

CONCLUSION

Diabetic patients with micro vascular complications have higher serum uric acid levels than those without complications. Also there was positive correlation between HbA1C and serum uric acid levels.

A Prospective Study of Correlatio of Magnetic Resonance Imaging of Brain Including MR Angiogram and Carotid Vertebral Arterial Doppler Study with the Clinical Features in Ischemic Stroke

Santni Manickam[1], Srinivasan T V[2], Velammal Petchiappan[3], Sujith Kumar S[4]

ABSTRACT

Introduction: Stroke is a global health problem. In this study we evaluated the risk factors, clinical features and their correlation with Magnetic Resonance Imaging (MRI) brain including Magnetic Resonance Angiogram (MRA) and Carotid Verteberal (CV) Doppler findings in patients presenting with acute ischemic stroke.

Material and methods: Seventy five patients of the age group 20 to 80 years admitted with acute ischemic stroke were enrolled for the study. A detailed history, clinical examination and blood investigations were done. MRI, MRA and CV Doppler were done in all patients. Serum Homocysteine levels and Anti-nuclear antibody assay (ANA) by Immunofluorescence (IF) were done in selected patients. Statistical analysis was done using SSPS version 16.0 for microsoft windows.

Results: In this study, there were more males than females. The mean age was 59 years. Young stroke population (<40 years) was 5%. Anterior circulation was predominantly involved than posterior circulation. Right Middle Cerebral Artery was the most common artery involved. There was positive correlation for clinical presentation and area of infarct and for areas of infarct and the vessels involved. Most common clinical presentations were weakness and slurring of speech. There were 3% intracranial anomalies. 56% had significantly elevated levels of homocysteine. 24% had ANA- IF positivity. Recurrence of stroke was seen in 17%; National Institute of Health Stroke Scale (NIHSS) score was higher in patients with recurrent stroke and right hemisphere infarcts.

Conclusion: There was positive correlation for clinical presentation and area of infarct and for areas of infarct and the vessels involved.

Keywords: Stroke, Anterior Circulation, Clinical co-relation, MRI, MRA Brain, Homocysteine, Area of Infarct.

INTRODUCTION

Stroke is a worldwide concern. Approximately two hundred lakh people every year suffer from stroke and of these fifty lakh do not survive.[1,2] In the developed nations, stroke is the leading cause for disability, second cause of dementia and third cause of death. Stroke is the second common cause of death and fourth leading cause of disability globally.[3] Stroke is an important cause for epilepsy, falls and depression in developed nations.[4] It is the leading cause of functional impairments, with 20% of survivors required hospital and nursing care for a prolonged period of more than 3 months duration and 15% - 30% of patient develop permanent disability.[5] Stroke is a life-changing event both financially and physically.

Stroke is caused by acute interruption of blood supply to the brain region it supplies, usually because of the blockade of a cerebral artery by a thrombus or emboli or by rupture of a vessel. This cuts off the supply of vital oxygen and nutrients to the brain, accumulation of free radicals causing damage to the brain tissue. An acute total occlusion of the vessels to the brain can cause death of the brain tissue within four to ten minutes. WHO clinically defines stroke as the rapid development of clinical signs and symptoms of a focal neurological disturbance lasting more than 24 hours or leading to death with no apparent cause other than vascular origin.[6] Among CVA, ischemic stroke constitutes 50%–85%[6,7] Hemorrhagic strokes - Subarachnoid hemorrhage and intra-cerebral hemorrhage, account for 1%-7% and 7%-27% respectively of all strokes worldwide.[8,9] In a study done, hemorrhagic stroke has significantly higher mortality when compared with ischemic stroke.

This study was conducted to evaluate various parameters like the risk factors of stroke, areas of brain involvement including the vessels involved and their clinical correlation in patients with acute ischemic stroke.

MATERIAL AND METHODS

This is a prospective observational study conducted in a tertiary hospital at Coimbatore between June 2015 and June 2016. A total of 75 patients in the age group of 20 to

DOI: http://dx.doi.org/10.21276/ijcmr.2019.6.6.60

80 years admitted with acute ischemic stroke to the medical and neurology wards were enrolled in the study. The study was initiated after obtaining clearance from the Institutional Ethical Committee. After obtaining informed consent, a detailed history attributable to the risk factors of stroke was obtained. A detailed clinical examination including baseline NIHSS score was obtained.

Investigations like complete hemogram, urine analysis, blood sugar, serum electrolytes, serum creatinine, blood urea, chest X-ray, fasting lipid profile, echocardiogram, electrocardiogram, MRI brain with MRA intracranium, CV Doppler were done in all patients. HbA1C was done if patient was found to be Diabetic based on random blood sugars. Investigations like ANA- IF and serum Homocysteine were done in selected patients.

STATISTICAL ANALYSIS

The data was reported as the mean +/- SD or the median, depending on their distribution. Frequencies were reported in percentages. The differences in quantitiative variables between groups were assessed by means of the unpaired t test. Non parametric test Wilcoxon signed test was used to assess the qualitative variables. To assess the difference in categoric variables between groups chi square test was used. Two tailed test was considered significant for all statistical tests when *P* value is <0.05. All data were analysed with a statistical software package (SSPS version 16.0 for microsoft windows).

Table-1: Clinical Presentation

RESULTS

Among the study population of 75 patients, 62 (83%) were males and 13 (17%) were females. 77% of total patients were aged more than 50 years. The mean age in the study population was 59 years. The young stroke population (<40 years) in this study was 5%.

The percentage of smokers, alcoholics and both was 17%, 5% and 24% respectively. In the study population the percentage of Type 2 Diabetes mellitus, Systemic hypertension, Dyslipidemia and combined was 11%, 9%, 35% and 41% respectively.

The most common symptoms were weakness, slurring of speech, deviation of angle of mouth as listed in Table 1.

In the study population, 47 patients (63%) had anterior circulation stroke and rest twenty eight patients (37%) had posterior circulation involvement. The most commonly involved arteries in the present study were Middle Cerebral Artery (MCA). Forty three out of seventy five patients (57%) had MCA involvement. Among the 43 patients with MCA involvement, right MCA was involved in 24 patients and 19 patients had diseased left MCA. Anterior cerebral artery (ACA) was involved in 4 patients. Posterior cerebral artery (PCA) was involved in twenty eight patients (Figure 1)

31% of the patients had intracranial obstruction due to atherothrombotic process which was classically seen in MRA intracraium. 11% of the patients had only extracranial occlusion which was seen in CV doppler studies. Twenty one percentage of the study population had both intracranial and extracranial leisions and 37% had normal IC & EC studies, probably related to small vessel ischemia.

Forty five patients (60%) had positive correlation of location of the infarct in the brain with either MRA or CV Doppler findings *P* <0.001. 37% had normal MRA & CV Doppler findings. Only in 3% of the study population there was no

			95% CI of mean				
	Mean	SD	Lower	Upper	Minimum	Maximum	Sig
Right	5.5	2.9	4.5	6.5	1	11	<0.05
Left	5.2	2.3	4.4	6.0	1	10	
Bilateral	4.8	3.3	2.0	7.5	2	12	
Total	5.3	2.7	4.7	5.9	1	12	

Table-2: Mean NIHSS score with Laterality

correlation of the same.

The clinical presentation was correlating with infarct in MRI in seventy patients (93%) P <0.05. There was no correlation in 7% of the study population due to bilateral involvement.

In this study population, recurrent CVA was seen in thirteen patients (17%). The mean age of recurrent CVA was 62 yrs and average NIHSS was 6.5 which were significantly higher than patients who had CVA for the first time. NIHSS was more in those with right hemisphere involvement when compared with left and bilateral involvement. The average NIHSS for right, left, bilateral involvement was 5.5, 5.2, and 4.8 respectively (Table 2). The maximum NIHSS in this study population was 12 which were noted with bi-hemisphere involvement.

Fasting serum Homocysteine levels and ANA –IF was done in 46 patients. Elevated homocysteine and ANA –IF positivity was noted in 56% and 24% respectively. Serum homocystiene was elevated in 36% of the alcoholics and 64% of non alcoholics. The highest value was 160 against <12 of the normal reference range.

In the study population, 2 (3%) had congenital anomalies. They were Frontal arteriovenous malformation and fetal PCA. None of the patients in the study population underwent thrombolysis.

DISCUSSION

Stroke among adults is rapidly increasing in the recent times. A systematic approach with good clinical history and examiantion, evaluation of risk factors, investigations and proper management of stroke is the need of the hour for acute ischemic stroke (AIS) patients.

In this study, males were more when compared with females. The male: female sex ratio among affected individuals is 7:1 in India. Among the females high risk groups are those taking oral contraceptives and pregnancy.[10,11]

The mean age was 59 years. In our study young stroke population (<40 years) was 5%. In a study at All India Institute of Medical Sciences (AIIMS), out of the 2,634 patients admitted with AIS, 440 patients (16.7%) were in the age group of 18-45 years and majority (83.4%) were male.[12] Smoking, alcoholism and dyslipidemia have been found to be significantly associated with stroke and its recurrence. Poor control of Diabetes Mellitus and systemic hypertension were associated with stroke recurrence.

Anterior circulation was predominantly involved than posterior circulation. Right MCA was the most common artery involved. There was positive correlation for clinical presentation and area of infarct and for areas of infarct and the vessels involved. Most common clinical presentation was weakness and slurring of speech. There were 3% intracranial anomalies

Eleven percent of patients had only extracranial occlusion. Extracranial occlusion that is carotid artery disease constitutes 10-20% of the strokes; stroke risk is directly proportional to the degree of occlusion. Carotid endarterectomy should be considered within 2 weeks if carotid stenosis of more than 70% involvement. There is less benefit of end carotidectomy and carotid stenting in patients with stenosis of carotids 50 to 69% and in asymptomatic patients, and there is literally no benefit in patients with stenosis of less than 50%

Hyperhomo-cysteinemia emerged as an important independent risk factor for ischemic stroke.[13] 56% had significantly elevated levels of homocystiene. The levels ideally have to be assessed 6 weeks later, for ideally diagnosing hyperhomocystinemia. Vitamins such as B12, B6 and folate play a vital role in the Homocysteine - methionine cycle[14], thus alcoholics are at risk of developing lower levels of folate and hence the increased Homocysteine levels. In contrary the proportion of elevated levels of Homocysteine was more in the non alcoholics when compared with alcoholics. There is correlation made in few studies that higher the Homocysteine values higher the mortality and recurrence of stroke.

24% had ANA- IF positivity but none of them had history of connective tissue disease. Incidental ANA- IF positivity in 24% of the study population raises concern whether it should be done routinely in all stroke patients and the same should be repeated to confirm the autoimmune etiology 6 weeks later.

Recurrence of stroke though was seen in 17%, but no mortality was observed among these patients. Relapse of alcohol, hard to kickoff smoking, poor adherence of medications was prime important in the stroke recurrence. NIHSS score was comparatively higher in these patients than in patients who had stroke for the first time. Similarly Right sided infarcts had higher NIHSS

None of the patients was thrombolysed due to varied reasons like exclusion criteria, after explaining the risks involved and mainly the time lapse in reaching the hospital. None of the patients was treated surgically.

CONCLUSION

There was positive correlation for the clinical presentation with area of infarct and for areas of infarct with the vessels involved. Elevated serum homocystiene levels and incidental positivity of ANA-IF noted in the present study raises concern; further studies are needed which will throw light in this area and indicate their significance in patients with acute ischemic stroke.

ACKNOWLEDGEMENT

I would like to thank all the patients who rendered their support for this study.

ABSTRACT

Background: Poorly controlled diabetes mellitus as indicated by elevated glycated haemoglobin (HbA1c) levels is associated with increased cardiovascular risk. C–reactive protein (CRP), an important cardiovascular risk factor, is elevated in diabetics with poor glycaemic control than those with good control. The present study assessed the correlation between HbA1c and CRP levels.
Methods: A prospective study was conducted in thirty type 2 diabetic patients irrespective of the disease duration and treatment; those with established target organ damage were excluded. HbA1c and hsCRP levels were measured at baseline; sugars were monitored monthly and medications optimised; at the end of six months HbA1c and hsCRP levels were measured.
Results: Mean age of the study subjects was 58.7±8.6 years; At the baseline, all had poor glycaemic control (HbA1c >7%); 15 had hsCRP >3 mg/L. At the end of 6 months, 5 achieved good glycaemic control (HbA1c <7%); 10 had hsCRP >3 mg/L. Baseline median hsCRP was 3.33 mg/L (0.68, 15.9) and at the end of 6 months it was 2.08 mg/L (0.48, 9.12). Mean HbA1c at baseline and end line was 10.6±1.55% and 8.43±1.84% respectively. There was significant reduction in both the mean HbA1c and median hsCRP at the end of 6 months (p <0.001). Positive correlation was observed between HbA1c and CRP at baseline (r=0.32, p=0.10). However, this was not observed at the end of 6 months.
Conclusions: There is positive correlation between the level of glycaemic control (HbA1c) and CRP levels; Better glycaemic control results in significant reduction in the hsCRP levels.

Keywords: C-reactive protein, Correlation, Glycaemic control, hsCRP, HbA1c

INTRODUCTION

Diabetes mellitus is a metabolic disorder characterised by the defects in insulin secretion or action; chronic hyperglycaemia can lead to microvascular and macrovascular complications if the blood sugars are not under optimal control. The glycaemic control is assessed by the measurement of glycated haemoglobin (HbA1c) which has its own advantages and disadvantages.[1] Till date HbA1c is the widely used tool to assess the glycaemic status. Poor glycaemic control as indicated by elevated HbA1c levels accelerates the atherosclerosis process and significantly increases the risk of cardiovascular events.[2] C-reactive protein measured by highly sensitive assays (hsCRP), is a very sensitive marker of the inflammatory activity in the arterial wall.[3,4] It is an important predictor of cardiovascular risk apart from the traditional risk factors.[5,6] It is interesting to note that chronic hyperglycaemia stimulates the release of various inflammatory cytokines (IL 6; TNF α) and induces the secretion of acute phase reactants by liver, which in turn results in elevation of CRP in association

with elevated fasting plasma glucose.[7] Studies had shown that elevated CRP levels is associated with an increased risk of future development of diabetes mellitus.[8] Also, people with diabetes mellitus had elevated levels of CRP than non -diabetics.[9,10] We understand that both chronic systemic inflammation and hyperglycaemia contribute to the development and progression of atherosclerotic cardiovascular disease. Experimental and clinical studies have confirmed the inter-relationship between CRP, hyperglycaemia and atherosclerosis.[11,12] In states of elevated CRP, hyperglycaemia exaggerates the pro-atherogenic effects of CRP.[12,13] Few studies which had assessed the relationship between CRP levels and the level of glycaemic status showed conflicting results; some studies had proven the positive co-relation between glycaemic control and CRP levels.[14-16] while some failed to do so.[6] Also, the effect of good glycaemic control on CRP levels is not clear. The aim of this study is to determine the co-relation of glycaemic control as measured by HbA1c levels with hsCRP in patients with type 2 diabetes mellitus and to determine if better glycaemic control reduces CRP levels.

METHODS

The study was conducted in the Department of Medicine, PSG Institute of Medical Sciences, Coimbatore. Patients with type 2 diabetes mellitus diagnosed on the basis of WHO criteria were prospectively enrolled in the study from September 2014 to May 2015 irrespective of disease duration and treatment. Patients with established cardiovascular disease, chronic kidney disease, infections, haemolytic anaemia, on drug therapy with statins and non-steroidal anti -inflammatory drugs were excluded from the study. The study was approved by the Institutional Ethics Committee (approval number: 14/184); informed consent was obtained from all the study participants.

At the time of enrolment in the study, blood samples were collected from the participants for measurement of HbA1c and hsCRP levels. HbA1c was measured by high pressure liquid chromatography (Variant II Turbo - HbA1c kit - 2.0). High sensitive CRP was measured by particle enhanced turbidometry assay (Cobas Integra 400 plus). They were followed up on a monthly basis, clinical evaluation was done; fasting and postprandial blood sugars were monitored and adjustment of anti-diabetic medications done on an individual basis in addition to re-enforcement on life style modification (diet and exercise). At 6 months, blood samples were collected for HbA1c and CRP levels.

Statistical analysis

Descriptive statistics were reported as mean ± SD for normally distributed data, median with 25th and 75th for the non-normal data. Paired t test or Wilcoxon Signed rank test was used to test the significance for the change in HBA1c and CRP after 6 months from baseline. Spearman's Rank correlation is used to assess the correlation between the variables. P value less than 5% was considered statistically significant. All the analyses were done using SPSS version 23.0.

RESULTS

Among the 30 subjects studied, 70% of people were between the age group of 50-70 years; the mean age of the study subjects was 58.7±8.6 years; there were 17 females (57%) and 13 males (43%).

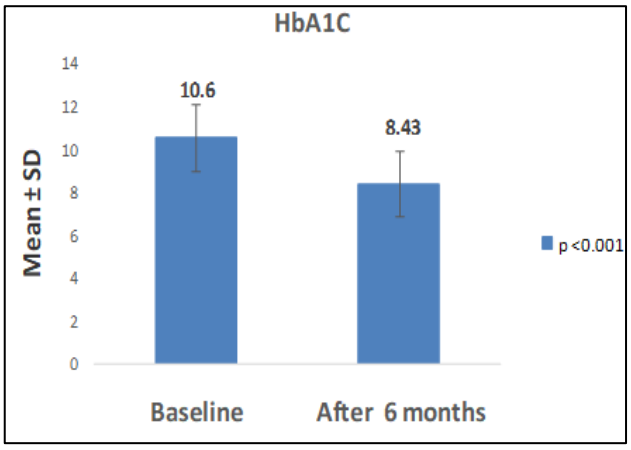

Figure 1: Mean HbA1c levels in % at baseline and at the end of 6 months.

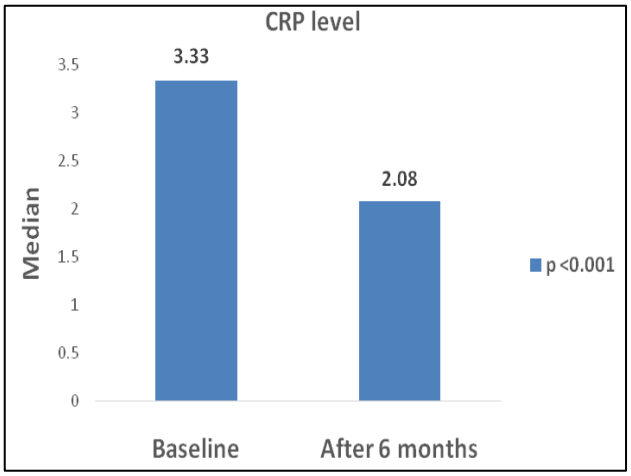

Figure 2: Median CRP levels in mg/L at baseline and at the end of 6 months.

At the baseline, all of them had poor glycaemic control (HbA1c >7%); 15 had hs CRP >3 mg/L. At the end of 6 months, 6 patients lost to follow up; HbA1c and hsCRP levels were measured for the remaining subjects; 5 achieved good glycaemic control (HbA1c <7%); 10 had hs CRP >3 mg/L. The mean hsCRP at baseline and at the end of 6 months was 7.85±9.75 and 4.88 ±5.41 mg/L respectively. Baseline median hsCRP was 3.33 (0.68, 15.9) and at the end of 6 months it was 2.08 (0.48, 9.12). The mean HbA1c at baseline and end line was

10.6±1.55% and 8.43±1.84% respectively. There was statistically significant reduction in both the mean HbA1c and median hsCRP values at the end of 6 months with effective individual based anti-diabetic treatment (p <0.001). The results are depicted in Figure 1 and 2. Positive co-relation was observed between HbA1c and CRP at baseline (r=0.32, p=0.10) although it was not statistically significant. However, this correlation was not observed at the end of 6 months.

DISCUSSION

The role of chronic low-grade inflammation contributing to the pathogenesis of diabetes and its related complications is well known. Chronic hyperglycaemia induces oxidative stress and chronic inflammatory state, which jointly contribute to the pathogenesis of atherosclerosis. C-reactive protein levels more than 3.0 mg/L is associated with worse cardiovascular outcome.[17] Various studies had demonstrated significantly elevated serum hsCRP levels in diabetics than non-diabetics.[15,16,18] Also, significant elevation was noted in those with poor glycaemic control compared to those with good glycaemic control.[15] Recent research has shown that HbA1c and CRP jointly contribute to the increased cardiovascular risk in patients with advanced cardiovascular disease.[19]

The mean hsCRP levels in the study population at baseline was 7.85±9.75 mg/l which is in accordance to that observed in another Indian study conducted in Bangalore (6.9±9.3 mg/l); while Saudi Arabian and Bangladesh studies had shown mean hsCRP levels lower than that observed in the present study, 1.13 and 2.3 mg/L respectively.[6,18] The reason for this difference in CRP levels is unclear; further studies are needed to assess the differences in ethnic groups; standardisation of the techniques used for measurement of hsCRP.

A positive co-relation was observed between HbA1c and hsCRP levels at the baseline in the present study indicating that the change in HbA1c affects hsCRP levels in the same direction. There are other studies which support our results. In a cross-sectional study conducted by Gohel et al, a significant positive linear relationship was observed between hsCRP and HbA1c.[15] Li et al, Khan DA et al, and Sarinnapakorn V et al, also had made similar observation in their studies.[20-22] Kashinakunti et al, in their case control study noted significantly high hsCRP levels in diabetics than controls; also noted positive co-relation between hsCRP and HbA1c, although non-significant.[16] Low HbA1c levels strongly related to negative hs-CRP levels as observed by Amanullah S et al.[23] Another study conducted in Sudan showed significant correlation between CRP levels with fasting plasma glucose and HbA1c.[24] All the above-mentioned studies were cross-sectional observational studies which assessed the relationship between Hba1c and CRP.

On literature search authors could find only one study conducted in Mexico which had assessed prospectively the effects of good glycaemic control on the CRP levels. The study was conducted on newly diagnosed type 2 diabetes patients; they were followed up for 6 months by intensive blood sugar management. There was significant reduction in HbA1c from baseline value of 13.0±4.9 to 8.9±2.9% at the end of 6 months, p <0.00001 which resulted in significant reduction in hsCRP levels (9.6±6.2 to 6.3±3.0 mg/l, p <0.00001). The present study also had shown similar results; significant reduction in hsCRP levels at the end of 6 months compared to baseline was observed following better glycaemic control and reduction in HbA1c levels. In that study, although glycaemic control was achieved in 71 patients at the end of 6 months, only 29 (40.8%) of them showed a reduction in CRP levels to 3 mg/l or less and the remaining 42 (59.2%) maintained a high CRP level. The study concluded that CRP is moderately influenced by glycaemic control.[25] Similar to that observation, the present study also showed that only 41.6% of the study subjects achieved CRP levels <3 mg/L by 6 months.

The positive co-relation observed between HbA1c and CRP at the baseline was not observed at 6 months; this may be because CRP is moderately influenced by glycaemic control.25 There are other variables which affect CRP levels like age, gender, body weight, LDL cholesterol levels. The present study did not take into considerations those variables which is a limitation of the present study.

CONCLUSION

There is positive correlation between the level of glycemic control (HbA1c) and CRP levels; Better glycemic control results in significant reduction in the hsCRP levels.

A Study of Serum Albumin Levels in Acute Ischemic Stroke and its Correlation with Clinical Outcome

Santni Manickam[1], Joel Franklin[2], Velammal Petchiappan[3], Sujaya Menon[4]

ABSTRACT

Introduction:: Stroke is a global health problem. Studies have shown that serum albumin level is an independent predictor of ischemic stroke outcome. In the present study we compared the serum albumin and the volume of infarct with the clinical outcome.

Material and methods: Fifty patients of age more than 18 years with clinical and radiological evidence of acute ischemic stroke were included in the study. The severity of stroke at admission was assessed by National Institute of Health stroke scale (NIHSS). Serum albumin levels were measured at admission within 36 hours after stroke onset. Functional outcome was measured 1 week post admission and after 3 months during follow up using modified Rankin scale (mRs). A score of mRs >3 or death was taken as poor outcome. Statistical analysis and interpretation of the data was done. *P* value of <0.05 was taken as statistically significant.

Results: The mean age group of the study population was 53 years, male patients had more severe stroke compared to female patients. Most common risk factors were diabetes mellitus and systemic hypertension. Patients with a good outcome had lower NIHSS score, low mRS score, high albumin and low volume of infarct. Those with worst outcome had higher NIHSS, high mRS and high volume of infarct.

Conclusion: Relatively high serum albumin level in acute stroke patients decreases the risk of poor outcome. It is not only serum albumin but volume of infarct also does play a role in the final outcome of the patient.

Keywords: Acute Ischemic Stroke, Serum Albumin, Volume of Infarct, Functional Outcome

INTRODUCTION

Stroke is a global health problem. Around 20 million people suffer from stroke every year and about 5 million people among them do not survive.[1,2] It is the second most common cause of death and fourth leading cause of disability worldwide.[3] Stroke is also a predisposing factor for epilepsy, falls and depression in developed countries.[4] It is a leading cause of functional impairments, with 20% of survivors requiring institutional care after 3 months and 15% - 30% being permanently disabled.[5]

It is a well known fact that if stroke patients have associated protein energy malnutrition they tend to have poor outcome.[6] Studies have shown that serum albumin level is an independent predictor of ischemic stroke outcome.[7,8] Experimental studies have shown that human albumin infusion after stroke onset significantly improves the neurological function and reduces the infarct volume.[9] Although low serum albumin is associated with poor neurological outcome, albumin therapy in acute stroke patients is not beneficial as shown by the ALIAS (Albumin in Acute Ischemic Stroke) part 1 and 2 trials which evaluated the efficacy and safety of human albumin therapy in acute ischemic stroke.[10,11] The volume of infarct and its co-relation with the serum albumin was not studied in any of the previous studies. In the present study we compared the serum albumin and also the volume of infarct with the clinical outcome.

MATERIAL AND METHODS

The study was a Hospital based prospective study which included a total of fifty patients of age more than 18 years with clinical and radiological evidence of acute ischemic stroke admitted to the department of General Medicine and Neurology in a tertiary care centre in South India. Patients with Cerebral haemorrhage of any aetiology, Liver disease; Cardiac failure, Nephrotic syndrome, Diabetic nephropathy, Protein losing enteropathies and Malignancies were excluded from the study. Diagnosis of ischemic stroke is based on clinical observation confirmed by radiological imaging.

Prior to the commencement of the study, ethical clearance was obtained from Institutional Human Ethical Committee. The selected patients were briefed about the nature of the study and written informed consent was obtained from them in regional language. Patients were examined clinically in detail and the severity of stroke was assessed by National Institute of Health stroke scale (NIHSS) at baseline. Blood samples for assessment of albumin were collected at admission within 36 hours after stroke onset. Serum albumin estimation was done using Bromo Cresol Green (BCG) end point method. Functional outcome was measured 1 week post admission and after 3 months during follow up using

modified Rankin scale (mRs). This scale runs from 0-6, running from perfect health without symptoms to death. A score of mRs: 0-3 was taken as favourable score and mRs: 4-6 was taken as unfavourable score. Serum albumin level <3.5 g% is considered as low.

The data were reported as the mean +/- SD or the median, depending on their distribution. The differences in quantitative variables between groups were assessed by means of the unpaired t test. Comparison between groups was made by the non-parametric Mann- Whitney test. ANOVA was used to assess the variables. The chi square test was used to assess the difference in categoric variables between groups.

Statistical analysis and interpretation of the data was done by using SPSS version 20. *P* value of <0.05 using two tailed test was taken as being of significance for all statistical tests

Serum albumin g/dl	NIHSS score		Total	*P* value
	≤10	>10		
3-3.4	0	1	1	0.124
3.5-3.9	10	3	13	
4-4.4	24	3	27	
>4.4	7	2	9	
Total	41	9	50	

Table-1: Serum Albumin with NIHSS Score

RESULTS

Among the study population of 50 patients, 44(88%) were males and 6(12%) were females. Out of 50 patients, 3 patients (1 male, 2 females) lost to follow-up. Number of patients with NIHSS score less than or equal to 10 was 41 and more than 10 was 9. Among those with NIHSS more than 10, there were seven males and two females. NIHSS score of 10 or less than 10 was seen in high numbers in 56-65 and >65 years age group. The risk factors of the study population and the nature of the ischemic stroke were tabulated in Figure 1and Figure 2 respectively.

Among the 47 patients, number of patients who had significant disability was 15. Among them 6 were in the age group of 56 to 65. Number of patients who had mild disability was 32.Among them about 11 patients were in the age group more than 65. After 3 months, number of patients with significant disability were 4 and number of patients with mild disability were 43.Significant improvement was seen in the age group of 56 to 65 (9 to 13).

Out of the 43 male patients, 14 patients had significant disability (mRs >3) and 29 patients had mild disability (mRs ≤3). Among the 14 with significant disability, 3 had death as outcome. Out of the 4 female patients, 1 had significant disability and died during the first week. Remaining 3

Table-5: Comparison with other studies

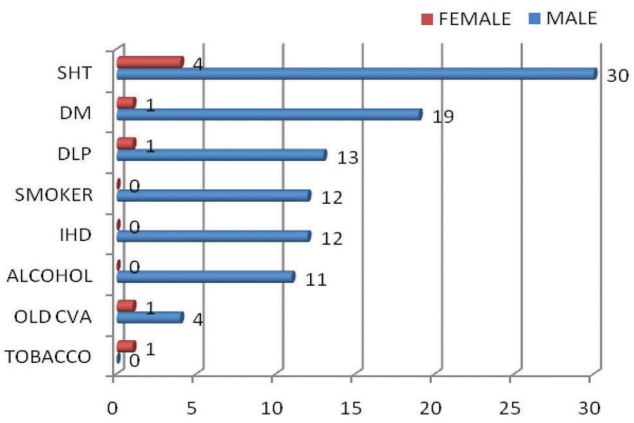

Figure-1: Risk factors of stroke in the study population

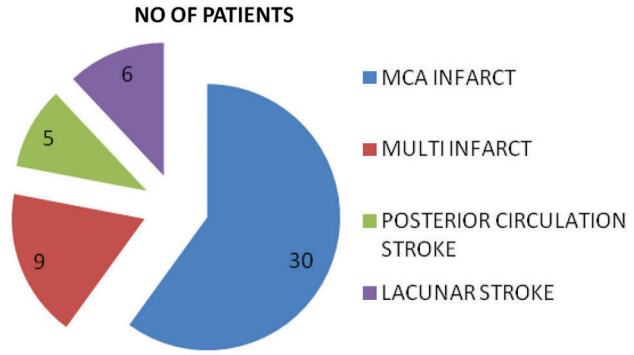

Figure-2: Frequency of lesion in MRI / CT brain

patients had mild disability. At 3 months follow-up, among the male patients, number of patients with significant disability dropped from 14 to 4. In the female group, the 3 patients with mild disability had improvement in the mRS score and didn't worsen.

Among 50 patients, only one patient in the age group of 46 - 55 had low serum albumin levels (<3.4 g/dl)). Mean albumin was 3.8. Majority of patients had albumin levels between 4 and 4.4. Both males and females showed similarity in this.

Table 1 showed that out of 9 patients with NIHSS score >10, only one patient had low serum albumin level<3.5 g/dl. The remaining 41 patients with a NIHSS score of less than 10 had serum albumin level above 3.5 g/dl.

On co-relating serum albumin level with mRS score at 1 week after stroke onset, while all the 32 patients with mRS ≤3 had serum albumin levels ≥3.5 g/dl, only one out of 15 with mRS > 3 had low serum albumin levels, the rest had serum albumin levels ≥3.5 g/dl. *P* value was 0.319. Hence there was no significant correlation. (Table 2) On co-relating serum albumin level with mRS score at 3 months after stroke, it was noted that out of 14 patients with high albumin levels who initially had mRS > 3 at 1 week, 9 had clinical improvement and the remaining 5 persisted to have mRS > 3 at 3 months post stroke. Also, a single patient with serum albumin <3.5 had an improvement in mRS score from baseline.

Out of 47 patients, volume of infarct could not be calculated for one patient. In the rest, the mean volume of infarct is significantly higher in those with mRs >3 than those ≤3 score at 1 week after stroke. (*P* value was 0.001) The results are tabulated in Table 3

The volume of infarct and mRS scale was compared during 3rd month using ANOVA method. *P* value was 0.146. This showed there was no correlation between volume of infarct and outcome during 3rd month. (Table 4)

DISCUSSION

It is well known that serum albumin plays a major role in the clinical outcome of vascular diseases. The neuroprotective effect of albumin is due to its various properties like anti-inflammatory and anti-oxidant effects, inhibition of thrombosis in microcirculation.[12-14] It reduces hematocrit level and also plays a vital role in aggregation of erythrocytes[15] by increasing low shear viscosity and decreasing erythrocyte sedimentation under no-flow conditions. Albumin has a good antioxidant property. Other neuroprotective effect of albumin in stroke includes Prevention of thrombosis and Prevention of leukocyte adhesion within post capillary microcirculation in the early reperfusion phase.

Albumin captures the oxygen free radicals and slows the production of reactive hydroxyl radical species. Albumin has a peculiar property of binding to copper ions by doing so it inhibits the process of copper ion dependent lipid per oxidation at cell membrane. It has also been postulated that albumin exerts neuroprotection by binding to lysophosphatidylcholine. Free lysophosphatidylcholine increases leukocyte adhesion molecules which lead to inflammatory mediated damage on vascular endothelium. It also causes apoptosis when it is present in high concentration. Based on the above said properties it was postulated that albumin infusion post ischemic stroke may be beneficial in long term outcome.

Experimental studies in rats done by Belayev et al. showed that high-dose human albumin therapy, if administered within 2 to 4 hours after stroke onset, is highly effective in improving neurological status and in reducing infarction volume and extent of brain swelling.[16]

Based on all the evidences human trial known as ALIAS (Albumin In Acute Ischemic Stroke) was conducted. It showed that treatment with intravenous albumin 25% at 2 g/kg was not associated with improved outcome at 90 days and was associated with increased incidence of intracerebral haemorrhage and pulmonary oedema. Further research is required to come to conclusive evidence that human albumin infusion can improve the clinical outcome of stroke patients as there were good results in rat models of stroke.

The mean age group of the study population was 53 years, predominantly middle aged group which is a decade lower than the peak age group of stroke in western countries.[17] In the present study, male patients had more severe stroke compared to female patients. Most common risk factors noticed in this study were diabetes mellitus and systemic hypertension.

Around 42 patients had good outcome in this study and only 5 patients had poor outcome. Most of the previous studies showed that patients with good outcome had lower NIHSS

score and high serum albumin level on admission and those with worst outcome showed high NIHSS score and low serum albumin level. In our study also patient with low NIHSS and high albumin had good neurological outcome. Only one patient had low albumin and high NIHSS score had unfavourable mRs score after 1 week; however his mRs score improved after 3 months

The studies which were done earlier didn't take volume of infarct into account. The patients with poor outcomes had a mean volume of infarct of around 26.51 and those with good outcome had a mean volume of infarct of around 5.59. Even though there was significant correlation between volume of infarct and mRS score at 1 week there was no significant correlation between them at 3 months

In this study, most patients with a good outcome had lower NIHSS score, low mRS score, high albumin and low volume of infarct. Those with worst outcome had higher NIHSS, high mRS and high volume of infarct. The one patient with low serum albumin also had a good outcome in 3 months. It is not only serum albumin but volume of infarct also do play a role in the final outcome of the patient which was not considered in other studies. Those who had poor outcome had a mean volume of infarct of around 25 cm^3 and also there was statistical significance between volume of infarct and mRS at 1 week. Even though clinically most of the patients had good outcome after 3 months based on mRS score, statistically *P* value was not significant. Hence this study is contrary to the evidence that serum albumin is a long term predictor of ischemic stroke outcome. The disadvantage of this study was that not enough number of patients could be obtained with low serum albumin levels.

CONCLUSION

Though the risk of stroke increases with age, our patients were predominantly in the middle aged group. Male patients had more severe stroke compared to female patients. Most common risk factors noticed in this study were diabetes mellitus and systemic hypertension. Most patients with a good outcome had lower NIHSS score, low mRS score, high albumin and low volume of infarct. Those with worst outcome had higher NIHSS, high mRS and high volume of infarct. The one patient with low serum albumin also had a good outcome in 3 months. It is not only serum albumin but volume of infarct also does play a role in the final outcome of the patient.

ACKNOWLEDGEMENT

We would like to acknowledge the patients who participated in the study.

ABSTRACT

Background: Dengue infection is a major public health threat; early recognition is crucial to improve the survival in severe dengue. Although there are various biomarkers to predict the severity of dengue, they are not routinely used in clinical practice for prognostication. We analyzed whether serum ferritin can be used to predict the severity at an earlier stage.
Methods: A hospital based prospective observational study was done involving 119 dengue cases diagnosed by positive NS1 antigen or dengue specific serology (capture ELISA). Serum ferritin was measured in all at the time of diagnosis. Clinical and platelet count monitoring was done daily; classified as severe and non-severe according to 2009 WHO criteria.
Results: Out of 119, 5 developed severe dengue; patients with severe dengue had significantly lower median platelet count ($p<0.0001$); higher ferritin levels ($p=0.03$) and hospital stay ($p<0.0001$) than non-severe group. Age had a significant negative co-relation with platelet count ($r= -0.427$; $p<0.0001$); positive correlation with ferritin levels ($r=0.16$; $p=0.08$) and hospital stay ($r= 0.26$; $p=0.004$) indicating that elderly subjects are at risk of severe disease. Serum ferritin levels negatively correlated with the platelet count ($r= -0.51$ $p<0.001$). High ferritin levels in severe cases are noted from day 4 of clinical illness.
Conclusions: Elevated serum ferritin levels can be used as a potential early prognostic marker to predict the severity of dengue infection in clinical practice.

Keywords: Predictor of severity, Serum ferritin, Early, Severe dengue

INTRODUCTION

Dengue infection poses a major health problem in tropical and subtropical countries.[1] According to World Health Organization, around 50 to 100 million new infections are estimated to occur every year in more than 100 endemic countries across the world; of which around 500000 people with severe dengue require hospitalization each year and about 2.5% of those affected die.[2] The burden of the disease is so much that in the year 2012 World Health Organization classified the disease as "the most important viral disease that is transmitted by mosquitoes".[3] Dengue is caused by dengue virus serotypes I-IV and transmitted to human beings by the bite of Aedes mosquitoes.[4]

The clinical spectrum of dengue infection is variable from mild fever to severe forms of dengue such as dengue hemorrhagic fever and dengue shock syndrome. Severe dengue is characterized by severe thrombocytopenia with major bleeding, plasma leakage resulting in fluid accumulation, respiratory distress and

multi-organ dysfunction.[5] The presence of certain clinical warning symptoms which help to predict the severity are bleeding, skin rash, nausea, vomiting, abdominal pain and hepatosplenomegaly.[6]

Clinically severe dengue results from interplay between virus related virulence factors and host factors which include inflammatory response of the host to infection with exuberant T and B cell activation, release of cytokines (cytokine storm), altered endothelial function with increased vascular permeability and nutritional status of the host. [7]

In clinical practice, patients with dengue infection are grouped as 1) those with warning signs that need intensive monitoring and aggressive management 2) those without warning signs. Non-severe cases without warning signs can develop into severe dengue later during the course of illness. They are at risk of developing complications related to plasma leakage and thrombocytopenia often at the end of febrile stage of illness (third to fifth day of illness) which if unrecognized can be fatal.

Studies had identified various biomarkers for immune and endothelial cell activation, biochemical and genetic markers to predict the severe dengue.[8] The clinical utility of these markers is limited since measurement of these markers like soluble receptors, cytokines, growth factors, vWF; genetic profiling etc. is technically difficult and not widely available. Acute phase reactants like alpha1 anti-trypsin, ceruloplasmin and ferritin levels are elevated during dengue infection; they have a longer half-life unlike the cytokines, and it is feasible to measure their levels.[9]

Increased serum ferritin has been associated with severe dengue in children.[10] Hyperferritinemia in dengue infected subjects is associated with intense immune activation and coagulation disturbances as noted in Aruba Dengue outbreak.[11] An Indian study had shown that serum ferritin levels are significantly elevated in dengue infected cases compared to the controls; On group analysis, cases with severe dengue had higher ferritin levels than milder forms which was noted both during the febrile and defervescence stages of the illness.[9]

Results from the previous studies had shown that hyperferritinemia is associated with severe disease which is noted throughout the disease course. In a Malaysian study, a large proportion of patients developed severe dengue early during febrile stage. [12] It is very crucial to predict the risk of progression to severe dengue at the earliest, by simple measurable tests to initiate appropriate intensive, supportive therapy.

In the present study, we analysed whether serum ferritin measured during early disease course can be used as a marker to indicate the severity which helps to triage and manage them appropriately.

METHODS

This is a hospital based prospective observational study conducted from April 2015 to June 2016 in a tertiary care centre, PSG Institute of Medical Sciences and Research Centre (PSGIMS and R), Coimbatore, South India. The study was conducted in accordance with the Declaration of Helsinki, and the study protocol was approved by the Institutional Human Ethics Committee, PSGIMS and R. All adult patients who were hospitalized and diagnosed with dengue infection either by dengue NS1 antigen or positive dengue specific serology were included in the study after obtaining their informed consent for participation in the study. Patients with chronic inflammatory conditions or diseases; iron overload status; sideroblastic anemia; thalasemia; malignancy; liver disease were excluded from the study.

Study methodology

The study was based on prospective collection of data in dengue infected patients who fulfill the criteria as mentioned above. Diagnosis was based on NS1 antigen test (done with J. Mitra dengue NS1 Ag Microlisa kit) when the presentation was less than 5 days of illness or positive dengue specific serology (dengue IgM and dengue IgG done by Panbio dengue IgM; dengue IgG capture ELISA) if presented after 5 days of illness. Serum ferritin levels were measured if the presentation was less than 7 days from the onset of fever. After informed consent, 2ml of blood was collected from the study subjects; ferritin assay was done (by electrochemiluminescence immunoassay -COBAS e411) at the time of diagnosis if the diagnosis was made in the study center; or at the time of admission if referred from an outside hospital with positive test results (NS1 or dengue serology positive).

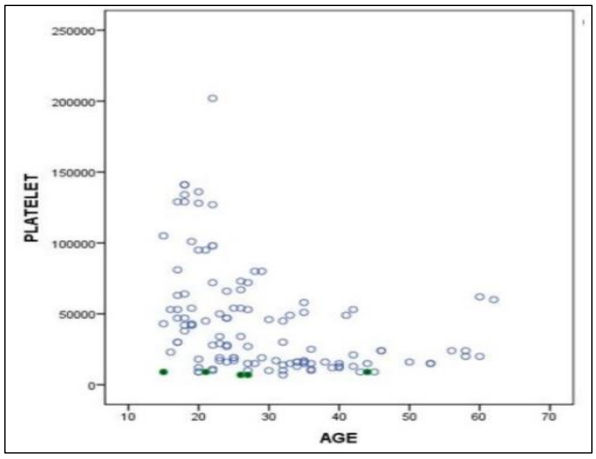
The clinical course of the disease and platelet count were monitored carefully on a daily basis and patients were classified as having severe and non-severe infection as per WHO 2009 criteria; classified as severe dengue when shock, respiratory distress, severe bleeding; organ impairment occur.[5] Mean lowest platelet count was calculated in both the subgroups from all the platelet count values obtained on a daily basis during the hospital stay. Mean ferritin levels were calculated and compared in both the subgroups.

Statistical analysis

Descriptive statistics were reported as mean±Standard deviation (SD), median with 25^{th} and 75^{th} percentiles. Mann Whitney U test was used to compare platelet count and serum ferritin between severe and non-severe dengue groups. Spearman's Rank correlation was used to assess the correlation between age with platelet count, serum ferritin and hospital stay. All analyses were done using SPSS version 21.0. P value less than 5% was considered statistically significant.

RESULTS

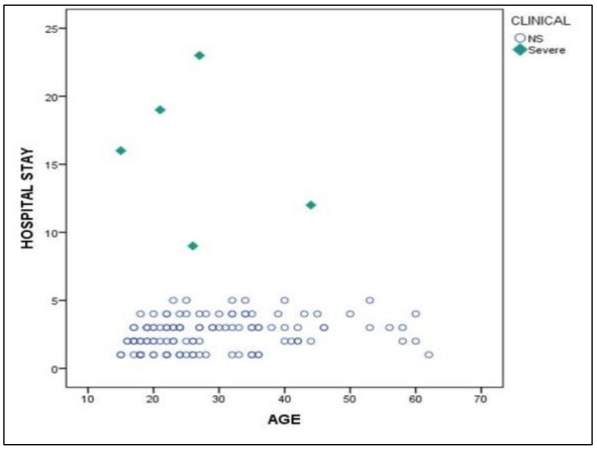
A total of 119 subjects were analyzed, of which there were 68 males (57.14%) and 51 (42.85%) females. The mean age of the study population was 29.1±11.4 years. About 50% of the study population was less than 25 years. There was no significant difference in the mean age between male and female. Diagnosis of dengue infection was established by positive NS1 antigen in 61 subjects while in the remaining 58, it was diagnosed by positive dengue serology.



Among the total 119, only 5 (4.2%) subjects had clinical severe dengue, of which 4 were males and one female. The mean lowest platelet count was 40426.47×10^9/L in males, 45000×10^9/L in females. Around 75% of the study population stayed in the hospital for ≤ 3 days; 16% stayed for 4 days; 5% stayed for 5 days. Around 5% had a hospital stay for ≥9 days. Serum ferritin levels were measured in 14 subjects on day 3; 19 on day 4; 36 on day 5; 29 on day 6 and for the remainder 21 subjects it was measured on day 7. The mean ferritin levels measured was 1399.53±690.68ng/ml; (median-1856). The mean hospital stay was 3.11 days.

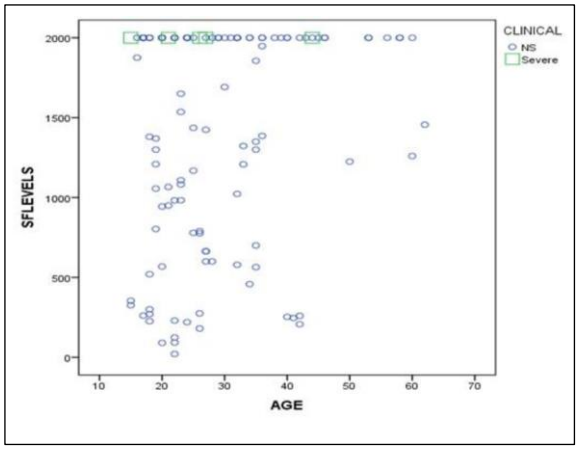
Table 1: Comparison of serum ferritin, platelet count and hospital stay in severe and non-severe dengue.

	Severe dengue	Non-severe dengue	P value
Serum ferritin ng/ml	2000 (2000, 2000)	1593 (757, 2000)	0.03*
Platelet count ×109/l	9000 (7000, 9000)	29500 (15750, 55000)	<0.0001*
Hospital stay days	16 (11, 21)	3 (2, 3)	<0.0001*



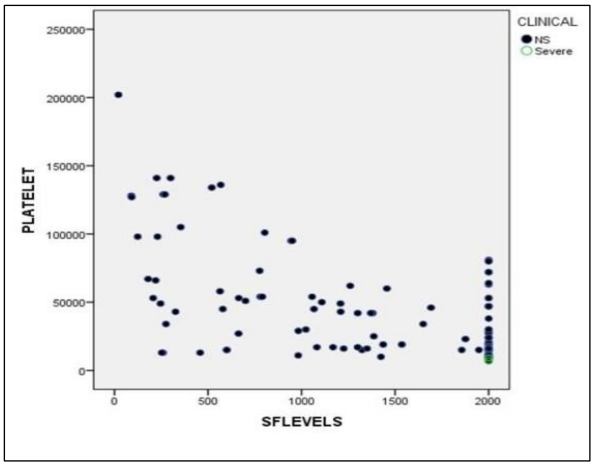
Median platelet count was significantly lower among patients who had severe dengue as compared to non-severe dengue group (Table 1). The median platelet count recorded during daily monitoring of platelets throughout the hospital stay were 9000 ×10^9/L (7000, 9000) in severe and 29500×10^9/L (15750, 55000) in non-severe dengue respectively. The median hospital stays, and serum ferritin levels were significantly higher among severe dengue subjects as compared to non-severe group (Table 1). The median serum ferritin levels and hospital stay among severe and non-severe dengue patients were 2000ng/ml (2000, 2000) vs. 1593ng/ml (757, 2000) and 16 (11, 21) vs. 3 days (2, 3) respectively.

In the present study, higher age showed a significant negative correlation with platelet count (Pearson co-efficient r= -0.427; p<0.0001). Also, higher age positively correlated with hospital stay (r= 0.26; p=0.004) and ferritin levels (r=0.16; p=0.08). The correlation with hospital stay is significant. Serum ferritin levels showed a significant negative correlation with the platelet count (Pearson co-efficient r= -o.51; p<0.001). The results are depicted in Figures 1-4.



Age negatively correlated with platelet count which is significant (r= -0.427; p<0.0001*)

Figure 1: The co-relation co-efficient between age (years) and platelet count(x109/L).



Age positively correlated with hospital stay which is significant (Pearson co-efficient r= 0.26; p=0.004*)

Figure 2: The co-relation co-efficient between age (years) and hospital stay (days).

Age positively correlated with serum ferritin levels (non significant r=0.16; p=0.08)

Figure 3: The co-relation co-efficient between age (years) and SF levels (serum ferritin in ng/ml).

Serum ferritin levels showed a significant negative correlation with the platelet count (Pearson co-efficient r= –o.51 p<0.001*)

Figure 4: The co-relation co-efficient between SF levels (serum ferritin in ng/ml) and platelet count.

Serum ferritin measured from day 3 to day 7 of illness was compared in both the severe and non-severe groups and reported in Table 2. It was observed that non-significantly, patients who had severe dengue had higher median serum ferritin levels from day 4 onwards as compared to non-severe dengue cases.

Table 2: Comparison of serum ferritin levels in severe and non-severe dengue measured from the day 3 to day 7 of illness.

Serum ferritin measurement	Ferritin level in ng/ml		P value
	Severe dengue	Non-severe dengue	
3 day	-	n=14 1486 (1013, 2000)	-
4 day	n=1 2000±0 2000 (2000, 2000)	n=18 1001±811 859 (242, 2000)	0.421
5 day	n=2 2000±0 2000 (2000, 2000)	n=34 1549±587 2000 (1183, 2000)	0.349
6 day	n=1 2000±0 2000 (2000, 2000)	n=28 1222±727 1315 (565, 2000)	0.414
7 day	n=1 2000±0 2000 (2000, 2000)	n=20 1512±722 1974 (1103, 2000)	0.571

Serum ferritin measured from day 4 to7 of illness was high in severe dengue compared to non-severe cases, although not statistically significant

DISCUSSION

Currently there is no specific drug or preventive vaccine available for dengue infection. The mainstay of management of dengue infected subjects is supportive care and close monitoring for complications.[13] Most of these patients recover within 5 to 7 days from onset of the febrile illness while only a small percentage progress to severe dengue, with a study quoting 5%.[14] Severe dengue often occurs at the end of febrile or during convalescent stage and carries a very high mortality. It is very crucial to predict the severe form well in advance even prior to the appearance of warning signs by a simple diagnostic marker so that early identification and appropriate management would improve the outcome in these patients.

Increased expression of acute phase reactants is observed in patients with severe dengue infection when compared to non-severe cases.[9] This serves to prognosticate the dengue infected patients well ahead of the appearance of clinical warning signs. One such acute phase reactant is ferritin which is produced by reticuloendothelial cells in response to infection and inflammation. Ferritin is highly elevated in dengue infected patients than in patients with other febrile illnesses.[11] Hyperferritinemia seen in these patients exhibit two opposite functions; Early in the phase of clinical illness, increased serum ferritin levels exert a protective effect by chelating the toxic free iron radicals at the site of inflammation.[15] while in severe cases, raised ferritin may assume a pathogenic role by activating immune cells resulting in cytokine storm.[9]

Males constitute 57.14% of the study population in the present study which was in accordance with other studies. The mean hospital stay was comparable with other studies. The mean duration of hospital stay was 2.73±1.41 days as observed by Ahmed at al, and 3.7±1.02 days in a study conducted in Rawalpindi.[16,17]

Results from the present study showed that hyperferritinemia is associated with severe dengue which is noted in other studies as well.[9-11, 17] To analyze whether serum ferritin can predict the severity earlier in the course of illness, day wise serum ferritin levels was compared in both the sub-groups; the serum ferritin levels were higher in severe dengue cases when compared to non-severe group and this increase is noted from day 4 of illness onwards which clearly indicates that serum ferritin can predict the severity of dengue at an earlier stage.

A study conducted during a dengue outbreak on the Caribbean island Aruba which compared the ferritin levels in dengue infected patients with those having other viral illnesses concluded that ferritin is a useful clinical marker to differentiate dengue from other febrile illnesses; serum ferritin levels >1500ng/ml is associated with severe disease ; serum ferritin levels measured on day 4-5 better predicts the outcome of dengue infection and it concluded that these patients with hyperferritinemia should be monitored carefully for complications.[11] Results from the present study also had shown that hyperferritinemia (2000ng/ml) is seen in all cases with severe dengue and this increase in serum

ferritin levels is noted from day 4 of clinical illness in severe cases when compared to non-severe cases.

Another study conducted in one hundred seventy-seven Thai children which measured serum ferritin levels during the entire clinical course (febrile, toxic and convalescent stages) showed similar results.[10] Increased serum ferritin was associated with severe dengue; patients with non-severe dengue had serum ferritin levels less than 1,200ng/ml during the entire course of illness, while severe forms recorded higher levels of serum ferritin during the febrile stage and the defevervescence stage. Patients with dengue hemorrhagic fever (DHF) grade III and IV had significantly higher median ferritin levels measured on day 5,6 and 7 of illness than those with grade I, II DHF and dengue fever. In that study it was concluded that serum ferritin level ≥1,200ng/ml from day 4 of the illness predicts the occurrence of dengue hemorrhagic fever.

In a study conducted in South India by Soundravally R et al, which included 48 dengue infected cases and 48 cases with other febrile illness as controls, serum ferritin levels were measured on the day of admission (which is a median of 4 days after the onset of fever) and day of defervescence (which is a median of 4 days after the day of admission).[9] Compared to other febrile illnesses, dengue cases demonstrated significant increase in serum ferritin levels ;also within clinical groups, severe disease exhibited higher ferritin levels compared to non-severe group throughout the febrile and defervescence stages of illness (940.09±568.31 in non-severe cases vs. 1264.71±492.59 in severe dengue on day of admission ; 418.19±404.59 vs. 1490.74±359.40 on day of defervescence) The study concluded that raised serum ferritin levels could predict the severity of dengue with a sensitivity and specificity of 76.9% and 83.3% respectively. The present study also showed similar results; hyperferritinemia was noted in severe cases compared to non-severe group from day 4 to day 7 of illness.

One another study showed significant association between raised serum ferritin levels on the day of admission and the development of severe dengue.[16] Serum ferritin was measured on the day of admission in a total of 104 dengue positive cases and they were grouped into a) Group A with normal ferritin levels (up to 100µg/dl) and b) Group B with high serum ferritin levels ; both the groups were followed up for the occurrence of severe dengue. Severe dengue was noted only in 2 out of 31 patients with normal serum ferritin levels while more than half of the patients with severe dengue (35 out of 73) had raised serum ferritin levels. The study concluded that serum ferritin can be used as an early marker to predict the severity of the disease.

Another significant observation made out in the present study was that age had a positive co-relation with the serum ferritin levels and the duration of hospital stay while it negatively co-related with the platelet count. This implies that age is an important predictor of severity of dengue infection. As age advances, there is increased risk of developing severe disease with low platelet count, high ferritin levels and prolonged hospital stay. Studies had shown that elderly individuals are at risk of developing severe disease. In a study conducted in Southern Taiwan during a dengue outbreak with 5336 dengue cases, the incidence of dengue hemorrhagic fever and dengue shock syndrome is significantly higher in persons aged 60 years and above when compared with younger age groups.[18] Similar observation was made in a Singapore study; persons aged more than 60 years had more occurrence of severe dengue (20.3% vs. 14.6%, P = 0.006) as compared to younger adults.[19]

Our study is unique in that serum ferritin was measured once at the time diagnosis whereas in most of the earlier studies serum ferritin levels were done at multiple times during various stages of clinical illness.[9-11] The results of the present study in which serum ferritin was measured either at the time of diagnosis (or at the time of admission if referred from outside) within 7 days from onset of fever, correlated with the findings of the previous studies . It would be simpler, easier and convenient to measure serum ferritin on a single day, which is practically feasible in clinical setting catering to a large population.

The present study has few limitations as well. First, is the small number of severe dengue observed in the present study; hence we were unable to derive the cut-off value of day wise ferritin levels which can predict the risk of development of severe dengue. A larger sample size with more number of severe cases would be appropriate before arriving at a definite conclusion. Second, the upper limit of serum ferritin measured in the present study was 2000ng/ml due to laboratory limitations; so higher values could not be observed which if available can enable us to better understand about its correlation with both the severity of thrombocytopenia and clinical severity with more accuracy.

Also, the nature of infection (primary or secondary); dengue serotypes were not taken into consideration. To address the limitations in the present study, future studies are needed to find out the cut off level of serum ferritin which can predict severe dengue at the earliest for effective disease management.

CONCLUSION

The present study had shown that elevated serum ferritin levels done early during the febrile stage of the illness (3rd to 7th day of illness) predict the severity of dengue.

We read with great interest the article published in International Journal of Rheumatology, "Long-Term Dietary Changes after Diagnosis of Rheumatoid Arthritis in Swedish Women: Data from a Population-Based Cohort" by Cecilia Lourdudoss et al. [1]. The role of diet in rheumatoid arthritis (RA) remains an ever-burning question for both the patient and the treating physician and, while it is quite acceptable for the lay person to think that the occurrence of the arthritis is influenced by the diet, unfortunately the scientific community is yet to produce a definite answer.

In a systematic review of dietary intervention studies in RA, it was concluded that the effect of various dietary manipulations on the disease is uncertain [2]. The potential risks associated with such intervention were also highlighted in that review. The present study is among the important observations in this field and the authors give specific dietary recommendations for patients with RA in the future. The authors noted that there was no change in dietary pattern in RA patients, whereas those without RA made certain changes to their dietary pattern during the study period. This might be because of the relatively small RA population when compared to the controls in this cohort. The duration of the disease, the disease activity, and the occurrence of comorbid illness also were not taken into consideration.

We did a study that assessed the role of diet in RA patients and its impact on arthritis-related symptoms as perceived by the patients themselves, using a simple questionnaire in their own language [3]. We categorized them as diet restrictors and nonrestrictors based on whether they are following any change in dietary pattern depending upon the aggravation of joint symptoms following a specific food intake. We also considered associated comorbidities and alternative medicine intake, which can influence the dietary pattern. Out of a total of 101 patients with an average disease duration of 50.2 ± 65.4 months, 44 (43.6%) followed dietary restriction while 57 (56.4%) did not observe any restriction. 20 of the 44 patients who restricted their diet (45.5%) felt a difference in joint symptoms on exposure to particular diet; 52 out of 57 (91.2%) nonrestrictors did not experience any influence of diet on their symptoms. Patients who observed changes in their joint symptoms on exposure to a particular diet adopted dietary restriction and we observe this association as statistically significant in our study ($p < 0.0001$). 20 out of the 44 and 52 out of 57 patients in either group appeared to be correctly judging whether or not to restrict their diets.

We concluded that the decision of modifying diet should be individual case-based rather than a generalized dietary restriction, which lacks a solid scientific proof as of now and might deprive the individual of the benefits of a nutritious diet. The voluntary addition or deletion of part of the diet might well have an influence on the overall dietary habits of the entire family, as most often RA affects women who

are often the main homemaker. Unlike gouty arthritis where there are definite dietary triggers, rheumatoid arthritis is a disease with complex pathogenesis and variable course and hence needs to be managed in a multifactorial manner with the basic recommendation for a healthy and nutritious diet till we have convincing data regarding the benefits of dietary manipulation.

Conflicts of Interest

The authors declare that they have no conflicts of interest.

Abstract

Background: There is increasing evidence for the role of diet in the etiopathogenesis of Rheumatoid Arthritis (RA) while it is not clear how it modifies the disease activity in view of inconclusive results of various dietary intervention studies. We intend to study the influence of diet on RA patients by a simple questionnaire.

Methods and findings: Descriptive cross-sectional study was carried out among 101 consecutive RA patients with simple questionnaire and analysed whether they had dietary restriction or not and how it affected their symptoms. There were 44 patients who restricted their diet and 57 who did not observe dietary restriction. Of the 44 dietary restrictors, 20 (44.5%) had reported worsening of joint pains after a particular food while 52 out of 57 non dietary restrictors (91.2%) did not feel a difference in the joint symptoms with food intake which was statistically significant ($p<0.0001$). Just like patient reported disease outcome measures which are less complicated and time consuming has emerged as a promising tool in the disease management, this study also observed that majority of our patients are right in restricting their diet based on their joint symptoms.

Conclusion: The patient has to decide on their own basis whether or not to restrict a particular food item based on their symptoms instead of imposing a specific dietary pattern until we get more evidence to prove the contrary.

Introduction

Rheumatoid arthritis (RA) is one of the commonest debilitating arthritis which has seen a sea change in the diagnosis and management over the past few decades. While pharmacological therapies receive prime importance in the management plan, non- pharmacological measures are often neglected, but the scenario is changing, and more focus is made on the non–pharmacological intervention measures including diet, exercise and healthy life habits.

The pathogenesis of RA is complex which includes genetic and non –genetic factors. Non-genetic factors account for around 40% of the risk for RA [1]. Among the non–genetic factors cigarette smoking is a well-established risk factor for the development of inflammatory polyarthritis [2-5]. Diet is another well studied risk factor [6,7]; it can influence the body weight which has a bearing on the individual's mobility; also it can affect the inflammatory process by altering the gut micro flora, anti-oxidant activity. The presence of altered intestinal micro flora is implicated in the pathogenesis as well as the disease progression in RA [8-10]. Diet can have positive and negative impact on the disease. High protein diets is implicated in the disease pathogenesis [11,12] while low protein diets can improve RA related symptoms [13-16]. A very high prevalence of RA is noted in countries with greater consumption of red meat [17]. Certain food items like fish [18,19], cooked vegetables, and β cryptoxanthin found in fruits and vegetables [20-22] have a possible protective effect while increased coffee intake is associated with the greater risk of RA [23,24]. Patients with RA were subjected to various dietary interventions to improve or lessen the burden of the disease. Studies done so far to find out the impact of the diet on disease activity and symptoms have shown variable results.

In a study by Proudman et al. [25], consumption of fish rich in omega 3 fatty acids, in combination with conventional Disease Modifying Anti –Rheumatic Drugs (DMARDS) is more likely to achieve remission than DMARDS alone. There are conflicting results with regard to protein intake. Pattison et al. [12] studied the intake of red meat and the occurrence of inflammatory polyarthritis and concluded that increased intake of red meat is associated with higher risk of developing inflammatory polyarthritis, whereas Nurses' Health Study [26] has given contradictory results.

In real life scenario, many patients with RA report that there is increase in their joint symptoms after taking a particular food and they adjust their dietary pattern based on their experience by restricting that particular diet in future and gets benefited by their own dietary manipulation. The question about the influence of diet on the occurrence of arthritis related symptoms remain

large for the patients. With this background, we intended to study the role of diet in RA patients and its impact on the arthritis related symptoms as perceived by the patients themselves using a simple questionnaire in their own language.

Aim

To study the influence of diet on the joint related symptoms in patients with Rheumatoid arthritis as perceived by them.

Methodology

Descriptive study was carried out among 101 consecutive Rheumatoid arthritis patients attending the out-patient services of Rheumatology Department during September 2012-March 2013 in a tertiary care centre, Coimbatore, Southern India. Patients aged more than 17 years of age with a diagnosis of RA as per American College of Rheumatology 2010 criteria and on standard DMARDS (Methotrexate 10 -25 mg/week; Hydroxychloroquine 200-400 mg/day; Leflunomide 10-20 MG/day; Prednisolone <7.5 mg/day) were included in the study however among them subjects were excluded if other Connective tissue diseases like Systemic lupus erythematosus, Fibromyalgia and Spondyloarthropathies, those who require frequent change in dose of DMARDS and not willing to participate in the study.

The study design was approved by the Institutional Ethics committee. After getting the consent, the participants were given a questionnaire in their local language which includes key details like disease duration, dietary pattern, history regarding co-morbidities and exposure to alternative medicine therapy; their regular diet patterns, whether they are restricting any particular food item; have they felt any change in the joint symptoms (new onset pain or stiffness, involvement of multiple joints) after a particular food intake and if so, they were asked to list down the name of food items which they think is responsible for the change in symptom.

Statistical analysis

Disease duration was calculated from the time of first symptom occurrence till the date of sampling and categorised as ≤ 6 months and >6 months. Diet restriction was categorised as diet restrictors and non-diet restrictors.

Descriptive statistics were reported using mean with standard deviation for continuous variables and percentages for categorical variables. Independent t test was used to compare the mean age between two groups. Chi-square test was used to test the association between diet restriction and disease duration with other study variables. P value less than 5% was considered as statistically significant. All the analyses were done using SPSS version 23.0 software.

Results

The characteristics of the study population are listed in Table 1. There were 85 female patients and 16 were male with ratio of 5.3:1. Mean age of the study subjects was 48.3 ± 11.6 years. The average disease duration of the study population was 50.2 ± 65.4 months. When we divided the patient into early with disease duration of ≤ 6 months and established RA with more than 6 months there were 80 with established disease while 21 had early disease.

Of the 101 patients 40(39.6%) had been exposed to complementary therapies in the past in the form of Ayurveda, Siddha and Homeopathy. 18 patients had associated co-morbid illness; most commonly reported was Systemic hypertension which was seen in 12 patients and 5 patients had diabetes while one had both Diabetes mellitus and Systemic hypertension. The diet pattern of the patient population is quite variable with 66 of them taking mixed diet (both vegetarian and non-vegetarian) and 35 were lacto-vegetarians.

There were a total of 44 patients (43.6%) who were following some kind of dietary restriction which was self-imposed in 5; by relatives and friends in 7 while 32 were advised by their primary care physicians itself. The remaining 57(56.4%) did mention that they did not follow any dietary restriction.

Of the total 101 patients, only 25 (24.8%) felt there was a change in the joint symptoms on taking particular diet, of this 20 were following diet restriction and the remaining 5 belonged to the non-diet restrictors group. The list of food items which worsened the joint symptoms is mentioned in the Table 2.

Disease duration and diet restriction

The mean disease duration in the early RA was 4.28 months and in established RA was 62.68 months. Although not statistically significant, the proportion of patients who had been exposed to alternative medicine was more in established RA (42.5%) than in early RA (28.6%).

In the early RA subgroup, seven patients (33.3%) had felt a need for diet restriction; the remaining fourteen (66.7%) did not have any restriction in the food intake. Eighteen among the early disease group (85.7%) did not observe any change in their joint symptoms after a particular food while three (14.3%) noticed worsening of their symptoms.

Table 3. *Comparison of characteristics by disease duration: Reported as number within parenthesis percentages; p value using chi-square test; * - p value using independent t test.*

	Disease Duration		
	≤ 6 months n-21	>6 months n-80	P value
Age in years	44.1 ± 10.6	49.4 ± 11.8	0.06*
Sex Female Male	 17 (81.0) 4 (19.0)	 68 (85.0) 12 (15.0)	0.65
Alternative Medications Yes No	 6 (28.6) 15 (71.4)	 34 (42.5) 46 (57.5)	0.24
Co morbid conditions Yes No	 5 (23.8) 16 (76.2)	 13 (16.3) 67 (83.8)	0.32
Any difference in arthritis Yes No	 3 (14.3) 18 (85.7)	 22 (27.5) 58 (72.5)	0.21
Diet restriction Yes No	 7 (33.3) 14 (66.7)	 37 (46.3) 43 (53.8)	0.28
Type of food Veg Mixed	 5 (23.8) 16 (76.2)	 30 (37.5) 50 (62.5)	 0.49

In established RA, thirty seven (46.3%) had diet restriction; while the remaining forty three (53.8%) did not. A majority of them (72.5%) did not feel any influence of diet on their joint symptoms while change in their symptoms in response to some dietary habits was observed in twenty two patients (27.5%). The results are summarised in Table 3.

Diet restrictors versus non restrictors

There were a total of 44 patients who restricted their diet while 57 of them have been not on any kind of diet restriction for arthritis.

Of the diet restrictors majority was female (81.8%); majority of them (84.1%) had established disease more than 6 months; 50% had been exposed to alternative medicine. The exposure to alternative form of medicine was slightly higher in diet restrictor as compared to non-restrictor groups (p=0.06). A majority (77.3%) of the diet restrictor group did not have any co-morbidities.

A significant association was observed between diet restriction and any difference/worsening of joint symptoms (p<0.0001). Twenty of the 44 patients who restricted their diet (45.5%) felt a difference in joint symptoms on exposure to particular diet while the remaining 24 patients (54.5%) did not feel so. 52 out of 57 (91.2%) non restrictors did not experience any influence of diet on their symptoms while 5 (8.8%) felt a change in symptoms even though they did not restrict any dietary foods in particular. The results are summarised in Table 4.

Discussion

In this study we analysed the influence of diet on joint symptoms in a group of patients by a simple questionnaire.

The mean age of our study population was 48.33 ± 11.74 years which is in comparable with the RA study population worldwide. Although our study did not target on established disease alone, we had more number of patients with established disease by consecutive picking. The mean disease duration in the study group was 50.22 ± 65.39 months which is important because this gives enough time for the patients to test various foods and to arrive at a conclusion regarding the influence of diet on their disease pattern.

The percentage of patients with associated co-morbid diseases like diabetes and hypertension requiring dietary restriction was less in our study population making this observation more relevant.

Almost all the alternative form of therapies mandates a specific dietary restriction. In our study, 50% of dietary restrictors had alternative therapy exposure previously; although this association is not statistically significant which indicates that alternative medicine exposure does not influence the dietary patterns for our study population.

Patients who observed any changes in the joint symptoms on exposure to a particular diet adapt dietary restriction and we observe this association as statistically significant in our study (p<0.0001). This emphasise the influence of diet on the disease activity as noted in other studies.20 out of the 44 and 52 out of 57 patients in either groups were rightly deciding what to eat and what not to eat.

When we searched for similar studies, we could find one such questionnaire based study [27] which assessed diet and disease symptoms in rheumatic diseases. The study included a total of 742 patients which consisted of 290 patients with RA; 51 with Juvenile Rheumatoid arthritis, 87 with Ankylosing spondylitis, 51 with psoriatic arthropathy, 65 with primary fibromyalgia and 34 with osteoarthritis. The median disease duration of RA patients in this study was 11 months (0-55) which is shorter than our present study (50.22 ± 65.39 months). One third of

Rheumatoid arthritis patients reported worsening of symptoms after a particular food intake which is comparable to our observation (one fourth). But there was not any definite answer for the same.

Understanding the association between diet and RA disease activity, numerous studies had been conducted in various parts of the world to ascertain whether dietary manipulation is rewarding in the management of RA patients in terms of improvement in joint pain, stiffness and physical function. Dietary intervention measures followed in various studies include fasting followed by vegetarian diet [14,28], vegan diet [16,29], elemental diet [30,31], Mediterranean diet [32,33], Elimination diet [34] and the results were compared with those put on ordinary diet but the results of these studies were variable.

Hagen et al. [35] did a systemic review of all these dietary intervention studies which included 14 randomised controlled trials, 1 case control study with a total of 837 patients and concluded that the effect of various forms of dietary manipulation on RA patients is uncertain. It was also noted that there was a high risk of dropout rates and weight loss in those subjected to dietary manipulation or restriction which can cause adverse potential effects.

Our study is one of its kinds which assessed the real life situation of patients with RA and their ever burning question of the influence of diet on the disease. It is easier to assess the role of drugs in the disease management and various trials can be formulated for the same while it is tough to assess the role of dietary factors and its influence on the disease course. Since RA as such has a variable course and each patient behaves in a different manner with periods of spontaneous remissions and exacerbations. Not all patients with RA are capable of sticking to a particular diet regimen. Most of the real life patients are in the lower to middle socio-economic class and following a special diet pattern will only add to the financial burden for their families.

We did make out from our study that the patients are the best judges of their symptoms and the influence of diet on their disease pattern. Our advice for the patients is to decide on their own basis whether or not to restrict a particular food item based on their symptoms instead of giving a dietary pattern for them.

So, till we have convincing data regarding the benefits of dietary manipulation in Rheumatoid arthritis patients, we encourage them to have a healthy, balanced diet with individual modifications in their diet pattern based on their own judgement regarding the influence of diet on their joint related symptoms.

Limitations of our Study

This is a cross-sectional study; we have not objectively assessed the influence of diet on the disease activity; instead our study was based on the assessment on arthritis related symptoms by patients themselves.

Funding

We have not received any funds from any agencies or sponsors.

Competing and Conflicting Interest

The authors disclose no conflicting or competing interest.

ABSTRACT

Background: While Immunofluorescence assay remains the gold standard for the detection of ANA, Immunoprofile by ELISA is being increasingly utilized in view of easy availability and quick results. The study was done to find out whether ANA profile results are comparable with IFA.
Methods: About 100 patients who had undergone both immunofluorescence and Immunoprofile were included. Immunofluorescence correlation with profile and their correlation with the disease were analyzed; sensitivity, specificity and predictive values were calculated.
Results: ANA was positive in 78% by immunofluorescence; 73% by ANA profile. 22 patients in whom ANA IFA was negative were picked up by ANA profile. 27 patients who were not detected by ANA profile were tested positive by IFA. ANA testing by immuno profile had a sensitivity of 65% with a positive predictive value of 69% when compared with IFA. Immunofluorescence pattern and ANA profile correlated with the diagnosed disease in 63% and 49% respectively. Immunofluorescence pattern correlated with the ANA profile in only 35% of the study subjects. On correlation with the disease, ANA profile scored less compared to ANA-IFA with a sensitivity and specificity of 46% each; positive predictive value of 59%; negative predictive value of 33%. On analysis of individual disease, ANA profile is as good as IFA in SLE and scleroderma in terms of sensitivity. In Sjogren's syndrome and MCTD, specificity and positive predictive value of ANA profile is high.
Conclusions: ANA IFA performs better than immunoprofile in the diagnosis of autoimmune diseases.

Keywords: Antinuclear antibody, ANA immunoprofile, Immunofluorescence, Immunofluorescence versus profile

INTRODUCTION

Connective tissue diseases (CTD) are a group of autoimmune disorders characterized by the presence of antinuclear antibodies (ANA). The detection of these auto antibodies in the sera of the affected persons is very much essential to diagnose these diseases. The history of ANA testing dates back to 1948 with the observation of LE cell by Hargraves et al.[1] in the bone marrow of Systemic Lupus Erythematosus (SLE) patients. Although they are called as anti-nuclear antibodies, these antibodies exhibit reactivity not only against nuclei but also against various other cellular structures like cell surface, nucleoli and cytoplasm.[2] Despite its varied sensitivity in various

connective tissue diseases and false positivity results in numerous conditions, ANA is still widely used as a screening test for connective tissue disorders.

The two broad categories of ANA include a) auto antibodies against double stranded DNA (ds -DNA) seen in SLE and against histones seen in drug induced lupus. 3, 4 b) auto antibodies to extractable nuclear antigens (ENA) like antibody to Smith (Sm) antigen which is specific for SLE; other subtypes of ENAs include antibodies against ribonucleoproteins (RNP), SSA/Ro, SSB/La, Scl-70, Jo-1 and PM1.5 The sensitivity and specificity of ANA and its clinically important specific antigen subtypes is listed in Table 1.[6,7]

Table 1: The sensitivity and specificity of ANA and its clinically important antigenic subtypes.

ANA	**SLE**	**93**	**57**
	Sjogren's syndrome	48	52
	Systemic sclerosis	85	54
	Polymyositis/ dermatomyositis	61	63
	MCTD		
Antigen subtypes			
Anti - dsDNA	SLE	57	97
Anti - Sm	SLE	25-30	High
Anti -SS A/Ro	Sjogren's syndrome, Subacute cutaneous SLE, Neonatal lupus syndrome	8-70	87
Anti-SSB/La	Sjogren's syndrome, Subacute cutaneous SLE, Neonatal lupus syndrome	16-40	94
Anti-U3-RNP	Systemic sclerosis	12	96
Anti-centromere	Limited cutaneous systemic sclerosis	65	99.9
Scl-70	Systemic sclerosis	20	100
Jo-1	Polymyositis	30	95

The most commonly used laboratory tests to detect anti-nuclear antibodies include immunofluorescence (IF) assay and enzyme linked immunosorbent assay (ELISA). In immunofluorescence assay (IFA), the presence of a specific staining pattern indicates the presence of certain auto antibodies which in turn is associated with certain clinical states.[8-10] In antigen specific ELISA assays, we can detect the presence of various auto antibodies directed against specific antigens (ANA profile). Also, it is simple to perform, automated and does not require skilled personnel to interpret the results unlike IF assays.

The interpretation of ANA by immunofluorescence assay which is the gold standard is limited by the cost, requirement of skills and proper handling of the specimen. The detection of ANA by IFA does not always yield the specific clinical diagnosis; most often specific antibody assay is required to diagnose the clinical syndrome. Also, the borderline ANA-IF staining (like 1+ positive; weak positive results) creates confusion which demands further diagnostic testing. It is noteworthy to understand that while certain diseases like MCTD can be diagnosed by the presence of a specific antibody anti - U1RNP, other autoimmune diseases have overlapping ANA IFA patterns and antibody profile. Detection of ANA by both immunofluorescence and ANA profile increases the cost and the time interval for diagnosis as each laboratory has its own turnaround times. Simply doing an ANA profile directly might cut short the time but sometimes it may not detect the antibodies when that specific antigen is not included in the kit in which case the diagnosis and thereby the treatment of the disease might get delayed. Each test has its own advantages and disadvantages. With this background, we intended to correlate the ANA results of 100 patients with autoimmune connective diseases who had simultaneously underwent ANA testing by both immunofluorescence (IF) and Immunoprofile (ANA profile) methods. These results were finally correlated with the disease diagnosed.

The aim of the study is to analyze the correlation between a) ANA- IFA pattern and ANA profile sub typing; b) ANA- IFA pattern and the disease diagnosed and c) ANA profile sub typing, and the disease diagnosed.

METHODS

The present study was a laboratory based observational study conducted in the adult patients who attended the Rheumatology OPD in a tertiary care centre in South India from August 2014 to June 2015. A total of 100 patients were included in the study.

Inclusion criteria

- Adults greater than 17 years and less than 60 years of age
- Who had underwent both ANA IFA and ANA profile tests.

Exclusion criteria

- Who had viral infections in the recent past
- Those on medications known to cause ANA positivity
- Those previously diagnosed to have rheumatic diseases
- Those above 60 years of age.

Thorough history and general physical examination were done for all the patients and diagnosis was made based on American College of Rheumatology (ACR) criteria.

Five milliliters venous blood was collected in a clean Wassermann tube, serum was separated from the clotted blood samples by centrifugation as per standard protocol. The serum was stored at -20°C until the time of assay. Determination of ANA was done by indirect

immunofluorescent techniques using HEp-2 Cell Line Substrate as per the standard recommendation; a titer of ≥1:100 was taken as positive for IF. ANA profile was done by using IMTEC-ANA-LIA MAXX for detecting antibodies against ds DNA, nucleosomes, histones, Sm D1, PCNA, SSA/Ro 60, SS A/Ro 52, SSB/La, CENP - B, Scl 70, U1sn RNP, AMA, M2, Jo 1, PM-Scl, Mi 2 and Ku as per the kit manual.

Table 2: Clinical significance of common Immunofluorescence patterns.

ANA –IF pattern	Antigen	Associated disease
Speckled	ENA, RNP, Sm, SSA/Ro, SSB/La, Scl-70, Jo-1, ribosomal-P	SLE, Mixed CTD, SS, Primary Sjogren's syndrome, PM
Homogenous	dsDNA, Histones	SLE, Drug induced SLE
Peripheral (rim)	RNP, Sm, SSA/Ro	SLE, SS
Nucleolar	Anti-PM-Scl, anti-RNA polymerase I-III, anti-U3-RNP, To RNP	SS, PM (polymyositis scleroderma)
Centromere	CENP A-E	Limited SS

The detection of ANA by profile method was compared with the standard IF assay. Also, the results of these two diagnostic assays (IFA and ANA profile) were subjected to correlation with the disease diagnosed. For example, when those patients diagnosed with SLE have homogenous pattern detected by IF method; double stranded DNA (dsDNA); histone antibodies in the ANA immunoprofile method, it is considered to be co-relating. The clinical significance of common ANA -IFA patterns and antibodies in ANA profile is listed in Table 2.

Statistical analysis

Descriptive statistics were reported using mean and standard deviation for the continuous variables, number and percentages for the categorical variables. Cross tabulation was done between ANA IFA (Gold standard) and ANA profile (ELISA). The sensitivity, specificity, positive and negative predictive values (PPV) and (NPV) were calculated. These values were calculated for both the ANA indices analysis.

RESULTS

Authors analyzed the ANA test results detected by both immunofluorescence and ANA profile method of 100 patients in whom diagnosis of rheumatic disease was made based on clinical and immunological criteria. Sjogren's syndrome and Mixed Connective tissue Disease (MCTD) accounted for two-thirds of the study population; the distribution of various diseases in the study population is listed in Table 3. There were 72 females and 28 males with the mean age of 34.23±5.8 years. The female preponderance was noted in the disease subsets as well.

Table 3: Distribution of various rheumatic diseases in the study population.

Disease	Total	Female	Male
Systemic Lupus Erythematosus (SLE)	20	15	5
Sjogren's syndrome (SS)	32	21	11
Scleroderma	10	7	3
Mixed Connective tissue Disease (MCTD)	30	22	8
Myositis	4	3	1
CTD associated ILD (CTD – ILD)	4	4	0

ANA was positive in 78% of our subjects by immunofluorescence method and in 73% by ANA profile. The IF pattern observed were homogenous in 11; speckled in 48; nucleolar in 17; centromere and cytoplasmic pattern one in each. 51 patients (51%) were found to be positive by both IFA and immuno-profile methods. 22 patients in whom ANA IFA was negative were picked up by ANA profile. Also 27 patients who were not detected by ANA profile were tested positive by IFA method. We found ANA testing by immunoprofile has a sensitivity of 65% with a positive predictive value of 69% when compared to standard IFA method. The results were tabulated in Table 4. Specificity and negative predictive value could not be calculated since all our study subjects had established rheumatic autoimmune disease.

Table 4: Comparison of ANA IFA and ANA profile results.

	ANA IFA	
	Positive	**Negative**
ANA profile	51	22
	27	0
	78	22

Correlation of ANA results with the disease

In 63% of the subjects, the pattern observed in the immunofluorescence correlated with the diagnosed disease; whereas ANA profile correlated with the disease in 49%.

Both the tests correlated with the disease in 29 patients. On correlating IFA pattern with ANA profile, we found that IFA pattern correlated with the observed antibodies in ANA profile in only 35% of the study subjects.

On cross tabulation of correlation with the disease, we found that ANA profile scored less compared to ANA-IFA with a sensitivity and specificity of 46% each; positive predictive value of 59% and negative predictive value of 33% (Table 5).

Table 5: ANA profile vs. IFA correlation with the disease.

	Immunofluorescence pattern correlation with the disease	
ANA profile correlation with the disease	Present	Absent
	29	20
	34	17
	63	37

Sub analysis based on individual disease

On comparison of ANA results with respect to individual disease, we found that in SLE, ANA profile is as good as Immunofluorescence assay in picking up the disease with a sensitivity of 90% although positive predictive value (PPV) was 47%. Out of 10 patients in whom ANA-IFA was negative, 9 were picked up by ANA profile. We noted a high PPV of 82% in Sjogren's syndrome with a sensitivity of 64% when compared with IFA method. All the scleroderma patients were picked up by ANA profile while IFA method fails to detect the disease in one. The performance of ANA profile in other diseases is less compared to standard IF method. The results are tabulated in Table 6.

Table 6: Comparison of ANA immunofluorescence assay (IFA) and ANA profile results in disease subsets.

		ANA IFA					
		Positive	**Negative**	**Sensitivity**	**Specificity**	**PPV**	**NPV**
SLE	ANA profile Positive	9	10	-	-	-	0
	Negative	1	0	90%	0	47%	0
Sjoren's syndrome	Positive	18	4	-	-	-	-
	Negative	10	0	64%	0	82%	0
Scleroderma	Positive	9	1	-	-	-	-
Myositis	Positive	1	2	-	-	-	-
	Negative	1	0	50%	0	33%	0
MCTD	Positive	13	4	-	-	-	-
	Negative	13	0	50%	0	76%	0
CTD	Positive	1	1	-	0	50%	0
	Negative	2	0	33%	-	-	-

PPV - positive predictive value; NPV- Negative Predictive value

Table 7: ANA immunofluorescence assay (IFA) and ANA profile correlation with the disease.

		ANA IFA correlation with disease					
		Present	**Absent**	**sensitivity**	**Specificity**	**PPV**	**NPV**
SLE	Present	8	10	80%	0	44%	0
	Absent	2	0	-	-	-	-
Sjoren's syndrome	Present	8	2	44%	86%	80%	55%
	Absent	10	12	-	-	-	-
Scleroderma	Present	5	3	100%	40%	62%	100%
	Absent	0	2	-	-	-	-
Myositis	Present	1	2	50%	0	33%	0
	Absent	1	0	-	-	-	-
MCTD	Present	6	2	24%	60%	75%	13%
	Absent	19	3	-	-	-	-
CTD	Present	1	1	33%	0	50%	0
	Absent	2	0	-	-	-	-

ANA profile correlation with the disease

PPV - positive predictive value; NPV- Negative Predictive value

Correlation with the disease

In SLE, ANA profile correlated well with the disease with a sensitivity of 80% and PPV of 44%. In Sjogren's syndrome, authors found that ANA profile scored well in ruling in the disease with a high specificity of 86% and NPV of 55%; also, its sensitivity is 44% with a very good PPV 80%. With respect to Scleroderma, ANA profile

performed well with 100% sensitivity and NPV; although specificity is 40%. Similarly, although sensitivity is low in MCTD, in 75% of the cases ANA profile is correct in predicting the disease. The results are tabulated in Table 7.

DISCUSSION

Very few investigations in the field of Medicine have such an important role in the diagnosis of diseases like the detection of anti-nuclear antibodies (ANA) for autoimmune diseases. Majority of referrals to a tertiary care centre for positive results following unnecessary ANA testing are often based on ELISA results rather than IFA; studies have revealed that majority of them are false positives.[11] Each method has its own advantages and disadvantages.

The present study analyzed the correlation between ANA results detected by IFA and ANA profile in 100 patients with autoimmune diseases.

There are many studies which had compared ANA results detected by IFA vs. ELISA in patients with suspected autoimmune disease.[12-14] But there were only few studies which had assessed the results in patients with established autoimmune disease.[15-17] The present study is one of its kind which had utilized both the tests (IFA and ANA profile) for establishing the diagnosis and then compared the performance of ANA profile with IFA pattern; correlated both the test results with the disease diagnosed.

Female preponderance is often observed in autoimmune diseases; the present study observed a female preponderance of 72% similar to that noted in other studies.[18-20]

ANA IFA was found positive in 78 patients (78%); of these ANA - IFA positives, 51 were found to be positive by ANA profile as well. The present study findings were similar to that observed by Latha M et al, who had reported that ANA IFA was positive in 71.3% out of 279 samples; 159(56.9%) were both ANA IF and Line Immuno assay (LIA) positive.[18] In another study conducted in East India, among 394 samples tested for both ANA IFA and ANA profile, 138 were ANA IFA positive (35.02%) in 1 in 40 dilution; of which 114 (82.6%) were also line immune assay positive.[19]

Positive ANA IFA with negative ANA profile is noted in 27% cases. This may be attributed to the fact that some rare auto antibodies may be missed by ANA profile if the kit fails to incorporate that specific antigenic substrate, which could be detected by IF staining. Review of the ANA pattern found in these 27 cases had shown speckled in 13; nucleolar in 12, homogenous and cytoplasmic pattern in 1 each. Similar observation was noted by Baronaite et al, who had studied the ANA results in 400 patients using IFA and Elisa immuno assay (EIA) techniques and found that the EIA method was less reliable for assessing nuclear and speckled reactivity patterns.[13]

22 patients who were ANA IFA negative were picked up by ANA profile in the present study. Almost half of them had dsDNA antibodies (12 patients); Ro 52 and Scl 70 antibodies in 3; Sm antibodies in 3; nRNP/Sm+RibP in 3; PCNA/ histone antibodies in 1. The negative immunofluorescence could be because SSA and dsDNA antibodies were not detected by ANA -IFA method. The negative immunofluorescence may be due to the low concentration of auto antigens or its destruction during the preparation process.[21]

Surprisingly SLE, which is largely diagnosed by ANA positivity, would have been missed in 50 percent of the cases if only IFA assay is done. This showcases few interesting thoughts, where in the past, ANA negative lupus had been diagnosed based on simple assays, when this advanced ANA profile was not available. This was also noted in other studies, where significant number of IFA assays missed reactivity to dsDNA which was picked by the sub typing analysis.[13,18]

Similar to present study observation, there are various studies, which have shown inconsistencies between ANA IFA and ANA profile results. Latha M et al, noted that 40 ANA IFA positive samples (20.1%) were negative by ANA profile. Of the 80 ANA-IFA negative samples, 14 (17.5%) were detected to be positive by IF method.[18] In one study, positive result by IFA was noted in 17.3 % cases although they were negative for line immunoassay; The pattern observed in that study was mostly homogenous (66%) while in present study it was speckled followed by nucleolar pattern. In the same study, 14.8% of the ANA negative samples were tested positive by line immunoassay.[19] Sebastian et al, noted that 17.5% of ANA IFA positive samples were not detected by LIA method while 13.5% which were negative by IF method were found positive by LIA.[22]

This observation stresses the importance of further investigation with immunoprofile although IFA is negative if the clinical features are strongly suggestive in a given clinical setting. So, it is noteworthy to understand that there are certain auto antibodies which may escape staining by IFA method while certain auto antibodies present in the patient's serum may not be detected by ANA profile if it does not contain that specific antigenic substrate. Hence ANA -IFA is considered to be the gold standard screening test while ELISA profile is taken as the confirmatory test.[23]

The results of various studies which had compared ANA -IFA with ANA profile are inconsistent with regards to sensitivity, specificity and predictive values.[24-26] Some studies have shown moderate agreement between Enzyme immune assay and IFA.[15,24,26] While some have found that IFA is better others have shown that ELISA is superior.[20,22,27,28]

In the present study, we found that ANA IFA pattern co-related with the disease in 63%; ANA profile with the disease only in 49%; On cross tabulation, we observed that ANA testing by immunoprofile has a sensitivity of 65% with a positive predictive value of 69% when compared to standard IFA. Present study observation was similar to that noted by Priyadarshini et al, who compared ANA profile with standard IFA and reported ELISA has a sensitivity of 71.43% and specificity of 86.84% when compared with IFA12. There are studies which had reported that ELISA with improved profile is as good as IFA.

In a study by Kolahi et al, the sensitivity and specificity of immunoblot assay (ANA profile) in comparison with IF assay was 98.65% and 90.91% respectively.[17] Another study which had compared ANA detection by ELISA kit with IFA had reported that ELISA showed a reasonably good sensitivity (90.7%) and positive predictive value (89.1%) when compared to IFA method.[28] Raman et al, reported that sensitivity of LIA when compared to IFA was 89% and specificity was 42%.[19]

The present study also observed that IFA correlated well with the disease than ANA profile. Compared to standard IFA, the sensitivity and specificity of ANA profile in correlating with the disease was 46% each; positive predictive value of 59% and negative predictive value of 33%.

The present study is unique in that we assessed the results of ANA profile and IFA with respect to individual disease. We found that in SLE, ANA profile is as good as Immunofluorescence assay in picking up the disease with a sensitivity of 90%. Authors noted a high PPV of 82% in Sjogren's syndrome; 76% in MCTD by ANA profile when compared with IF method. All the scleroderma patients were picked up by ANA profile while IFA fails to detect the disease in one.

This observation tells that ANA profile is a very useful test in SLE and scleroderma. When the specific antibodies are positive in Sjogren's syndrome and MCTD, it is very likely that person is suffering from that specific autoimmune disease.

On correlation of ANA profile and IFA with the disease, we found that in SLE, ANA profile correlated well with the disease with a sensitivity of 80% and PPV of 44%. In Sjogren's syndrome, we found that ANA profile scored well in ruling in the disease with a high specificity of 86% and a very good PPV 80%. Authors also found a very good correlation of ANA profile with the disease in Scleroderma, with 100% sensitivity and NPV; Similarly, in MCTD, in 75% of the cases ANA profile is correct in predicting the disease.

Authors had used a mixed population of autoimmune diseases with small numbers which might again differ when used in larger sample.

CONCLUSION

ANA profile correlation with the disease is less when compared to Immunofluorescence assay. Also, ANA profile has a very low sensitivity and specificity when compared to IFA. ANA detection by immunofluorescence remains the investigation of choice when compared to ANA profile in the diagnosis of autoimmune disorders. In certain diseases like SLE and Scleroderma, ANA profile is as good as IF assay in picking up the disease and correlation with the disease.

Urinary Tract Infection in Diabetics - A Five Year Retrospective Study on the Prevalence of Bacterial Isolates and its Antibiotic Susceptibility Patterns in A Tertiary Care Hospital in South India

Jagadeeswaran G[1], Mohammad Zeya Ansari[2], Tolstoy Rajangam[3]

ABSTRACT

Introduction: Urinary tract infection (UTI) is almost most common seen infection in the diabetic patient due to various local and systemic immunopathogenetic reasons. This causes multiple renal and extrarenal complications and even death if not intervened early. We aimed to find out the prevalence of different bacteria in urine culture and the antibiotic susceptibility pattern amongst diabetic patients admitted in our hospital and to start empirical antibiotics for early recovery and to prevent complications.

Material and Methods: Retrospectively, 651 culture positive urine samples were taken for study with inclusion and exclusion criteria. We saw all the case records and investigations of every subject to correlate with criteria of selection. Our laboratory follows the standard protocols for urine sampling, timely transportation and microbiological study. Antibiotic susceptibly was tested by Kirby Bauer method and interpretations were done by clinical laboratory and standards institute (CLSI) guidelines.

Results: Out of total 651 patients most commonly affected age group was 51-60 years (30.26%).Here males (53.3%) dominated females (46.7%) in number with little difference. Most common Gram-negative bacteria were Escherichia coli (69.12%) and Klebsiella pneumoniae (8.60%) while most common Gram-positive bacteria were Enterococcus faecalis (10.90%) and Staphylococcus aureus (2.91%).Most of the gram-negative bacteria were having a good susceptibility to amikacin, piperacillin/tazobactam, cefoperazone/sulbactam and carbapenems while Gram-positive bacteria were mostly sensitive to nitrofurantoin, linezolid and vancomycin.

Conclusion: in our study, the occurrence of UTI among the diabetic is commoner in the sixth decade with a male predominance. We found E.coli, E.faecalis, and K.pneumoniae as the most commonly grown organisms in descending order. Most of the Gram-negative isolates were susceptible to amikacin, piperacillin/tazobactam, cefoperazone/sulbactam and carbapenems, while most of the Gram-positive cocci were sensitive to nitrofurantoin, linezolid, and vancomycin. Antibiotic resistance is seen very commonly in our setup. We cannot depend upon frequently used oral antibiotics and certain groups like fluoroquinolones and cephalosporin (except for sulbactam containing ones) and ampicillin for empirical treatment in UTI especially the complicated ones.

INTRODUCTION

The urinary tract is a principal site of infection in diabetics.[1] UTI (Urinary Tract Infection) encompasses a variety of clinical entities, including ABU (asymptomatic bacteriuria), cystitis, prostatitis, and pyelonephritis. There can be an increased risk of ABU or symptomatic UTI in diabetics.[2]

Urinary tract infection can be uncomplicated or complicated. Uncomplicated UTI can be asymptomatic bacteriuria, cystitis, pyelonephritis, in men and nonpregnant women, also prostatitis in men. Complicated UTI can be symptomatic episodes of cystitis or pyelonephritis in men or women with an anatomic predisposition to infection, with a foreign body in the urinary tract, or factors predisposing to a delayed response to therapy. There can be a relapse or reinfection. A relapse is a recurrent infection with an organism similar to the pretherapy isolate, usually following persistence of the organism in the genitourinary tract. A reinfection is a recurrent infection with a new organism. The quantitative criteria of at least 10^5 CFU (colony forming units)/mL are generally appropriate for the microbiological identification of complicated urinary infection. Bacteriuria is more common in diabetics than in non-diabetics due to a combination of host and local risk factors.[3] Some microorganisms become more virulent in a high glucose environment. Therefore, screening for UTI in diabetic patients is very important to enable bacteruria to be properly treated.[4] There is a significant correlation between duration of diabetes and UTI.[5] Changes in host defense mechanisms, the presence of diabetic cystopathy and of microvascular disease in the kidneys may play a role in the higher incidence of UTI in diabetic patients. As diabetics are more prone to UTI, it is necessary to pay special attention to early diagnosis and treatment.[6]

The aim of this study was to determine the causative bacteria, culture and sensitivity pattern in diabetics with Urinary tract infection in our setup. This will guide us to start an

DOI: 10.21276/ijcmr.2018.5.4.45

appropriate timely empirical antibiotic which will prevent the diabetic patients from the complications of UTI like pyelonephritis, urosepsis, renal failure etc. This can decrease the hospital stay, morbidity, and mortality.

MATERIAL AND METHODS

This was a 5 year (August 2010 to August 2015) study done in PSG Hospital, Peelamedu, Coimbatore and was based on the retrospective collection of data from case records of patients who were admitted under medicine department of PSG Hospital. Only those cases that fulfill the inclusion criteria were analyzed. To know the reliability of causative organism, we went through the case records and looked into the various clinical and laboratory parameters of the Diabetic patients who have culture positive UTI.

As per the standard protocol clean voided midstream urine samples were collected in sterile containers. In sampling procedure, all the patients were given proper information while collecting the urine sample. Urine culture reports that exhibited CFU of more than 10^5/ml were considered positive. Only single isolates were taken for study purpose and mixed growths were excluded. The pathogens were isolated and identified using phenotypic methods and biochemical testing. Antimicrobial susceptibility testing was performed using Kirby-Bauer disc diffusion method as described by the Clinical and Laboratory Standards Institute (CLSI). We took nine types of isolates and went through their susceptibility patterns to 26 antibiotics. Ethical clearance was obtained before the start of the study.

Inclusion criteria:

1. Diabetic patients
2. Sex: Both male and female
3. Age: 18 years and above
4. Urine culture positive cases

Exclusion criteria:

1. Nondiabetic
2. Pregnancy
3. Known congenital/acquired urogenital anomaly
4. Patients on chronic catheterization
5. Candiduria

STATISTICAL ANALYSIS

The data was descriptively analyzed using Microsoft Excel 2007 software.

RESULT

As per our finding depicted in Table 1 most of the patients were in the age range 51 to 60 years (30.26%) followed by 61 to 70 years (22.27%) and next 41 to 50 years (20.89%) while lower and higher of age groups are lesser affected.

In figure 1 regarding the gender predilection, males were more affected than females (53.3% vs 46.7%).

From the distribution pattern seen in figure 2, it is clear that most common Gram-negative bacteria were E.coli (69.12%) followed by Klebsiella pneumoniae (8.60%). Out of Gram-positive organisms most frequently seen bacteria (figure 3), were Enterococcus faecalis (10.90%) followed by Staphylococcus aureus (2.91%). So, the actual second most common bacteria seen were E.faecalis.

Age	No.of patients	Percentage

Table-4: Resistance to commonly used antibiotics (in percentage)

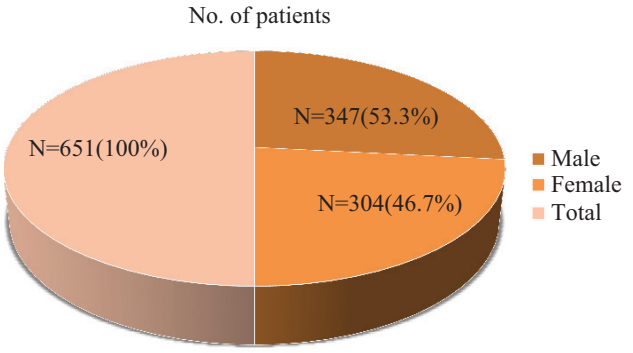

Figure-1: Distribution of patients by gender

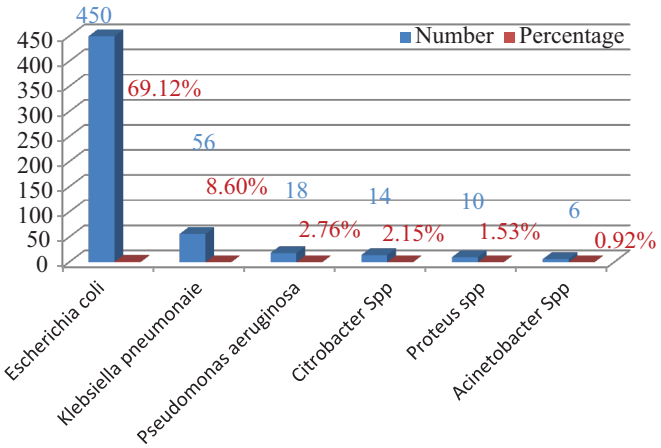

Figure-2: Distribution of Gram –negative bacteria

From table 2 we observed that males had higher prevalence of bacteriuria compared to females in all the age groups. There were only two young patients above 18 and below 20 years age group.

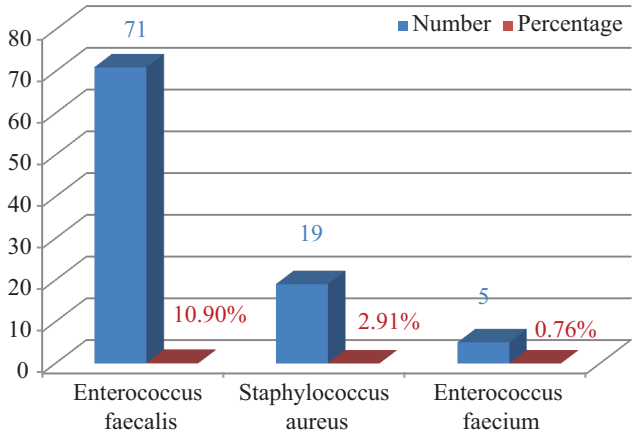

Figure-3: Distribution of Gram-positive bacteria

As shown in table 3 and 4, good susceptibility was seen to amikacin by E.coli (96%) K.pneumoniae (81%), P.aeruginosa (72%) and Proteus spp. (91%). Linezolid and Vancomycin showed 100% activity against Enterococci and Staphylococcus aureus. Amongst fluoroquinolones, ciprofloxacin has low activity (40%) against Pseudomonas while levofloxacin stands good (100%) for Citrobacter and lower (60%) for Proteus. We saw poor response to norfloxacin against most bacteria grown except Proteus spp. which has good (82%). From amongst the cephalosporins, cephalexin, cefixime and ceftazidime are not good options for most bacteria but Cefoperazone-sulbactam stands good (>65%) against E.coli, P.aeruginosa and Proteus spp. Ceftazidime shows 68% and 89% sensitivity against P.aeruginosa and Proteus spp.respectively. ceftriaxone which is very commonly used injectable to start empirically in inpatient setup is not a good choice due to very low sensitivity in E.coli (22%) and

K.pneumoniae (35%). High level Ampicillin resistant is seen in both Gram-positive and negative bacteria.

If we look at E.coli –ESBL (71.42%) and Klebsiella pneumoniae - ESBL(56.90%), best options were carbapenems, colistin, tigecycline, amikacin, piperacillin-tazobactam and nitrofurantoin. There were carbapenemase producers also like in E.coli (4-5%) and Klebsiella (20%). Cotrimoxazole and amoxicillin-clavulanic acid have no good response (<60% sensitivity) to any of these bacteria. Linezolid is good for both the species of Enterococcus (100% susceptible). Nitrofurantoin sensitivity was good in Staph. aureus (96%), E. faecalis (82%) and E.coli (81%). Best response giving carbapenems against K.pneumonaie and P.aeruginosa was by imipenem (83% and 78% respectively) while against Proteus spp.meropenem has good activity (88%). Acinetobacter spp. Which was seen in 6 patients has poor sensitivity to amikacin (20%), imipenem (40%) and colistin (50%) but good sensitivity to cotrimoxazole (80%). We found 3 MRSA out of 19 isolates.

High-grade resistance was seen for many commonly used antibiotics like ampicillin, cotrimoxazole, cefixime, nalidixic acid and amoxicillin/clavulanate (table: 5).

DISCUSSION

In this study, we were supposed to see the prevalence of various bacteria in diabetics with proven UTI and antimicrobial susceptibility patterns. We found that Diabetic males are outnumbering females in terms of prevalence of UTI. This is in contrast to an Indian study[7], a Nigerian study[8] but in favor of study in Sudan[9] and east India.[10]

Most frequently patients were in the affected age group from 51 to 60 years(30.26%).This was Similar to a study by R. Simkhada.[11] but dissimilar to a study in Kuwait by May Sewify et al[12] and in Nepal by PK Jha et al.[13]

Like in almost all the studies from international or national locations[14,15], the most common bacterial isolate was E.coli(59.12%). It was similar to a case-control study done in New Delhi[16] which showed E.coli as most common bacteria in UTI (64.3%). In a study from Nepal[11], it was 52.38%. While in Romanian study[17] it was 70.4%.

In our study, we found Klebsiella pneumoniae (8.60%) and Pseudomonas aeruginosa (2.76%) as next common isolate amongst Gram-negative while Enterococcus faecalis (10.90%) and Staphylococcus aureus (2.91%) are most common Gram-positive isolates. In a study done in Turkey, K.pneumoniae and P.aeruginosa were 9.1% and 3% respectively[18] which was in the same line as ours. Overall in our study second most common isolate is E.faecalis (10.90%) after E.coli (59.12%) which is on the same trend as seen by N.Chatterjee et al.[10] In contrast, second most common isolate in the above mentioned Turkish study was CoNS (24.2%). If we see a retrospective study in Nepal, there was a similar trend of the frequency of Enterococcus spp.(13.84%), K.pneumoniae (8.3%) and S.aureus (7.11%). We also found Citrobacter spp, Proteus spp, and Acinetobacter spp though less frequently.

In this study, seeing antibiotic resistance we found that ampicillin and cefixime are not good options as high-level resistance is seen for commonly grown isolates of E.coli and K.pneumonaie. Citrobacter spp.is 100% resistant to nalidixic acid and cotrimoxazole and equally resistant to amikacin and gentamycin i.e 50%.There is high resistance to gentamycin, ampicillin and amoxicillin-clavulanic acid against Gram-positive organisms especially Enterococcus spp.Fluoroquinolones and cephalosporins are resistant to most of the Gram-negative isolates. Cephalosporin resistance was similarly seen in Nepal[13] and Bangladesh.[19] Good options for them are amikacin, piperacillin/tazobactam, and cefoperazone/sulbactam. Our study has a high prevalence of ESBL in E.coli (71.42%) and K.pneumonaie (56.90%) which needs to be managed with carbapenems as first-line drugs and if not feasible, second-line drugs should be piperacillin/tazobactam or cefoperazone /sulbactam. Though ESBL organisms are in similar frequency as shown in many other studies it was lower compared to a study from Kerala[20] which showed very high-level ESBL growth (approximately 90%) and from Manipal[21] by M.Srinivas et al which showed it 78.6%. Though amikacin is a cost-effective injectable for both non-ESBL and ESBL isolates, its renal toxicity restricts its widespread use.

In our findings, nitrofurantoin had good activity against E.coli and Gram-positive isolates similar to as seen by PK Jha et al[13] and Citrobacter spp. had approximately 50% susceptibility to most of the tested antibiotics but 100% for levofloxacin.

If we see options with antipseudomonal activity in our set up and susceptibility pattern, best antibiotics are Piperacillin / tazobactam and colistin with equal efficacy (82%) followed by imipenem and amikacin (78% and 72% respectively). Here ciprofloxacin has low efficacy (40%) and cotrimoxazole was 100% resistant to P.aeruginosa. Similar findings were seen by M.Srinivas et al[21] with 82% susceptibility to Piperacillin/ tazobactam and 68.2% to cefoperazone/ sulbactam but a very good response to amikacin (93.8%). Meropenem activity against P.aeruginosa in our study was only 50% while M.Srinivas et al[21] found it 87.5%.

In our findings, Gram-positive isolates have shown 100% sensitivity to vancomycin while an article from south India shows 81% and 94% susceptibility respectively by Enterococcus and Staphylococcus.[22] We have less nephrotoxic linezolid with 100% sensitivity against Gram-positive isolates. In an Indian study, Enterococcus faecalis was the most commonly isolated Gram-positive organism with 3.2 percent resistance to vancomycin.[23] We found Acinetobacter spp.in 6 cases showing multidrug-resistant with very low sensitivity even to carbapenems and colistin.

Multi-drug resistant bacteria commonly arise due to the prolonged use of cephalosporins and other antibiotics, particularly their use as prophylaxis treatment, inadequate dosage or inaccurate frequency of administration. This also produces class and cross-resistance. Pseudomonas spp. has become a big challenge to treat. Plasmid-mediated resistance due to the usage of broad-spectrum antibiotics has been considered as one of the factors associated with this

phenomenon.[24]

Amikacin which is easily available and cost-effective remains a good choice for most of the uropathogens if renal status allows and there is a facility to follow renal function test regularly. There is good sensitivity even in current era due to its ability to evade attacks by all antibiotic-inactivating enzymes that are responsible for antibiotic resistance in bacteria, except for aminoacetyltransferase and nucleotidyltransferase.[25] This is accomplished by the L-hydroxyaminobuteroyl amide (L-HABA) moiety attached to N-1 (compare to kanamycin, which simply has a hydrogen), which blocks the access and decreases the affinity of aminoglycoside-inactivating enzymes.[26,27] Amikacin ends up with only one site where these enzymes can attack, while gentamicin and tobramycin have six.

Enterococci are getting commoner in many culture samples especially from urine due to inappropriate and intensive use of broad-spectrum antibiotics.[28] Same are the reasons in cases of other microorganisms. Poultry farms and human foods of animal origin are also contributing significantly to the increasing multidrug resistance amongst isolates.

These are the reasons, why to have knowledge of the pattern of local microbial prevalence and antimicrobial susceptibility to start the most appropriate empirical drug depending on clinical and laboratory profile of patients.

CONCLUSION

Most commonly affected age group with UTI amongst diabetics was from 51 to 60 years where males exceeded females in prevalence. We found E.coli, E.faecalis, and K.pneumoniae as the most commonly grown organisms in descending order. Most of the Gram-negative isolates were susceptible to amikacin, piperacillin/tazobactam, cefoperazone/sulbactam and carbapenems, while Gram-positive cocci were mostly sensitive to nitrofurantoin, linezolid, and vancomycin. Ampicillin, cephalosporins (with the exception of sulbactam combination), cotrimoxazole, and fluoroquinolones are not good choices to start on an empirical basis.

A Study of Prevalence of Depression in Type 2 Diabetic Patients in a Tertiary Care Centre

Tolstoy Rajangam[1], Mritheika Priyashini R[2], Santni Manickam[3]

ABSTRACT

Introduction: Diabetes mellitus and depression are mutually aggravating conditions. Here we present a study on the prevalence of depression and their association with the control of the Type 2 diabetes patients above 40 years of age in a tertiary care center.

Material and Methods: It was a cross-sectional study involving 100 patients with Type 2 Diabetes mellitus above the age of 40 years with HbA1c of < 8% was taken as the controlled group and with HbA1c of ≥ 8% as the uncontrolled group. 'The Hamilton's Depression Scoring' questionnaire was used to assess their level of depression. Both the groups were correlated statistically.

Results: There was a statistically significant association between the depression and the control of the diabetes mellitus in patients aged above 40 years ($p<0.0016$). There was also a statistically significant correlation between the suicidal tendency with the control of the diabetes mellitus in those patients ($p<0.05$). However, there was no positive correlation between the control of diabetes and anxiety.

Conclusion: People with uncontrolled diabetes were more prone to depression and suicidal tendencies than the controlled diabetics.

Keywords: Diabetes Mellitus, Depression, Suicidal Tendency, Anxiety, Elderly Men

INTRODUCTION

One of the greatest challenges of medicine in the 21st century is co morbidity, where two or more disease occurs together in the same individual.[1] Diabetes mellitus is a chronic disease which affects virtually every organ in the human system. The World Health Organization projected that 300 million people will suffer from diabetes by 2025.[2] Globally, an estimated 43 million diabetics have symptoms of depression.[3] People with diabetes who have depression often find it more difficult to follow diabetes treatment recommendations and have poor metabolic control. Thus depression can further aggravate the blood sugar levels and hence 'a vicious cycle' occurs. These patients also have higher complication rates, increased health care use and increased disability, lost productivity, lower quality of life and increased risk of death.[4]

There are several international studies evaluating the prevalence of depression in the diabetic patient. A study on Diabetes and Depressive Symptoms in Korean Women was performed for 6,572 women obtained from the Fifth Korean National Health and Nutrition Examination Survey conducted in 2010 to 2011 which concluded saying that physicians should manage diabetes in consideration to depression, as depressive symptoms were observed in 22.6% of subjects with diabetes.[5] The prevalence of Depression, anxiety and stress symptoms among diabetics was studied by a cross-sectional study in Malaysia which concluded that these symptoms were prevalent among Type 2 diabetics, with a third being classified as anxious.[6] A study on the bidirectional association between depression and Type 2 diabetes in Women available on Arch Intern Med suggests that the relative risk of developing depression is greater in diabetics when compared to non-diabetics.[7]

In patients with Diabetes and essential hypertension, the prevalence of depression and suicidal tendencies was studied and was found that depression and suicidal tendencies are found prominent in the diabetic patient as well as hypertensive, more being in the uneducated side.[8] Diabetes may be diagnosed and treated, but the depression in these patients goes unnoticed. Most of the time, depression is not considered an important factor, often ignored and left untreated.

The available data regarding the prevalence of depression in type 2 diabetes patients in India are limited. We investigated the prevalence of depression in patients with Type 2 Diabetes attending a tertiary care hospital in south India and its relationship with glycemic control was examined.

MATERIAL AND METHODS:

It was a cross-sectional study of 2 months duration involving 100 patients with Type 2 Diabetes of more than 5 years duration above the age of 40 years who presented to the Department of General Medicine and Endocrinology. The controlled group was taken as the one with HbA1c of < 8% and the uncontrolled group was with HbA1c of ≥ 8%. Patients with gestational diabetes, cardiac failure, severe renal failure, stroke and other such complications may be excluded.

A standard questionnaire for depression, 'The Hamilton's Depression Scoring' questionnaire was given to each patient. The questionnaire was given to the patients to assess their

level of depression. The glycemic control of each patient was verified by their HbA1c results. Statistical analysis was performed using SPSS version 20. Prevalence of depression in both populations of controlled and uncontrolled diabetic patients was presented in percentage. Major determining factors like suicidal thoughts and anxiety are elaborated in addition to the depression score.

Ethical clearance was obtained from the institutional Human Ethics Committee and Informed consent was obtained from the respondents before administering the questionnaire.

STATISTICAL ANALYSIS

Descriptive statistics like mean and percentages were used for the analysis for the interpretation of results. Comparision of groups was done by chi sqaure test.

RESULTS

The study was conducted to find out the prevalence of depression in Type 2 Diabetic people who are over 40 years of age and the relation with controlled vs. uncontrolled diabetic status. A total of around 100 people were involved in this study and the results are tabulated below based on Hamilton's scoring.

Table-1 shows that when compared to the controlled diabetic patients, the uncontrolled patients have more prevalence of depression in each of the mild, moderate and severe segment. On doing a statistical analysis comparing the controlled and the uncontrolled diabetic groups using Chi-square, the p-value was found to be p<0.0016 which is statistically significant. The Odds ratio obtained was 2.79 which imply that the uncontrolled diabetics have twice the risk of confronting with depression when compared to the patients with good glycemic control.

	Frequency (Percentage)	
	Controlled diabetes	**Uncontrolled diabetes**
Normal (0-5)	17 (38%)	9 (18%)
Mild (6-8)	8 (16%)	11 (22%)
Moderate (8-11)	11 (22%)	16 (32%)
Severe (>12)	12 (24%)	14 (28%)

Table-1: Depression

	Frequency (Percentage)	
	Controlled diabetes	**Uncontrolled diabetes**
Normal (0-5)	47 (94%)	34 (68%)
Mild (6-8)	3 (6%)	6 (12%)
Moderate (8-11)	0 (0%)	6 (12%)
Severe (>12)	0 (0%)	4 (8%)

Table-2: Suicidal tendencies

	Frequency (Percentage)	
	Controlled diabetes	**Uncontrolled diabetes**
Normal (0-5)	11 (22%)	9 (18%)
Mild (6-8)	22 (44%)	25 (50%)
Moderate (8-11)	15 (30%)	14 (28%)
Severe (>12)	2 (4)	2 (4%)

Table-3: Anxiety

Table 2 also shows the similar pattern that the uncontrolled diabetic patients exhibit more suicidal tendencies than the controlled group in all segments – mild, moderate and severe. Comparing the two groups by the Chi-square test, it was found to be statistically significant (P< 0.05). Suicidal tendencies, like the depression score, are associated with the uncontrolled diabetic status.

Table 3 shows that in both the controlled as well as the uncontrolled diabetic group, the anxiety is variable in its severity and there is no statistical correlation between either of the two groups with anxiety (P-value - 0.935).

DISCUSSION

Our study confirms that people with uncontrolled diabetes have increased chances of depression when compared with the controlled diabetics. The uncontrolled diabetics have twice the risk of confronting with depression when compared to the patients with good glycemic control. Our results were similar to many other studies. Anderson et al summarised 20 cross-sectional reports and that the odds of depression in the diabetic group were twice that of the non-diabetic comparison group.[9]

A study by Rajesh Rajput et al showed that depression and anxiety symptoms were two-fold higher in diabetic patients as compared to healthy controls.[10] In a population-based study in Chennai, it was found that the prevalence of depression was 23.4%.[11] Raval *et al*. found a very high prevalence (41%) of depression in 300 patients with type 2 diabetes in a tertiary care hospital in Northern India.[2] Another study conducted at a tertiary care center found the prevalence of depression in T2DM patients to be 16.9%.[12] A multi-center study done in Pakistan found prevalence at 43.5%.[13]

In the present study, 94% of the patients with controlled diabetes do not exhibit suicidal tendencies and 6% of them exhibit mild symptoms. Whereas in uncontrolled group, the suicidal tendencies are nil in 68% of the patients while 12% has mild and moderate symptoms. There is a severe tendency of suicidal tendencies in 8% of uncontrolled group. According to Subramani et al the percentage of subjects with suicidal thoughts is 12.4%.[14] It was 3.1 % in study by Kessler et al.[15] It was 9.2% according to Nock M K et al.[16] According to study by Siddharth Sarkar et al suicidal ideas and attempts are more frequent in patients with diabetes mellitus than healthy or medically ill controls, Psychological morbidity, including depression, precedes suicidal ideas and attempts.[17] Thus a detailed psychiatric analysis to rule out depression is mandatory for all diabetic patients as each influences the other significantly.

CONCLUSION

In our study, we found that people with uncontrolled diabetes were more prone to depression and suicidal tendencies than the controlled diabetics. However, there is no statistical correlation between either of the two groups with anxiety. Interventional studies would bring out the effect of treating

diabetes as well the depression on each other. As the association between diabetes and depression is bidirectional, a proper approach towards both is required in order to prevent them from becoming worse.

ABSTRACT

Background and Objective: There is a higher prevalence of vitamin D deficiency and associated osteoporosis in south Indian men despite abundant sunlight. Here we present a study on the effect of dietary calcium on bone mineral density in elderly men. **Methods:** This study was done as a part of an original study on the prevalence of osteoporosis and vitamin D deficiency. One hundred twenty elderly men were included. The dietary calcium intake was determined by a trained dietician. Quantitative and qualitative aspects of food intake were accessed and the Published data on Indian food was used to estimate dietary calcium intake. Phytate to calcium ratio was calculated. Bone mineral density (BMD) was done for all the subjects in the lumbar spine, hip and forearm. We also studied sunlight exposure pattern and its effect on vitamin D level. **Results:** The Mean calcium intake of the study population was 455 mg/day which was lower than recommended dietary value. There was a significant positive correlation between calcium intake and BMD at all three sites. The mean phytate to calcium ratio was 1.0643. Phytate to calcium ratio was negatively associated with hip and lumbar spine BMD. The mean vitamin D level was 20.4 ng/dl and the mean BMI (Body mass index) was 23.3 kg/m^2. **Conclusion**: The calcium intake in south Indian elderly men was lower than the recommended allowance and there was a positive correlation between calcium intake and bone mineral density.

Keywords: Bone mineral density, Dietary calcium, Elderly men, South India, Osteoporosis, Phytate, Vitamin D

INTRODUCTION

Calcium and vitamin D play an important role in bone mass accrual[1]. Normal calcium intake varies in different geographical regions[2]. Adequate calcium intake has shown a positive effect on bone mineral density (BMD) and vertebral fracture reduction in post-menopausal women[3]. Vitamin D plays an important role in calcium absorption from the intestines and suppresses parathyroid hormone production. Dietary calcium intake is associated with greater BMD in post-menopausal women than calcium supplementation[4]. Low calcium intake is also associated with increased bone turnover markers and osteoporosis[5]. Adequate dietary calcium intake during adolescence increases BMD. Vitamin D deficiency among Indian population is high even with adequate sunlight exposure[6]. This may be due to skin pigmentation and dressing habits among certain communities[7]. Because vitamin D is essential for calcium absorption, communities with poor calcium intake may be further compromised by vitamin D deficiency. We have already reported a higher prevalence of vitamin D deficiency and osteoporosis in South Indian men[8]. Hence, we undertook this study to find the effect of calcium intake on BMD in elderly South Indian men. We also studied sunlight exposure pattern and its effect on vitamin D level.

METHOD AND MATERIALS

This study was done as a part of an original study of the prevalence of osteoporosis. It is a cross-sectional prevalence study of osteoporosis in South Indian men and the influence of lifestyle factors on BMD, done after getting the permission from the Institutional Ethics Committee. One hundred twenty men of the original study were analysed.

This study was done in an urban area of Vellore, South India (12.9202°N, 79.1333°E), for 1 year duration from August 2010 to July 2011. After the initial survey, men above the age of 50 years were recruited by the cluster sampling method. Men with a history of chronic liver disease, renal disease or drugs that can affect bone health were excluded from the study.

The dietary calcium intake was determined by a trained dietician. Quantitative and qualitative aspects of food intake were accessed using semi-quantitative food frequency questionnaire. It includes a meal plan recall that covers the menu for a week. Published data on Indian food were utilised for estimating dietary calcium intake[9]. As a part of the study, phytate intake was assessed, and the phytate-to-calcium ratio was calculated because it is more predictive of calcium absorption[10]. History of sunlight exposure and clothing patterns were also assessed. The study was done during summer to minimise the effect of sunlight on vitamin D status. Twenty-four-hour urinary calcium excretion was done to assess the adequacy of nutritional calcium intake.

Biochemical analysis was done as a part of the original study. Fasting sample was obtained for estimation of serum calcium (8.6–10.2 mg/dl), phosphorus (2.5–5 mg/dl), albumin (3.5–5 g/ml), alkaline phosphatise (40–125 IU/L), creatinine (0.6–1.2 mg/dl), 25-hydroxy (25-OH) vitamin D (30–75 ng/ml), intact parathyroid hormone (iPTH)(8–50 pg/ml) and testosterone (300–1000 ng/dl). BMD was assessed at the lumbar spine, hip and forearm using Hologic DXAQDR 4500 Discovery A machine. Precision was 2% at both the measured sites (the spine and neck of the femur).

Statistical analysis was done using SPSS V.16.O Software (IBM Corp., USA). The independent sample 't' test was used to compare the measures of two continuous variables if they were normally distributed and nonparametric test was used if it was not normal.

RESULTS

One hundred twenty men from the original study were the part of this sub-study. The mean age of the study population was 58 years. The mean 25-OH vitamin D level of the study population was 20.4 ng/ml (range 4–58 ng/ml), the mean PTH was 44.5 pg/ml (range 14.5–151 pg/ml) and mean body mass index was 23.3 kg/m^2 (range 16.2–41.6 kg/m^2). The mean testosterone level was 620 ng/dl (range 270–980 ng/dl).

The mean calcium intake of the study population was 455 mg/day (range 131–1565 mg/day), and the mean urinary calcium excretion was 185 mg/24 hours (range 26–558 mg/24 hours). Out of 120 subjects, only one subject had a documented calcium intake of 1,000 mg and above. About 62% of the study population consumed less than 500 mg of calcium per day (Table 1).

Table 1: Mean Calcium Intake and Urinary Calcium Excretion

Characteristic	Mean (Std Deviation)	Range
Calcium intake (mg/24 hours)	455.9 (184.2)	131–1565
24-hour urine calcium (mg/24 hours)	185(108)	26–558

There was a positive correlation between calcium intake and BMD in all three sites, which is statistically significant (Figures 1–3).

In our study, the mean phytate-to-calcium ratio was 1.0643 (SD 0.616). The phytate-to-calcium ratio was negatively associated with hip and lumbar spine BMD. About 64% of the study population had adequate sunlight exposure of at least 20 minutes per day during daytime (between 10 a.m. to 3p.m.). Mean vitamin D level was higher in subjects with adequate sunlight exposure (21.1ng/ml vs.18.9 ng/ml).

DISCUSSION

The aim of this study was to evaluate the dietary calcium intake and its effect on BMD in men above 50 years of

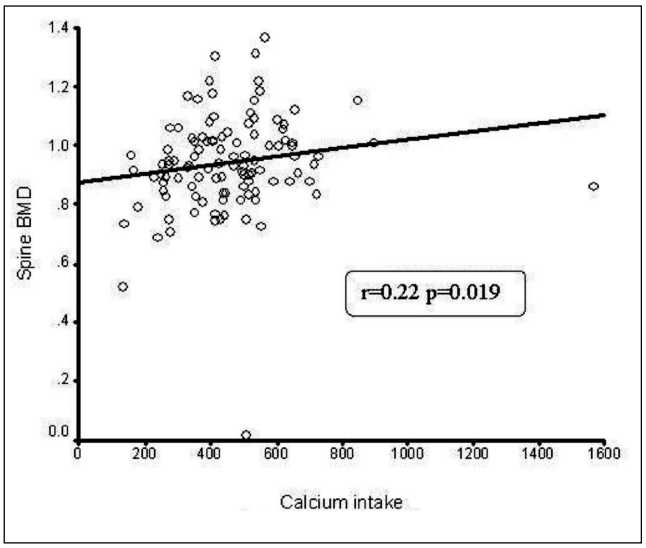

Figure 1: Correlation between Calcium Intake and Lumbar Spine BMD

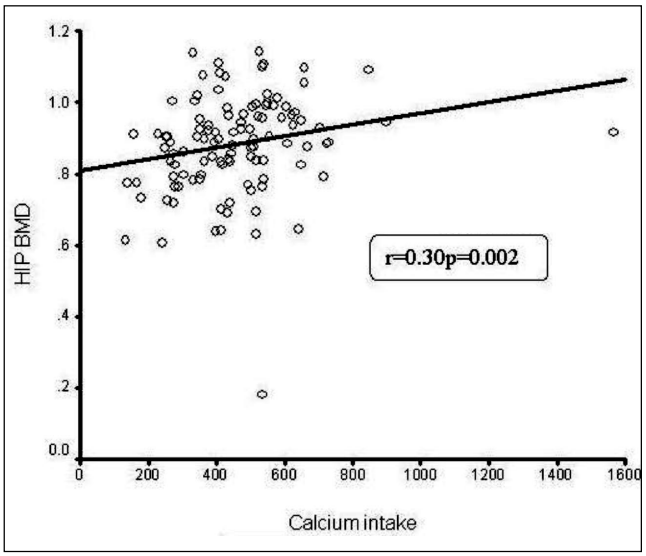

Figure 2: Correlation between Calcium Intake and Total Hip BMD

age. Dietary calcium intake plays an important role in bone health. Calcium and phosphorous are principle constituents of bones accounting for 65% of its weight[11]. Vitamin D plays an important role in calcium absorption and bone health by suppressing PTH level[12]. Hence, optimal vitamin D is necessary for calcium absorption. Even under normal conditions, only about 30%–40% of dietary calcium is absorbed[13].

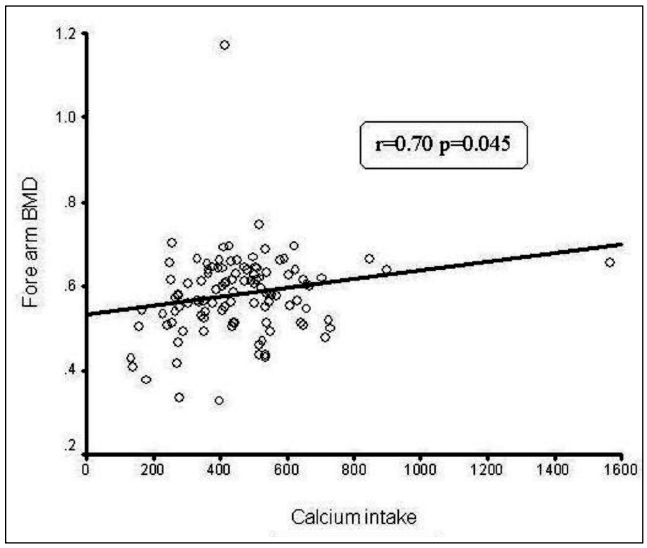

Figure 3: Correlation between Calcium Intake and Forearm BMD

Absorption of calcium is affected by dietary phytate, oxalate and sodium. Myo-inositol hexaphosphate (phytate), a saturated cyclic acid, is a storage form of phosphorus in cereals and legumes[14]. When consumed, it forms a complex with minerals such as zinc, calcium and iron and retards their intestinal absorption[15–17].

Effect of calcium intake on BMD and fracture risk is not consistent. In a large epidemiological study, reduced calcium intake was not associated with increased incidence of the forearm or hip fracture in men[18].

The mean calcium intake in our study was 455 mg/day (range 131–1565 mg/day). This is lower than the recommended intake as per Indian Council of Medical Research, which suggested at least 600 mg/day[19]. In several studies, it was shown that dietary calcium intake is lower in the Indian subcontinent[20–22]. It was shown that in subjects with low calcium intake, there is an accelerated conversion of vitamin D to its inactive polar metabolite, mediated by 1,25-dihydroxyvitamin D [23]. This may explain the widely prevalent vitamin D deficiency in the Indian subcontinent. It was postulated in UK Asians that inadequate sunlight exposure, low calcium intake and high cereal consumption may lead to secondary hyperparathyroidism, which may lead to progressive vitamin D reduction[24].

Harinarayan *et al*. from the same geographical area published data regarding dietary intake of calcium in both urban and rural subjects. In that study, the mean dietary intake of calcium in urban and rural men were 322±8 and 306±2, respectively, which is lower than that in our study[25].

In our study, there was a positive correlation between calcium intake and BMD (spine, total hip and forearm) with a respective r value of 0.22 (p value 0.019), 0.30 (p value 0.002) and 0.70 (p value 0.045). The mean phytate-to-calcium ratio was 1.0643 (SD 0.616).

A low calcium intake is considered as a risk factor for fracture because it is one of the principle constituents of the bone. In a study by Lee *et al.*, there was a positive relationship between dietary calcium intake, calcium/phosphorus intake ratio and femoral neck BMD in men older than 50 years[26]. Tandon *et al.* have shown that dietary calcium intake was positively associated with BMD and negatively associated with dietary phytate intake[27]. In that study, even with adequate calcium intake, about 10% of subjects had osteoporosis at the lumbar spine. Even though large epidemiology studies have shown no association between calcium intake and fracture risk, in our study, increased calcium intake was associated with increased BMD.

Dietary phytate impairs the absorption of calcium. In our study population where dietary calcium intake was low, this might further impair the calcium availability[28]. Harinaryan *et al*. published a study from a similar geographical area. They showed that low calcium and high phytate consumption in both rural and urban subjects. These studies clearly highlight the need for an increase in recommended dietary allowance of calcium intake in elderly Indian subjects.

The vitamin D levels are lower even in subjects with optimal sunlight exposure (21.1 ng/ml vs. 18.9 ng/ml). This may be due to dressing habits among certain communities, skin pigmentation and environmental pollution[29].

CONCLUSION

As there is a positive correlation between calcium intake and BMD and the calcium intake in the South Indian elderly men is low, this study clearly highlights the need to take measures to increase the calcium intake in elderly subjects to improve the bone health and to prevent osteoporotic fractures. The recommended dietary allowance of calcium is also to be increased, at least in the elderly population, in view of consumption of dietary phytates. In addition, the study also necessitates the need for screening of vitamin D deficiency in elderly Indian subjects even with adequate sunlight exposure. An interventional study with calcium and Vitamin D supplementation can be done as a follow-up.

A Rare Etiology of Severe Thrombocytopenia in Patient with Chronic Liver Disease

Mohammad Zeya Ansari, R Tolstoy, G Jagadeeswaran

Abstract

Thrombocytopenia is a common complication in patients with chronic liver disease and is multi-factorial. It complicates the management and worsens the prognosis. Treatment options are costly and include platelet transfusion, splenectomy, splenic artery embolization, TIPPS and thrombopoietin (TPO) agonists.

Here we are presenting a patient with decompensated liver disease with known chronic alcoholism and profound thrombocytopenia despite multiple platelet transfusions. On further work up we found a coexistent autoimmune etiology. Thrombocytopenia promptly responded to steroids, a cost effective option.

Introduction

Thrombocytopenia, a common complication in patients with chronic liver disease, is seen in nearly 75% of cirrhotic patients.[1] The pathogenesis of thrombocytopenia in chronic liver disease is multi-factorial.[1] Initially it was thought that thrombocytopenia in CLD is only due to portal hypertension where there will be an enlargement of spleen which causes destruction of platelets. So initially treatment for thrombocytopenia was aimed at reversing portal hypertension. But persistently decreased platelets were noted even in patients without splenomegaly.[2] So other factors like intrasplenic production of autoantibodies and plasma expansion resulting in hemodilution also contribute to thrombocytopenia. Suppression of platelet production in bone marrow is also another factor which is seen in HCV infection and alcohol related chronic liver disease. Antiviral therapy like interferon alfa also induces thrombocytopenia.[3] In some patients of CLD there is an evidence based autoantibodies related destruction of platelets and it is mostly observed in HCV related cases.[4] Here autoantibodies are directed against platelet surface antigens and enhance the removal of platelets by splenic and hepatic reticuloendothelial systems there by triggering rapid destruction as seen in chronic ITP. TPO is a potent cytokine produced by liver, bone marrow and kidney which regulates megkaryocytes and platelet production.[5] In cirrhotic patients with thrombocytopenia, low circulating levels of TPO is seen compared to cirrhotic patient with normal platelet count.[6] The treatment options available for severe thrombocytopenia are platelet transfusion, splenic artery embolization, splenectomy and TIPS. Platelet transfusion is indicated in patients with less than 10,000-20,000/µl platelets in uncomplicated patients and less than 50,000/µl in patients undergoing procedures.[7] Newly derived options include recombinant interleukin-11, eltrombopag and recombinant TPO.

Case Summary

A, 50 year old male patient with ethanol related chronic liver disease and no other comorbidities, came to EMD with the complaints of melaena, gum bleed and haematuria for 10 days, fever with chills, abdominal pain and distention for 3 days.

On examination, patient was pale and febrile with stable vital parameters. He had minimal ascites and epigastric tenderness.

Serial CBC, LFT and RFT are summarized in Table.1. Upper GI endoscopy showed esophageal varices and portal gastropathy and EVL done immediately. Ultrasound abdomen Showed features of CLD and portal hypertension with medical renal disease. Ascitic fluid analysis had no evidence of peritonitis. Urine culture showed significant bacteria (E.coli) and managed accordingly. He had severe thrombocytopenia which was managed with platelet transfusions. Bone marrow aspiration and biopsy showed dimorphic anemia with thrombocytopenia, megaloblastic erythroid hyperplasia and mild megakaryocytic hyperplasia. His serum B12 and folate level were within normal range. Hepatis B, C, HIV, Dengue virus, *Helicobacter pylori*, scrub typhus, leptospirosis infection and Coomb's test were negative. Renal failure was stabilized with hemodialysis.

As his thrombocytopenia persisted despite multiple platelet transfusions (total 19 units) and other common causes of thrombocytopenia being ruled out, we suspected of some uncommon etiology including an autoimmune condition. ANA tested was positive with fine granular++, cytoplasmic+ pattern. He was positive for smooth muscle antibody and negative for anti-ds DNA Ab and hence he was diagnosed to have autoimmune hepatitis type-1 with associated ITP. We started steroids (Inj. methylprednisolone 125 mg IV OD for 3 days followed by oral prednisolone 60mg OD). His platelet count started improving from 2nd day of IV steroid.

On follow-up visits, his platelet count was in safe range (> 1 lakh / cu.mm3) with low dose oral steroid and is currently being managed as ITP.

Discussion

The causes of thrombocytopenia in chronic liver disease may be due to sequestrating function of spleen, presence of antiplatelet antibodies and impaired thrombopoietin production in cirrhotic patients.[6] It is very important to differentiate ITP from common cause of thrombocytopenia in CLD as the management differs. Hypersplenism in liver disease due to portal hypertension

Department of General Medicine, PSG IMS & R, Coimbatore, Tamil Nadu

causes increased sequestration of platelets within spleen leaving less in circulation. However it is also to be clear that thrombocytopenia can occur in liver cirrhosis without splenomegaly.[2] Thrombopoietin is a cytokine produced by the liver which plays a key role in platelet production and subsequent function may be low in cirrhosis. Thrombocytopenia in liver disease without evidence of cirrhosis, splenomegaly and interferon is recognized especially in patients with hepatitis C and auto immune hepatitis.

Based on persistent thrombocytopenia, ANA and anti SMA positivity we diagnosed him as AIH type-1 and associated ITP. The International Autoimmune Hepatitis Group proposed a scoring system to standardize the diagnosis, useful for clinical trials, but that may be inaccurate in individual cases.[8] Liver biopsy was not done for two reasons-severe thrombocytopenia and patient refusal.

Autoimmune hepatitis (AIH) is a chronic and progressive necroinflammatory and fibrotic process of the liver of unknown cause that occurs in children and adults, usually associated with the presence of autoantibodies and Hypergammaglobulinemia.[8] Affected individuals often have concurrent extrahepatic autoimmune disorder like rheumatoid arthritis, Sjogren's syndrome and auto immune thyroiditis but association with idiopathic (immune) thrombocytopenic purpura has been rarely reported.[9-13]

ITP is an autoimmune disease characterized by a low platelet count, mucocutaneous bleeding, normal bone marrow findings and the absence of other causes of thrombocytopenia in which anti-platelet autoantibodies such as PAIgG induces platelet destruction.[14] There is a case series of 5 patients with AIH type-2 where patients had at least one associated autoimmune disorder including IgE-induced IgA deficiency, ITP, and arthritis.[15] In an Indian case series of 10 patients with AIH, three had underlying rheumatic disease (SLE, Sjogren's and Rheumatoid arthritis each one), while others had primary AIH. In the same report, 2 patients were found to have autoimmune thrombocytopenia and were managed by immunosuppressant.[16] Indeed prednisolone administration is a treatment option for AIH and is also effective for ITP. Therefore ITP should be considered when liver dysfunction is accompanied by severe thrombocytopenia particularly in the autoimmune types of liver disease.

Though in our patient there was normal bilirubin, SGOT and SGPT (which is usually elevated in hepatitis) but persistent thrombocytopenia and positive ANA with SMA made us to consider it AIH type-1.

Conclusion

It is worthy to evaluate for an alternative autoimmune etiology for CLD if thrombocytopenia is severe or persisting as there are better and cost effective treatment options i.e. steroids.

Learning points

1. All CLD with history of alcohol ingestion is not purely alcohol related.
2. Thrombocytopenia in CLD should be evaluated for causes other than alcohol and hypersplenism.
3. All autoimmune hepatitis may not have gross LFT derangement.

A Tertiary Care Hospital based Study on the Prevalence of Pulmonary Hypertention in Patients with Glomerular Filtration Rate less than 30 Ml /Min Per 1.73 Meter Square on Dialysis

Tolstoy Rajangam[1], Jagadeeswaran Govindarajan[2], Vignesh[3], Mohammad Zeya Ansari[4]

ABSTRACT

Introduction: Pulmonary artery hypertension (PAH) which can be primary or secondary, has been found to be associated with chronic kidney disease, especially end stage renal disease. Finding prevalence of pulmonary hypertension in early stages of chronic kidney disease is important because it creates very high burden of cardio vascular morbidity and mortality. In this study we have assessed various factors associated with prevalence of pulmonary hypertension in patients with glomerular filtration rate less than 30ml/min per 1.73 meter square on dialysis.

Material and methods: This is a one year, hospital based, prospective observational study of patients aged more than 18 years with GFR less than 30 ml/min per 1.73-meter square on dialysis, who were found to have pulmonary hypertension on echocardiography. The prevalence of pulmonary hypertension in this group of patients and the risk factors in CKD associated with it are calculated followed by a descriptive analysis and interpretation of the data.

Results: The various factors we analyzed and p value for association of pulmonary hypertension in CKD for the percentage of male and female in our study group is 0.241, for distribution of the pulmonary hypertension among different age groups is 0.503, for the significance of diabetic mellitus is 0.595,for systemic hypertension is 0.206, for arterial venous fistula is 0.780,for superimposed infections 0.166, for volume overload is 0.560, for anemia is 0.780, for left ventricular diastolic dysfunction is 0.662, for creatinine clearance is 0.717,for duration of dialysis is 0.000. With above results, only association with significant p-value (0.000) in our study population with pulmonary hypertensions longer duration.

Conclusion: Prevalence of pulmonary hypertension in our study is 22%. The risk factors like age,sex, diabetes, systemic hypertension, AVF, superimposed infection, volume overload, anaemia, LVDD has no influence on pulmonary hypertension in our study, only strong association that we have in our study population with pulmonary hypertension with CKD is longer duration of dialysis.

Keywords: Pulmonary Hypertension (PH), CKD

INTRODUCTION

Though, there has been fast advancement in the medical field which helps in the early and accurate diagnosis of health status of a patient, pulmonary hypertension remains a hidden problem that takes plenty of time in diagnosis from the presence of first symptom. Many patients are diagnosed only in advanced stage of disease.[1] Normal pressure in pulmonary artery is 25/10 mmHg and if the pulmonary artery pressure exceeds 40/20 mmHg or average pressure exceeds 25 mmHg, then the pulmonary hypertension is said to be present.Though the cut off value varies in many studies. If the pressure in the pulmonary artery remains persistently high then the right ventricle of the heart may get hypertrophied,so right ventricle will not be able to pump properly and the symptoms of right heart failure will occur. Pulmonary artery pressure is increased by many conditions and so pulmonary hypertension is classified accordingly. Prevalence of pulmonary artery hypertension inWHO's class1 which is caused mainly by connective tissue disorder, drug, and toxic agents is 15 cases/million adult population.[2,3] Prevalence of idiopathic pulmonary artery hypertension is 5.9 cases/million adult population.[4] Pulmonary hypertension due to systemic sclerosis, portal hypertension, congenital heart disease, and sleep apnea is 7-12%[5,6], 2-16%,[7] 30%[8], and 15-20%[9] respectively. Up to 60%of the patients with severe left ventricular systolic dysfunction and 70% of those with the heart failure with preserved ejection fraction may present with pulmonary hypertension. Almost all the patients with mitral valve diseases have pulmonary hypertension and 65% of those with symptomatic aortic stenosis also will have pulmonary hypertension.[10,11] Chronic thrombo-embolic pulmonary hypertension (CTEPH) prevalence was 3.2 cases/million/year and incidents were 0.9 cases/million/year. A large survey that is conducted in united states that registered information from all form of pulmonary hypertension from 1980-2002 documented that death rate in patients with pulmonary hypertension during these times were stable and ranging from 5.2-5.4deaths/1,00,000.[12,13,14,15]

Chronic kidney disease(CKD) is the global health burden with high economic cost to health system and is an

DOI: http://dx.doi.org/10.21276/ijcmr.2019.6.10.5

independent risk factor for coronary vascular disease. All stages of CKD are associated with increased risk of cardio vascular premature mortality, morbidity and decreased quality of life.

Pulmonary artery hypertension in renal disease is an on-going research topic since it has very limited data. Prevalence of pulmonary hypertension in patients on hemodialysis, peritoneal dialysis and in stage - 5 CKD, ranges from 18.8 - 68.8%, 0.4-2% and 9-39% respectively. No proper epidemiological data are available yet for early stages of CKD. Pulmonary hypertension has direct association with mortality in end stage renal disease. Pulmonary hypertension in end stage renal disease is associated with the worst outcomes.[16-22] It is important to prevent pulmonary hypertension in patient with ESRD in early stages where even kidney transplantation may not reverse the condition,it alsohas high risk of mortality.

Study aimed to find the prevalence of pulmonary hypertension in patients with glomerular filtration rate less than 30ml/min per 1.73-meter square on dialysis in tertiary care hospital, to find the percentage of male and female in our study group and to find the significance of their association with pulmonary hypertension, to find the distribution of the pulmonary hypertension among different age groups and to find the significance of association pulmonary hypertension with diabetic mellitus, systemic hypertension, arterial venous fistula, superposed infection, volume overload, anaemia, left ventricular diastolic dysfunction, creatinine clearance, and duration of dialysis.

MATERIALS AND METHODS

In this prospective observational study conducted during the period of August 2016 to August 2017, we included total of 50 patients who were admitted in hospital fulfilling inclusion criteria. A proforma was made which included the detailed history, clinical examinations, and requisite investigations. After taking informed consent from each patient, detailed history was obtained and complete examination was done. Investigations like complete hemogram, routine urine analysis, blood sugar, serum electrolyte, serum creatinine, blood urea, thyroid function test, liver function test, ultrasound abdomen and pelvis, retroviral serology, hepatitis B and C serology, chest X-ray, echocardiogram, and electrocardiogram were done. GFR is calculated with the help of Cockcroft-Gault formula. Finally, the prevalence of pulmonary hypertension and the risk factors association with it were calculated and statistical analysis was done with the available data.

Inclusion criteria

-Age more than 18years

-Patients with GFR less than 30 ml/minper 1.73-meter square on haemodialysis

Exclusion criteria

Patients who has ejection fraction less than 45%

Patients who are known case of chronic lung disease, thrombo-embolic disease, sarcoidosis, sickle cell disease, HIV, connective tissue disorder, sleep disordered breathing, portal hypertension, congenital heart disease.

STATISTICAL ANALYSIS

The data collected from the patients is tabulated using Microsoft Excel. The chi square test was used to assess the difference in categorical variables between groups. Variables were presented as frequencies (numbers) and proportions (%) and Chi square test was used to compare frequencies. Results were presented in tables with an explanatory paragraph for each table by using Microsoft Office word software version 2010. Level of significance (P value) was considered at 0.05 as cut-off point for significant association.

RESULTS

Distribution of PH in various Age Groups

As seen in table -1, out of the total of number of 50 patients those belonging to age groups less than 40 years, 41-50 years, 51-60years,61-70 years and above 70 years were 6(12%), 7(14%), 24(48%), 9 (18%) and 4(8%) respectively. Patients who were found to have PH in these age groups were 3(50%), 0(0%), 6(25%), 1(11.1%), 1(25%) respectively. So,

Age (in years)	Pulmonary hypertension		Total	P value
	Yes	No		
<=40	3(50%)	3(50%)	6(100%)	0.241
41-50	0(0%)	7(100%)	7(100%)

was not significant.

In the table 2 we compared the PH distribution among male and female population, in which males 5(17.9%) patients are found to have pulmonary hypertension and among females 6 (27.3%) patients had pulmonary hypertension. There were no significant association of pulmonary hypertension among male and female, since the p value was 0.503.

In the table 3 we analysed significance of association of diabetic mellitus with pulmonary hypertension. In total of 50 patients, 31(62%) patients were found to have DM, and among them 7(22.6%) patients were found to have PH. P value was 0.595, hence there was no significance of DM association with PH.

In the table 4 we analysed significance of association of systemic hypertension with pulmonary hypertension. In total of 50 patients, 46(92%) patients were found to have SHTN, and among them 9(19.6%) patients were found to have PH. P value was 0.206, hence there was no significance of SHTN association with PH.

In the table 5 we analysed significance of association of AVF with pulmonary hypertension. In total of 50 patients, 49(98%) patients were on AVF and one patient was on peritoneal dialysis, and among patients on arteriovenous fistula 11(22.4%) patients were found to have PH, and patient with peritoneal dialysis had no PH and P value was 0.780,which is not significance of AVF association with PH.

In the table 6 we analysed significance of association of super imposed infection with pulmonary hypertension. In total of 50 patients, 21(42%) patients were found to have super imposed infection, and among them 7(33.3%) patients were found to have PH. P value was 0.166, which also no significance of super imposed infection association with PH.

In the table 7 we analysed significance of association of volume overload with pulmonary hypertension. In total of 50 patients, 26(52%) patients were found to have volume overload, and among them 6(23.1%) patients were found to have PH. P value was 0.560, hence there was no significance of volume overload association with PH.

In the table 8 we analysed significance of association of anaemia with pulmonary hypertension. In total of 50 patients, 49(98%) patients were found to have anaemia, and among them 11(22.4%) patients were found to have PH. P value was 0.780, hence there was no significance of anaemia association with PH.

In the table 9 we analysed significance of association of LVDD with pulmonary hypertension. In total of 50 patients,

41(82%) patients were found to have LVDD, and among them 10(24.4%) patients were found to have PH. P value was 0.662, hence there was no significance of LVDD association with PH.

In the table 10 we analysed the pulmonary hypertension distribution and significance of association among the patients with varying range of creatinine clearance. In our study group 6(12%), 33(66%), 9(18%), 2(4%) patients were found to have creatinine clearance between 0-5%, 5-10%, 10-15%, 15-30% respectively and among them pulmonary hypertension was found in 1(16.7%), 7(21.2%), 3(33.3%), 0(0%) respectively. P value is 0.717 insignificant.

In the table 11 we analysed significance of association of duration of dialysis with pulmonary hypertension. In total of 50 patients, 15(30%), 30(60%), 5(10%), 15(30%) patients were found to be between 0-5, 5-10,10-15 years of dialysis respectively, and among them 0(0%), 6(20%), 5(100%), 11(22%) patients were found to have PH respectively. P value was 0.00, hence association of duration of dialysis with pulmonary hypertension is statistically significant.

DISCUSSION

There is no availability of epidemiological data in many developing countries including India for cause of pulmonary hypertension, but in India most common causes of PH are due to rheumatic heart disease, obstructive airway disease and congenital heart disease unlike western countries where idiopathic pulmonary artery hypertension and PH due to right heart disease are common.

Craddock et al say that exposure of dialysis membrane to blood leads to activation of neutrophils which leads to sequestration of neutrophils in the lungs. This phenomenon, is more common if cellulose membranes are used and it causes worsening of lung disease in HD patients.[23]

Presence of connective tissue disease, super imposed infections, haematological and liver diseases can cause pulmonary hypertension in patients with CKD. These conditions cause PH mainly by affecting micro vascular tone in lungs. Endothelial dysfunction has association with pulmonary hypertension in patients with CKD on HD, Main mechanism behind that includes imbalance between vasoconstrictors and vasodilators and high endothelin-1 and low nitric oxide levels affect vascular tone leading to PH.[24,25,26]

The prevalence of PH in CKD in our study was 22%, and the maximum affected age group was 51-60 years.In the study by Qian Zhang et al[27], the total prevalence of PH in CKD was 47.38% with the maximum number of patients seen in age 46.44(±14.63) years. Similarly another study from Iraq[28], showed maximum patients in 50 to 60 years and 60 to 70 years age group (35.3% in both groups).Male and female patients had prevalence of 55.32% and 44.68% respectively and their total number of patients compared to ours was large (n=705) while we had male and female prevalence of 17.95 and 27.3% respectively.

As noted by Qian Zhang et al[27], multivariate odds ratio(with 95%CI) for prevalence of PH in CKD showed that gender, diabetes, systemic hypertension had no significant correlation with PH while eGFR was contributing significantly to it. But, in our study all these parameters were insignificant for PH. Similarly, Ali Abdul Majid Dyab Allawi et al[28] and Thenappan T[29] also found no association between PH in CKD and hypertension even though hypertension is an established risk factor in for PH. Chronic volume overload leads to increased venous return in CKD patients may induce PH but as such we did not get any association between them. Severe anaemia is a well-known cardiovascular risk factor in CKD patients as low haemoglobin leads to hypoxic injury in tissues including pulmonary vasculature.[30] In our study we found no significant association of PH with anaemia while In a retrospective study low haemoglobin had significant impact on PH(P-value-0.000).[27]

In our study, we did not find a correlation between Left ventricular diastolic dysfunction and PH although LV end - diastolic pressure is taken as gold standard for its definition. Measuring LVDD in cases where pulmonary systolic pressure may not be estimated may help in predicting a relation with PH.[31]

According to Yigla M et al, pulmonary hypertension (PH) is a progressive, fatal pulmonary circulatory disease that accompanies many conditions (including left to right side shunt) with compensatory elevated cardiac output. PH also complicates chronic haemodialysis (HD) therapy immediately after the creation of an arteriovenous (AV) access, even before starting HD therapy. It tends to regress after temporary AV access closure and after successful kidney transplantation. This syndrome is associated with a statistically significant survival disadvantage. The laboratory hallmark of this syndrome is reduced basal and stimulatory nitric oxide (NO) levels. It appears that patients with end-stage renal disease (ESRD) acquire endothelial dysfunction that reduces the ability of their pulmonary vessels to accommodate the AV access-mediated elevated cardiac output, exacerbating the PH.[32]

We found 22.4% patients with AV fistula who had PH but this was not significant(p-value>0.780) while flow dependent significance of AV fistula was seen by Magdy M Emara et al.[33] In our study we have not measured AVF flow rate so could not assess its significance.

Comparing our study with Domenici et al[34], who noticed PH in 58.9% cases on HD and 22.2% on PD, we found 22.2% patients on HD having PH but no PH in patient on PD. Similarly another study by Yigla et al[35], found PH 39.7% in patients on HD but none on PD. An study in Iran, based on echocardiographic evaluations, found PH in 30-40% patients on chronic dialysis.[36]

Duration of dialysis significantly added to the development of PH which is evident from our study. This is well supported by Magdy et al[33], who reported duration of dialysis to be quite significantly associated with PH(P-value<0.001 and Pearson correlation 0.780).

Compared with previous studies, risk factors like age, sex, diabetes, systemic hypertension, AVF, superimposed infection, volume overload, anaemia, LVDD are not

associated with pulmonary hypertension in our study. But we found that the longer the duration of dialysis, the higher the possibility of pulmonary hypertension.

Limitations

A larger population based study may provide better data and correlations of above mentioned risk factors.

We have excluded secondary causes of PH in those who are known cases of chronic illness from available information only but have not investigated completely.

CONCLUSION

Prevalence of pulmonary hypertension in our study is 22 percentages. The risk factors like age, sex, diabetes, systemic hypertension, AVF, superimposed infection, volume overload, anaemia, LVDD has no influence on PH in our study. only association that we have in our study population in patients with PH is longer duration of dialysis.

ABBREVIATIONS

PH - Pulmonary hypertension, CKD - Chronic kidney disease, AVF - Arteriovenous fistula, LVDD - Left ventricular diastolic dysfunction, EF - Ejection fraction, ESRD - End stage renal disease, HD - Haemodialysis, PD - Peritoneal dialysis, GFR - Glomerular filtration rate, DM - Diabetes mellitus, SHTN - Systemic hypertension

ABSTRACT

Context: It is well-documented that high-fidelity simulated training can be used to improve very important aspects of clinical interventions which include clinical decision-making, technical skills, soft skills like communication and leadership qualities. Many of the procedural skills can also be learnt effectively through simulations, using manikins of lower fidelity. **Aim:** Present report is an attempt to substantially enhance the 'must possess' attributes of a good clinician, which are quite often difficult to achieve by conventional teaching methods. **Methods:** This programme was aimed at providing training to the medical interns in cardiopulmonary resuscitation, as well as basic and advanced cardiac life support in medical emergencies, in an attempt to help them to efficiently manage commonly encountered cardiorespiratory emergencies. The programme was evaluated by comparing their performance before and after the intervention. **Results:** Their performance scores reflected the positive effects of the simulation-based teaching. In general, in addition to improving their skills in handling certain selected medical emergencies, the programme has also proved to enhance 'entrustable professional activities' of the young medical graduates. **Conclusion:** Our study, while highlighting the desirability of utilising simulation-based clinical training (SBCT), has also sought ways and means of incorporating SBCT as a mandated programme during the medical internship at an institutional level.

INTRODUCTION

The realm of medical education is undergoing significant changes globally. Some of these changes are warranted because of the great technological advances made in this field and others are due to an increasing awareness of patient safety measures warranted during the clinical procedures. The latter set of changes affects the general approach to patient care and calls for curricular changes to be brought in while training the medical undergraduate students, to effectively bring in the required attributes in the qualifying doctors. As it has been established that human error is a very significant factor as a cause for fatalities in a hospital, it is important to be able to avoid this single deterring factor while training the undergraduate medical students. There is increasing evidence to suggest that this can be achieved by effectively adopting simulation-based clinical training (SBCT), as an adjunct to conventional clinical teaching[1].

Competency-based medical education was advocated as an effective remedy for bringing in effective clinical training with consistency between different medical schools in terms of skills taught and competencies achieved[2]. In an effort to achieve this, many schools of medicine quite correctly thought of resorting to simulation-based medical education (SBME). This, in

turn, saw the usurping of skill laboratories using manikins of varying fidelities being established to train the medical, nursing and physiotherapy students at undergraduate and postgraduate levels of training. SBME has been practiced in many medical schools abroad and there are reports concerning their success in achieving the goals[3]. It is well-documented that a high fidelity simulator can be used to improve very important aspects of clinical interventions which include clinical decision making, technical skills, soft skills like communication and leadership qualities. Procedural skills like administering intravenous drugs, urinary catheterisation, endotracheal intubation and many other practical skills can be taught and learnt effectively through simulations, using manikins of lower fidelity. It is not surprising to realise that simulated learning is becoming an integral part of the curriculum in many medical schools as these modules enhance learning in cognitive, psychomotor and affective domains[4]. These exercises can also be used to assess the student performance in all the domains of learning[5–7].

Establishment of a standard skills laboratory involves many challenges which include organisation of the equipments required and huge finances for these infrastructural facilities. In addition, this also involves careful training of enough resource personnel[8–10].

Internship is a critical and final stage of medical training, wherein a candidate is expected to acquire all the skills to practice medicine under supervision, ensuring that at the end of the training, he/she becomes capable of executing the functions of a doctor independently[11]. Considering the importance of the internship period, it would be desirable to incorporate simulated learning into this programme. As of now, since Medical Council of India (MCI) has not stipulated a compulsory posting for the conduct of simulation-based training, it is not easy to find the appropriate time for this programme[12].

In our medical school, which is a 30-year-old teaching institution, and which is equipped with the state-of-the-art centre of clinical simulation, an organised programme of SBCT is being conducted for the last 2 years. This is an attempt to substantially enhance the 'must possess' attributes of a good clinician, which is quite often difficult to achieve by conventional teaching methods.

All the Compulsory Rotatory Residential Interns (CRRIs) need to have training in cardiopulmonary resuscitation, as well as basic and advanced cardiac life support (ACLS). This will enable them to efficiently manage commonly encountered cardiorespiratory emergencies.

SBCT is relevant for the training of medical interns to function as inter-professional health team member and also as an individual learner.

METHODOLOGY

This study had the approval of Institutional Ethics Committee vide 14/167. Medical interns underwent this training in groups of 10–12 per batch.

Programme Design

1. Clinical material which dealt with evidence-based guidelines for simulated scenario and ACLS protocol was distributed a week prior to the workshop.
2. The participants took a pretest in the MCQ (multiple-choice questions) format which was designed to assess their basic knowledge of Basic Life Support (BLS) protocol, respiratory emergencies and fundamentals of cardiac life support scenarios. Participants took this test a day prior to the workshop.
3. Students who failed to score 75% in the test were asked to revise the study material and appear for training on a subsequent session. This made sure that the participants knew the background material of the course.
4. The programme started with a brief introduction on the logistics and sequence of the programme. They were then introduced to the features of the high-fidelity simulator, SimMan 3G – 15 min.
5. The clinical scenario was presented with volunteers helping to act as the attendant to the patient and the skilled assistant in the ward. Students were

summoned to treat a patient brought to the emergency ward.

The clinical scenario started with a patient presenting signs of respiratory emergency. The scenario included an episode of cardiac arrest, followed by cardiac symptoms of arrhythmias, which called for intervention through ACLS algorithms. They handled the scenario, and their performance was recorded on a video, to be used during debriefing – 20 min.

6. Global rating scales in form of checklists which were designed to assess clinical skills, communication and problem solving skills were used to rate the performance of the students. Debriefing was done which focussed on clinical knowledge, team performance, constructive feedback, communication, interpersonal and leadership skills – 45 min; students' discussion and interactions – 30 min.
7. Debriefing was followed by a brief session of power point presentations by the faculty on the relevant theory underlying the respiratory and cardiovascular scenarios, presented on that day – 30 min.
8. Students had another chance to go through the scenario – 15 min.
9. Students' feedback – 15 min.

Data analysis was done by comparison of their performance before and after the debriefing, using the checklist. Data was analysed using the software SPSS 19.0.

RESULTS

A total of 122 medical interns participated in this study which was conducted over 1-year period from January 2016 to January 2017 in clinical simulation laboratory of our tertiary care teaching hospital. The participants had to qualify in a pretest with a minimum of 75% marks. This test was designed to assess their basic knowledge of BLS protocol, respiratory emergency scenarios and fundamentals of cardiac life support, in an effort to make sure that the participants are familiar with the background information. In the pretest which was conducted to assess the clinical knowledge in simulated scenarios with MCQ, 98% students scored more than 75% which qualified them to undergo simulated training.

In the scenario of respiratory emergency (COPD – chronic obstructive pulmonary disease), only 19% of students could ask relevant question in clinical history which improved to 35% after the programme. 26% of students were able to apply clinical knowledge gained by traditional learning methods, which improved to 41%. Ability of problem-based learning also improved remarkably. Only about 9% students exhibited proven ability to effectively communicate well amongst their team members. By the end of the programme, they recorded an improvement showing that 30% of the participants effectively communicated during the scenarios.

In the segment of cardiac arrhythmias, requiring ACLS scenario protocol, there was significant difference amongst team dynamics, inter-communication skills and professionalism after debriefing session. Patient care and clinical knowledge which were earlier 33% and 26%, respectively, improved remarkably to 48% and 74% subsequently after the session of simulated learning.

The differences observed in all six domains of simulated COPD scenario showed a *p* value of *p* value (0.0009), which is less than 0.05 and hence statistically significant. Similarly, the five domains of ACLS scenario were also statistically significant with the *p* value of 0.01, which is less than 0.05; therefore, training does have significant impact on the students.

Qualitative data analysis was done from feedback questionnaire student compared traditional methods with simulation-based training. They felt that there is a need to have SBCT training as evinced by the positive effects the programme in their general behaviour and competence and were of the opinion that SBCT improved their decision-making skills and was helpful in improving their confidence in handling clinical emergencies. They appreciated the infrastructural facilities and qualities of the instructors (Table 1). CRRIs, as a group, felt that this programme need to be made

Professionalism (PR)	08	25

mandatory for the medical interns and felt they could have more occasions to go through this drill.

DISCUSSION

End of the medical graduate training is marked by a year-long internship, which is an intense training period, wherein the young doctors learn to confidently administer healthcare interventions, under supervision. It is extremely important for these graduates to possess the requisite level of clinical knowledge, skills and qualities that help them to don the role of a healer. Competencies are achieved, skills are learnt and correct attitudes are imbibed during this crucial period of their training. For all these to happen, the medical school and the management/administration need to gear-up training programmes which equip the young doctors with 'entrustable professional activities', as suggested by MCI[13,14]. Successful adoption of such programmes is restricted mainly to reports from United Kingdom, USA and Western Australia.

Considering the fact that establishment of a standard skills laboratory involves huge funding for infrastructural facilities and training of required resource personnel, MCI has recommended a phase-wise establishment of skill laboratories to enable the young doctors to master various levels of competence in the medical colleges (MCI). MCI has suggested that in the initial phase, facilities to impart basic life support, surgical skills and conducting normal labour can be provided, subsequently followed by the establishment of advanced life support, laparoscopic skills, neonatal and paediatric resuscitation, leaving the facilities to impart microsurgical and advanced laparoscopic skills along with human patient simulator for critical training in anaesthesiology for the final phase[13]. A few medical schools with awareness of the significance of clinical simulation and who have the required resources have made attempts to incorporate clinical simulation at various stages of undergraduate medical education, realising that clinical simulation of an appropriate nature can be incorporated into the curriculum at all stages of medical education[15]. However, it appears that most of the medical schools in India are yet to gear up to accept these norms for SBME. Hence, there is a paucity of information regarding organised implementation of such programmes in India.

Even though a few institutions in India have started employing SBME in their routine training of medical undergraduates, this trend is yet to gain acceptance. It is assumed that first and foremost for the acceptance of a new method of educational tool will require acceptance of the same by the faculty and administrators. Lack of expensive equipment and the required infrastructural facilities for this interesting and academically rewarding programme could also pose as a significant factor for lack of implementation of SBME in Indian medical colleges. Yet another very important reason could be the difficulty in identifying a time for this exercise, which is not yet strictly mandated by the regulatory authorities. SBME requires faculty specially trained in this method of instruction. Faculty need to be fully trained to run the scenario, to impart the skills and to debrief. They need to feel confident in extending health care at primary level and also need to be aware of their limitations. Our attempts of training them using simulated clinical scenarios have proved to be of significance in inculcating 'must possess' competencies in an intern.

Our programme had scenarios selected from more than one speciality. For instance, a patient with respiratory emergency (COPD) was shown to go in for cardiac arrest which then followed with a couple of episodes of arrhythmias. Thus, the clinical case scenario was made to be 'holistic' and appeared as realistic as possible. The participants handled the situation as a team. It is important that the exercises provide for simulation is as close to the reality as possible. The scenarios were

www.IndianJournals.com
Members Copy, Not for Commercial Sale
Downloaded From IP - 182.19.39.245 on dated 19-May-2018

planned to include all the domains of competencies expected out of the interns. Thus, scenarios had highlights on patient care, clinical knowledge and system-based practices. In addition, scenarios had enough scope to address issues of including team dynamics, interpersonal communication skills. When all components are put together, successful management of the scenarios also required substantial degree of professionalism. The learning objectives from the scenarios were noted. These objectives constituted the content for debriefing session (Table 2).

Table 2: Results of ACLS scenario

Domain	Debriefing	
	Pre	Post
Patient care (PC)	24	48
Clinical knowledge (CK)	42	74
Team dynamics (TD)	02	36
Inter-communication skills (ICS)	11	19
Professionalism (PR)	03	18

Results of evaluation of our current programme indicate that the majority of the participants improved their scores on all the competencies analysed after the session, and this reiterates the role of clinical scenarios in enhancing the clinical competencies of the participants and subsequently the success of this programme.

To address some of the comments raised by the participants, it would certainly be a right move to offer this course at the beginning of their internship, probably during the CRRI induction programme. The practical difficulty would be to find enough time for all the interns to go through this programme. As the benefits of such a programme are well-felt, efforts could be taken to make SBCT mandatory for the internship. As success of such an event would be dependent on the providers of the course, necessary efforts need to be taken to train the trainers for this programme. Making SBCT programme as a part of training of postgraduate students in general medicine, emergency medicine and respiratory medicine would be a welcome idea to get enough number of

Table 3: Catalogued set of suggestions from the CRRI's feedback

Frequency	More often – varying from 'twice a month' onwards
Choice of clinical scenarios	More clinical scenarios in emergency medicine required
Benefits	Improved our confidence of handling emergency care
	Ideal for inculcating team dynamics, communication skill and professionalism
	Helps us to face the reality
	Helps us to be open-minded in our approach in dealing with a clinical scenario
	SBCT helps to make decisions logically and quicker
	Realised the value of 'debriefing'
	Helps in gaining confidence in clinical management
Timing	Programme to be before posting in EMD
	Introduce SBCT during the orientation programme of the CRRIs
Mandate	Should be made mandatory for the interns
	For the pre-final and final year UG students
	Must be included in the UG curriculum
General	Very informative and useful
	Demonstration of a scenario before SBCT desirable
	The concept of SBCT is 'great' – learning outcome is 'superb'
	Equipment and infrastructural facilities were of the 'top' order
	Sim lab experience will help us save lives
	Considered introducing a 'credit point system' for SBCT
	Learnt 'what not to do'

Downloaded From IP - 182.19.39.245 on dated 19-May-2018

trainers for this course. Training of the postgraduate students in surgical specialities also could be included in this programme. It is to be understood that the medical interns are hard pressed for time and to get them to participate in a programme of this nature has not been easy. We were able to mobilise the interns during their postings in ENT and ophthalmology, when they are relatively less busy. It certainly required the co-operation and the concurrence of the heads of these two departments to depute the interns to take part in this important programme (Table 3).

Faculty members from the departments of respiratory medicine, general medicine and emergency medicine volunteered to be resource persons for this programme. They, in turn, managed to train their postgraduate students to utilise simulated clinical training as an effective method of teaching learning activity which needs to be nurtured further.

Postgraduate students in the specialities were requested to help in conducting this programme. This has facilitated in training of the postgraduate students of the concerned specialities in the upcoming realm of clinical simulation, which is gaining importance and significance in medical education.

Challenges involved mainly were concerned with identifying the time for SBCT. Training the resource persons from relevant specialities is yet another thrust area. Institutions with the infrastructural facilities for simulations will find it not too hard to embark on the emerging trend of simulated teaching.

Urinary Tract Infection in Diabetics - A Five Year Retrospective Study on the Prevalence of Bacterial Isolates and its Antibiotic Susceptibility Patterns in A Tertiary Care Hospital in South India

Jagadeeswaran G[1], Mohammad Zeya Ansari[2], Tolstoy Rajangam[3]

ABSTRACT

Introduction: Urinary tract infection (UTI) is almost most common seen infection in the diabetic patient due to various local and systemic immunopathogenetic reasons. This causes multiple renal and extrarenal complications and even death if not intervened early. We aimed to find out the prevalence of different bacteria in urine culture and the antibiotic susceptibility pattern amongst diabetic patients admitted in our hospital and to start empirical antibiotics for early recovery and to prevent complications.

Material and Methods: Retrospectively, 651 culture positive urine samples were taken for study with inclusion and exclusion criteria. We saw all the case records and investigations of every subject to correlate with criteria of selection. Our laboratory follows the standard protocols for urine sampling, timely transportation and microbiological study. Antibiotic susceptibly was tested by Kirby Bauer method and interpretations were done by clinical laboratory and standards institute (CLSI) guidelines.

Results: Out of total 651 patients most commonly affected age group was 51-60 years (30.26%).Here males (53.3%) dominated females (46.7%) in number with little difference. Most common Gram-negative bacteria were Escherichia coli (69.12%) and Klebsiella pneumoniae (8.60%) while most common Gram-positive bacteria were Enterococcus faecalis (10.90%) and Staphylococcus aureus (2.91%).Most of the gram-negative bacteria were having a good susceptibility to amikacin, piperacillin/tazobactam, cefoperazone/sulbactam and carbapenems while Gram-positive bacteria were mostly sensitive to nitrofurantoin, linezolid and vancomycin.

Conclusion: in our study, the occurrence of UTI among the diabetic is commoner in the sixth decade with a male predominance. We found E.coli, E.faecalis, and K.pneumoniae as the most commonly grown organisms in descending order. Most of the Gram-negative isolates were susceptible to amikacin, piperacillin/tazobactam, cefoperazone/sulbactam and carbapenems, while most of the Gram-positive cocci were sensitive to nitrofurantoin, linezolid, and vancomycin. Antibiotic resistance is seen very commonly in our setup. We cannot depend upon frequently used oral antibiotics and certain groups like fluoroquinolones and cephalosporin (except for sulbactam containing ones) and ampicillin for empirical treatment in UTI especially the complicated ones.

Keywords: Urinary Tract Infection, Diabetics, Prevalence, Isolates, Antibiotic Susceptibility

INTRODUCTION

The urinary tract is a principal site of infection in diabetics.[1] UTI (Urinary Tract Infection) encompasses a variety of clinical entities, including ABU (asymptomatic bacteriuria), cystitis, prostatitis, and pyelonephritis. There can be an increased risk of ABU or symptomatic UTI in diabetics.[2]

Urinary tract infection can be uncomplicated or complicated. Uncomplicated UTI can be asymptomatic bacteriuria, cystitis, pyelonephritis, in men and nonpregnant women, also prostatitis in men. Complicated UTI can be symptomatic episodes of cystitis or pyelonephritis in men or women with an anatomic predisposition to infection, with a foreign body in the urinary tract, or factors predisposing to a delayed response to therapy. There can be a relapse or reinfection. A relapse is a recurrent infection with an organism similar to the pretherapy isolate, usually following persistence of the organism in the genitourinary tract. A reinfection is a recurrent infection with a new organism. The quantitative criteria of at least 10^5 CFU (colony forming units)/mL are generally appropriate for the microbiological identification of complicated urinary infection. Bacteriuria is more common in diabetics than in non-diabetics due to a combination of host and local risk factors.[3] Some microorganisms become more virulent in a high glucose environment. Therefore, screening for UTI in diabetic patients is very important to enable bacteruria to be properly treated.[4] There is a significant correlation between duration of diabetes and UTI.[5] Changes in host defense mechanisms, the presence of diabetic cystopathy and of microvascular disease in the kidneys may play a role in the higher incidence of UTI in diabetic patients. As diabetics are more prone to UTI, it is necessary to pay special attention to early diagnosis and treatment.[6]

The aim of this study was to determine the causative bacteria, culture and sensitivity pattern in diabetics with Urinary tract infection in our setup. This will guide us to start an

Urinary tract infection in diabetics - a five year retrospective study on the prevalence of bacterial isolates and its antibiotic susceptibility patterns in a tertiary care hospital in South India. International Journal of Contemporary Medical Research 2018;5(4):D33-D38.

DOI: 10.21276/ijcmr.2018.5.4.45

appropriate timely empirical antibiotic which will prevent the diabetic patients from the complications of UTI like pyelonephritis, urosepsis, renal failure etc. This can decrease the hospital stay, morbidity, and mortality.

MATERIAL AND METHODS

This was a 5 year (August 2010 to August 2015) study done in PSG Hospital, Peelamedu, Coimbatore and was based on the retrospective collection of data from case records of patients who were admitted under medicine department of PSG Hospital. Only those cases that fulfill the inclusion criteria were analyzed. To know the reliability of causative organism, we went through the case records and looked into the various clinical and laboratory parameters of the Diabetic patients who have culture positive UTI.

As per the standard protocol clean voided midstream urine samples were collected in sterile containers. In sampling procedure, all the patients were given proper information while collecting the urine sample. Urine culture reports that exhibited CFU of more than 10^5/ml were considered positive. Only single isolates were taken for study purpose and mixed growths were excluded. The pathogens were isolated and identified using phenotypic methods and biochemical testing. Antimicrobial susceptibility testing was performed using Kirby-Bauer disc diffusion method as described by the Clinical and Laboratory Standards Institute (CLSI). We took nine types of isolates and went through their susceptibility patterns to 26 antibiotics. Ethical clearance was obtained before the start of the study.

Inclusion criteria:

1. Diabetic patients
2. Sex: Both male and female
3. Age: 18 years and above
4. Urine culture positive cases

Exclusion criteria:

1. Nondiabetic
2. Pregnancy
3. Known congenital/acquired urogenital anomaly
4. Patients on chronic catheterization
5. Candiduria

STATISTICAL ANALYSIS

The data was descriptively analyzed using Microsoft Excel 2007 software.

RESULT

As per our finding depicted in Table 1 most of the patients were in the age range 51 to 60 years (30.26%) followed by 61 to 70 years (22.27%) and next 41 to 50 years (20.89%) while lower and higher of age groups are lesser affected.

In figure 1 regarding the gender predilection, males were more affected than females (53.3% vs 46.7%).

From the distribution pattern seen in figure 2, it is clear that most common Gram-negative bacteria were E.coli (69.12%) followed by Klebsiella pneumoniae (8.60%). Out of Gram-positive organisms most frequently seen bacteria (figure 3), were Enterococcus faecalis (10.90%) followed by Staphylococcus aureus (2.91%). So, the actual second most common bacteria seen were E.faecalis.

Table-4: Resistance to commonly used antibiotics (in percentage)

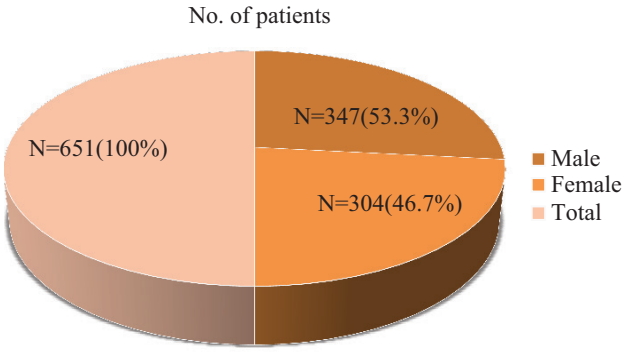

Figure-1: Distribution of patients by gender

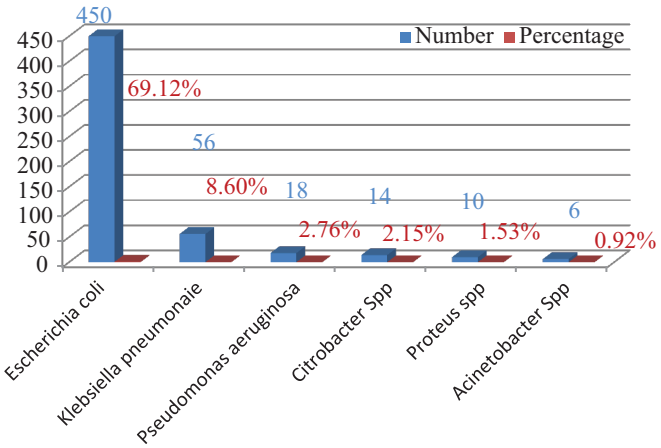

Figure-2: Distribution of Gram –negative bacteria

From table 2 we observed that males had higher prevalence of bacteriuria compared to females in all the age groups. There were only two young patients above 18 and below 20 years age group.

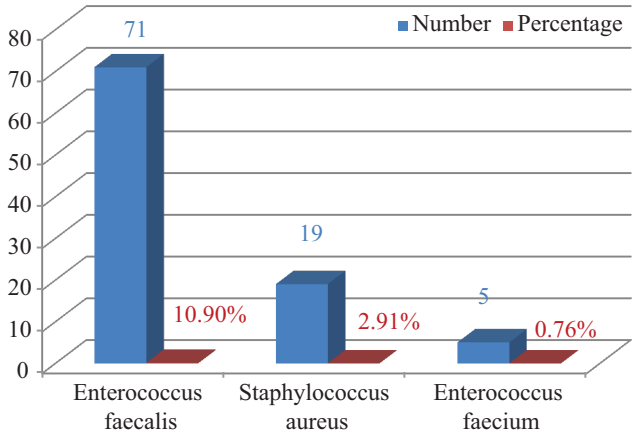

Figure-3: Distribution of Gram-positive bacteria

As shown in table 3 and 4, good susceptibility was seen to amikacin by E.coli (96%) K.pneumoniae (81%), P.aeruginosa (72%) and Proteus spp. (91%). Linezolid and Vancomycin showed 100% activity against Enterococci and Staphylococcus aureus. Amongst fluoroquinolones, ciprofloxacin has low activity (40%) against Pseudomonas while levofloxacin stands good (100%) for Citrobacter and lower (60%) for Proteus. We saw poor response to norfloxacin against most bacteria grown except Proteus spp. which has good (82%). From amongst the cephalosporins, cephalexin, cefixime and ceftazidime are not good options for most bacteria but Cefoperazone-sulbactam stands good (>65%) against E.coli, P.aeruginosa and Proteus spp. Ceftazidime shows 68% and 89% sensitivity against P.aeruginosa and Proteus spp.respectively. ceftriaxone which is very commonly used injectable to start empirically in inpatient setup is not a good choice due to very low sensitivity in E.coli (22%) and

K.pneumoniae (35%). High level Ampicillin resistant is seen in both Gram-positive and negative bacteria.

If we look at E.coli –ESBL (71.42%) and Klebsiella pneumoniae - ESBL(56.90%), best options were carbapenems, colistin, tigecycline, amikacin, piperacillin-tazobactam and nitrofurantoin. There were carbapenemase producers also like in E.coli (4-5%) and Klebsiella (20%). Cotrimoxazole and amoxicillin-clavulanic acid have no good response (<60% sensitivity) to any of these bacteria. Linezolid is good for both the species of Enterococcus (100% susceptible). Nitrofurantoin sensitivity was good in Staph. aureus (96%), E. faecalis (82%) and E.coli (81%). Best response giving carbapenems against K.pneumonaie and P.aeruginosa was by imipenem (83% and 78% respectively) while against Proteus spp.meropenem has good activity (88%). Acinetobacter spp. Which was seen in 6 patients has poor sensitivity to amikacin (20%), imipenem (40%) and colistin (50%) but good sensitivity to cotrimoxazole (80%). We found 3 MRSA out of 19 isolates.

High-grade resistance was seen for many commonly used antibiotics like ampicillin, cotrimoxazole, cefixime, nalidixic acid and amoxicillin/clavulanate (table: 5).

DISCUSSION

In this study, we were supposed to see the prevalence of various bacteria in diabetics with proven UTI and antimicrobial susceptibility patterns. We found that Diabetic males are outnumbering females in terms of prevalence of UTI. This is in contrast to an Indian study[7], a Nigerian study[8] but in favor of study in Sudan[9] and east India.[10]

Most frequently patients were in the affected age group from 51 to 60 years(30.26%).This was Similar to a study by R. Simkhada.[11] but dissimilar to a study in Kuwait by May Sewify et al[12] and in Nepal by PK Jha et al.[13]

Like in almost all the studies from international or national locations[14,15], the most common bacterial isolate was E.coli(59.12%). It was similar to a case-control study done in New Delhi[16] which showed E.coli as most common bacteria in UTI (64.3%). In a study from Nepal[11], it was 52.38%. While in Romanian study[17] it was 70.4%.

In our study, we found Klebsiella pneumoniae (8.60%) and Pseudomonas aeruginosa (2.76%) as next common isolate amongst Gram-negative while Enterococcus faecalis (10.90%) and Staphylococcus aureus (2.91%) are most common Gram-positive isolates. In a study done in Turkey, K.pneumoniae and P.aeruginosa were 9.1% and 3% respectively[18] which was in the same line as ours. Overall in our study second most common isolate is E.faecalis (10.90%) after E.coli (59.12%) which is on the same trend as seen by N.Chatterjee et al.[10] In contrast, second most common isolate in the above mentioned Turkish study was CoNS (24.2%). If we see a retrospective study in Nepal, there was a similar trend of the frequency of Enterococcus spp.(13.84%), K.pneumoniae (8.3%) and S.aureus (7.11%). We also found Citrobacter spp, Proteus spp, and Acinetobacter spp though less frequently.

In this study, seeing antibiotic resistance we found that ampicillin and cefixime are not good options as high-level resistance is seen for commonly grown isolates of E.coli and K.pneumonaie. Citrobacter spp.is 100% resistant to nalidixic acid and cotrimoxazole and equally resistant to amikacin and gentamycin i.e 50%.There is high resistance to gentamycin, ampicillin and amoxicillin-clavulanic acid against Gram-positive organisms especially Enterococcus spp.Fluoroquinolones and cephalosporins are resistant to most of the Gram-negative isolates. Cephalosporin resistance was similarly seen in Nepal[13] and Bangladesh.[19] Good options for them are amikacin, piperacillin/tazobactam, and cefoperazone/sulbactam. Our study has a high prevalence of ESBL in E.coli (71.42%) and K.pneumonaie (56.90%) which needs to be managed with carbapenems as first-line drugs and if not feasible, second-line drugs should be piperacillin/tazobactam or cefoperazone /sulbactam. Though ESBL organisms are in similar frequency as shown in many other studies it was lower compared to a study from Kerala[20] which showed very high-level ESBL growth (approximately 90%) and from Manipal[21] by M.Srinivas et al which showed it 78.6%. Though amikacin is a cost-effective injectable for both non-ESBL and ESBL isolates, its renal toxicity restricts its widespread use.

In our findings, nitrofurantoin had good activity against E.coli and Gram-positive isolates similar to as seen by PK Jha et al[13] and Citrobacter spp. had approximately 50% susceptibility to most of the tested antibiotics but 100% for levofloxacin.

If we see options with antipseudomonal activity in our set up and susceptibility pattern, best antibiotics are Piperacillin / tazobactam and colistin with equal efficacy (82%) followed by imipenem and amikacin (78% and 72% respectively). Here ciprofloxacin has low efficacy (40%) and cotrimoxazole was 100% resistant to P.aeruginosa. Similar findings were seen by M.Srinivas et al[21] with 82% susceptibility to Piperacillin/ tazobactam and 68.2% to cefoperazone/ sulbactam but a very good response to amikacin (93.8%). Meropenem activity against P.aeruginosa in our study was only 50% while M.Srinivas et al[21] found it 87.5%.

In our findings, Gram-positive isolates have shown 100% sensitivity to vancomycin while an article from south India shows 81% and 94% susceptibility respectively by Enterococcus and Staphylococcus.[22] We have less nephrotoxic linezolid with 100% sensitivity against Gram-positive isolates. In an Indian study, Enterococcus faecalis was the most commonly isolated Gram-positive organism with 3.2 percent resistance to vancomycin.[23] We found Acinetobacter spp.in 6 cases showing multidrug-resistant with very low sensitivity even to carbapenems and colistin.

Multi-drug resistant bacteria commonly arise due to the prolonged use of cephalosporins and other antibiotics, particularly their use as prophylaxis treatment, inadequate dosage or inaccurate frequency of administration. This also produces class and cross-resistance. Pseudomonas spp. has become a big challenge to treat. Plasmid-mediated resistance due to the usage of broad-spectrum antibiotics has been considered as one of the factors associated with this

phenomenon.[24]

Amikacin which is easily available and cost-effective remains a good choice for most of the uropathogens if renal status allows and there is a facility to follow renal function test regularly. There is good sensitivity even in current era due to its ability to evade attacks by all antibiotic-inactivating enzymes that are responsible for antibiotic resistance in bacteria, except for aminoacetyltransferase and nucleotidyltransferase.[25] This is accomplished by the L-hydroxyaminobuteroyl amide (L-HABA) moiety attached to N-1 (compare to kanamycin, which simply has a hydrogen), which blocks the access and decreases the affinity of aminoglycoside-inactivating enzymes.[26,27] Amikacin ends up with only one site where these enzymes can attack, while gentamicin and tobramycin have six.

Enterococci are getting commoner in many culture samples especially from urine due to inappropriate and intensive use of broad-spectrum antibiotics.[28] Same are the reasons in cases of other microorganisms. Poultry farms and human foods of animal origin are also contributing significantly to the increasing multidrug resistance amongst isolates.

These are the reasons, why to have knowledge of the pattern of local microbial prevalence and antimicrobial susceptibility to start the most appropriate empirical drug depending on clinical and laboratory profile of patients.

CONCLUSION

Most commonly affected age group with UTI amongst diabetics was from 51 to 60 years where males exceeded females in prevalence. We found E.coli, E.faecalis, and K.pneumoniae as the most commonly grown organisms in descending order. Most of the Gram-negative isolates were susceptible to amikacin, piperacillin/tazobactam, cefoperazone/sulbactam and carbapenems, while Gram-positive cocci were mostly sensitive to nitrofurantoin, linezolid, and vancomycin. Ampicillin, cephalosporins (with the exception of sulbactam combination), cotrimoxazole, and fluoroquinolones are not good choices to start on an empirical basis.

A Rare Etiology of Severe Thrombocytopenia in Patient with Chronic Liver Disease

Mohammad Zeya Ansari, R Tolstoy, G Jagadeeswaran

Abstract

Thrombocytopenia is a common complication in patients with chronic liver disease and is multi-factorial. It complicates the management and worsens the prognosis. Treatment options are costly and include platelet transfusion, splenectomy, splenic artery embolization, TIPPS and thrombopoietin (TPO) agonists.

Here we are presenting a patient with decompensated liver disease with known chronic alcoholism and profound thrombocytopenia despite multiple platelet transfusions. On further work up we found a coexistent autoimmune etiology. Thrombocytopenia promptly responded to steroids, a cost effective option.

Introduction

Thrombocytopenia, a common complication in patients with chronic liver disease, is seen in nearly 75% of cirrhotic patients.[1] The pathogenesis of thrombocytopenia in chronic liver disease is multi-factorial.[1] Initially it was thought that thrombocytopenia in CLD is only due to portal hypertension where there will be an enlargement of spleen which causes destruction of platelets. So initially treatment for thrombocytopenia was aimed at reversing portal hypertension. But persistently decreased platelets were noted even in patients without splenomegaly.[2] So other factors like intrasplenic production of autoantibodies and plasma expansion resulting in hemodilution also contribute to thrombocytopenia. Suppression of platelet production in bone marrow is also another factor which is seen in HCV infection and alcohol related chronic liver disease. Antiviral therapy like interferon alfa also induces thrombocytopenia.[3] In some patients of CLD there is an evidence based autoantibodies related destruction of platelets and it is mostly observed in HCV related cases.[4] Here autoantibodies are directed against platelet surface antigens and enhance the removal of platelets by splenic and hepatic reticuloendothelial systems there by triggering rapid destruction as seen in chronic ITP. TPO is a potent cytokine produced by liver, bone marrow and kidney which regulates megkaryocytes and platelet production.[5] In cirrhotic patients with thrombocytopenia, low circulating levels of TPO is seen compared to cirrhotic patient with normal platelet count.[6] The treatment options available for severe thrombocytopenia are platelet transfusion, splenic artery embolization, splenectomy and TIPS. Platelet transfusion is indicated in patients with less than 10,000-20,000/µl platelets in uncomplicated patients and less than 50,000/µl in patients undergoing procedures.[7] Newly derived options include recombinant interleukin-11, eltrombopag and recombinant TPO.

Case Summary

A, 50 year old male patient with ethanol related chronic liver disease and no other comorbidities, came to EMD with the complaints of melaena, gum bleed and haematuria for 10 days, fever with chills, abdominal pain and distention for 3 days.

On examination, patient was pale and febrile with stable vital parameters. He had minimal ascites and epigastric tenderness.

Serial CBC, LFT and RFT are summarized in Table.1. Upper GI endoscopy showed esophageal varices and portal gastropathy and EVL done immediately. Ultrasound abdomen Showed features of CLD and portal hypertension with medical renal disease. Ascitic fluid analysis had no evidence of peritonitis. Urine culture showed significant bacteria (E.coli) and managed accordingly. He had severe thrombocytopenia which was managed with platelet transfusions. Bone marrow aspiration and biopsy showed dimorphic anemia with thrombocytopenia, megaloblastic erythroid hyperplasia and mild megakaryocytic hyperplasia. His serum B12 and folate level were within normal range. Hepatis B, C, HIV, Dengue virus, *Helicobacter pylori*, scrub typhus, leptospirosis infection and Coomb's test were negative. Renal failure was stabilized with hemodialysis.

As his thrombocytopenia persisted despite multiple platelet transfusions (total 19 units) and other common causes of thrombocytopenia being ruled out, we suspected of some uncommon etiology including an autoimmune condition. ANA tested was positive with fine granular++, cytoplasmic+ pattern. He was positive for smooth muscle antibody and negative for anti-ds DNA Ab and hence he was diagnosed to have autoimmune hepatitis type-1 with associated ITP. We started steroids (Inj. methylprednisolone 125 mg IV OD for 3 days followed by oral prednisolone 60mg OD). His platelet count started improving from 2nd day of IV steroid.

On follow-up visits, his platelet count was in safe range (> 1 lakh / cu.mm3) with low dose oral steroid and is currently being managed as ITP.

Discussion

The causes of thrombocytopenia in chronic liver disease may be due to sequestrating function of spleen, presence of antiplatelet antibodies and impaired thrombopoietin production in cirrhotic patients.[6] It is very important to differentiate ITP from common cause of thrombocytopenia in CLD as the management differs. Hypersplenism in liver disease due to portal hypertension

causes increased sequestration of platelets within spleen leaving less in circulation. However it is also to be clear that thrombocytopenia can occur in liver cirrhosis without splenomegaly.[2] Thrombopoietin is a cytokine produced by the liver which plays a key role in platelet production and subsequent function may be low in cirrhosis. Thrombocytopenia in liver disease without evidence of cirrhosis, splenomegaly and interferon is recognized especially in patients with hepatitis C and auto immune hepatitis.

Based on persistent thrombocytopenia, ANA and anti SMA positivity we diagnosed him as AIH type-1 and associated ITP. The International Autoimmune Hepatitis Group proposed a scoring system to standardize the diagnosis, useful for clinical trials, but that may be inaccurate in individual cases.[8] Liver biopsy was not done for two reasons-severe thrombocytopenia and patient refusal.

Autoimmune hepatitis (AIH) is a chronic and progressive necroinflammatory and fibrotic process of the liver of unknown cause that occurs in children and adults, usually associated with the presence of autoantibodies and Hypergammaglobulinemia.[8] Affected individuals often have concurrent extrahepatic autoimmune disorder like rheumatoid arthritis, Sjogren's syndrome and auto immune thyroiditis but association with idiopathic (immune) thrombocytopenic purpura has been rarely reported.[9-13]

ITP is an autoimmune disease characterized by a low platelet count, mucocutaneous bleeding, normal bone marrow findings and the absence of other causes of thrombocytopenia in which anti-platelet autoantibodies such as PAIgG induces platelet destruction.[14] There is a case series of 5 patients with AIH type-2 where patients had at least one associated autoimmune disorder including IgE-induced IgA deficiency, ITP, and arthritis.[15] In an Indian case series of 10 patients with AIH, three had underlying rheumatic disease (SLE, Sjogren's and Rheumatoid arthritis each one), while others had primary AIH. In the same report, 2 patients were found to have autoimmune thrombocytopenia and were managed by immunosuppressant.[16] Indeed prednisolone administration is a treatment option for AIH and is also effective for ITP. Therefore ITP should be considered when liver dysfunction is accompanied by severe thrombocytopenia particularly in the autoimmune types of liver disease.

Though in our patient there was normal bilirubin, SGOT and SGPT (which is usually elevated in hepatitis) but persistent thrombocytopenia and positive ANA with SMA made us to consider it AIH type-1.

Conclusion

It is worthy to evaluate for an alternative autoimmune etiology for CLD if thrombocytopenia is severe or persisting as there are better and cost effective treatment options i.e. steroids.

Learning points

1. All CLD with history of alcohol ingestion is not purely alcohol related.
2. Thrombocytopenia in CLD should be evaluated for causes other than alcohol and hypersplenism.
3. All autoimmune hepatitis may not have gross LFT derangement.

A Tertiary Care Hospital based Study on the Prevalence of Pulmonary Hypertention in Patients with Glomerular Filtration Rate less than 30 Ml /Min Per 1.73 Meter Square on Dialysis

Tolstoy Rajangam[1], Jagadeeswaran Govindarajan[2], Vignesh[3], Mohammad Zeya Ansari[4]

ABSTRACT

Introduction: Pulmonary artery hypertension (PAH) which can be primary or secondary, has been found to be associated with chronic kidney disease, especially end stage renal disease. Finding prevalence of pulmonary hypertension in early stages of chronic kidney disease is important because it creates very high burden of cardio vascular morbidity and mortality. In this study we have assessed various factors associated with prevalence of pulmonary hypertension in patients with glomerular filtration rate less than 30ml/min per 1.73 meter square on dialysis.

Material and methods: This is a one year, hospital based, prospective observational study of patients aged more than 18 years with GFR less than 30 ml/min per 1.73-meter square on dialysis, who were found to have pulmonary hypertension on echocardiography. The prevalence of pulmonary hypertension in this group of patients and the risk factors in CKD associated with it are calculated followed by a descriptive analysis and interpretation of the data.

Results: The various factors we analyzed and p value for association of pulmonary hypertension in CKD for the percentage of male and female in our study group is 0.241, for distribution of the pulmonary hypertension among different age groups is 0.503, for the significance of diabetic mellitus is 0.595,for systemic hypertension is 0.206, for arterial venous fistula is 0.780,for superimposed infections 0.166, for volume overload is 0.560, for anemia is 0.780, for left ventricular diastolic dysfunction is 0.662, for creatinine clearance is 0.717,for duration of dialysis is 0.000. With above results, only association with significant p-value (0.000) in our study population with pulmonary hypertensions longer duration.

Conclusion: Prevalence of pulmonary hypertension in our study is 22%. The risk factors like age,sex, diabetes, systemic hypertension, AVF, superimposed infection, volume overload, anaemia, LVDD has no influence on pulmonary hypertension in our study, only strong association that we have in our study population with pulmonary hypertension with CKD is longer duration of dialysis.

Keywords: Pulmonary Hypertension (PH), CKD

INTRODUCTION

Though, there has been fast advancement in the medical field which helps in the early and accurate diagnosis of health status of a patient, pulmonary hypertension remains a hidden problem that takes plenty of time in diagnosis from the presence of first symptom. Many patients are diagnosed only in advanced stage of disease.[1] Normal pressure in pulmonary artery is 25/10 mmHg and if the pulmonary artery pressure exceeds 40/20 mmHg or average pressure exceeds 25 mmHg, then the pulmonary hypertension is said to be present.Though the cut off value varies in many studies. If the pressure in the pulmonary artery remains persistently high then the right ventricle of the heart may get hypertrophied,so right ventricle will not be able to pump properly and the symptoms of right heart failure will occur. Pulmonary artery pressure is increased by many conditions and so pulmonary hypertension is classified accordingly. Prevalence of pulmonary artery hypertension inWHO's class1 which is caused mainly by connective tissue disorder, drug, and toxic agents is 15 cases/million adult population.[2,3] Prevalence of idiopathic pulmonary artery hypertension is 5.9 cases/million adult population.[4] Pulmonary hypertension due to systemic sclerosis, portal hypertension, congenital heart disease, and sleep apnea is 7-12%[5,6], 2-16%,[7] 30%[8], and 15-20%[9] respectively. Up to 60%of the patients with severe left ventricular systolic dysfunction and 70% of those with the heart failure with preserved ejection fraction may present with pulmonary hypertension. Almost all the patients with mitral valve diseases have pulmonary hypertension and 65% of those with symptomatic aortic stenosis also will have pulmonary hypertension.[10,11] Chronic thrombo-embolic pulmonary hypertension (CTEPH) prevalence was 3.2 cases/million/year and incidents were 0.9 cases/million/year. A large survey that is conducted in united states that registered information from all form of pulmonary hypertension from 1980-2002 documented that death rate in patients with pulmonary hypertension during these times were stable and ranging from 5.2-5.4deaths/1,00,000.[12,13,14,15]

Chronic kidney disease(CKD) is the global health burden with high economic cost to health system and is an

DOI: http://dx.doi.org/10.21276/ijcmr.2019.6.10.5

independent risk factor for coronary vascular disease. All stages of CKD are associated with increased risk of cardio vascular premature mortality, morbidity and decreased quality of life.

Pulmonary artery hypertension in renal disease is an on-going research topic since it has very limited data. Prevalence of pulmonary hypertension in patients on hemodialysis, peritoneal dialysis and in stage - 5 CKD, ranges from 18.8 - 68.8%, 0.4-2% and 9-39% respectively. No proper epidemiological data are available yet for early stages of CKD. Pulmonary hypertension has direct association with mortality in end stage renal disease. Pulmonary hypertension in end stage renal disease is associated with the worst outcomes.[16-22] It is important to prevent pulmonary hypertension in patient with ESRD in early stages where even kidney transplantation may not reverse the condition,it alsohas high risk of mortality.

Study aimed to find the prevalence of pulmonary hypertension in patients with glomerular filtration rate less than 30ml/min per 1.73-meter square on dialysis in tertiary care hospital, to find the percentage of male and female in our study group and to find the significance of their association with pulmonary hypertension, to find the distribution of the pulmonary hypertension among different age groups and to find the significance of association pulmonary hypertension with diabetic mellitus, systemic hypertension, arterial venous fistula, superposed infection, volume overload, anaemia, left ventricular diastolic dysfunction, creatinine clearance, and duration of dialysis.

MATERIALS AND METHODS

In this prospective observational study conducted during the period of August 2016 to August 2017, we included total of 50 patients who were admitted in hospital fulfilling inclusion criteria. A proforma was made which included the detailed history, clinical examinations, and requisite investigations. After taking informed consent from each patient, detailed history was obtained and complete examination was done. Investigations like complete hemogram, routine urine analysis, blood sugar, serum electrolyte, serum creatinine, blood urea, thyroid function test, liver function test, ultrasound abdomen and pelvis, retroviral serology, hepatitis B and C serology, chest X-ray, echocardiogram, and electrocardiogram were done. GFR is calculated with the help of Cockcroft-Gault formula. Finally, the prevalence of pulmonary hypertension and the risk factors association with it were calculated and statistical analysis was done with the available data.

Inclusion criteria

-Age more than 18years

-Patients with GFR less than 30 ml/minper 1.73-meter square on haemodialysis

Exclusion criteria

Patients who has ejection fraction less than 45%

Patients who are known case of chronic lung disease, thrombo-embolic disease, sarcoidosis, sickle cell disease, HIV, connective tissue disorder, sleep disordered breathing, portal hypertension, congenital heart disease.

STATISTICAL ANALYSIS

The data collected from the patients is tabulated using Microsoft Excel. The chi square test was used to assess the difference in categorical variables between groups. Variables were presented as frequencies (numbers) and proportions (%) and Chi square test was used to compare frequencies. Results were presented in tables with an explanatory paragraph for each table by using Microsoft Office word software version 2010. Level of significance (P value) was considered at 0.05 as cut-off point for significant association.

RESULTS

Distribution of PH in various Age Groups

As seen in table -1, out of the total of number of 50 patients those belonging to age groups less than 40 years, 41-50 years, 51-60years,61-70 years and above 70 years were 6(12%), 7(14%), 24(48%), 9 (18%) and 4(8%) respectively. Patients who were found to have PH in these age groups were 3(50%), 0(0%), 6(25%), 1(11.1%), 1(25%) respectively. So,

Age (in years)	Pulmonary hypertension		Total	P value
	Yes	No		
<=40	3(50%)	3(50%)	6(100%)	0.241
41-50	0(0%)	7(100%)	7(100%)	
51-60	6(25%)	18(75%)	24(100%)	
61-70	1(11.1%)	8(88.9)%	9(100%)	
>70yr	1(25%)	3(75%)	4(100%)	
Total	11(22%)	39(78%)	50(100%)

Total	11(22%)	39(78%)	50(100%)	

Table-11: Duration of Dialysis and pulmonary Hypertension

was not significant.

In the table 2 we compared the PH distribution among male and female population, in which males 5(17.9%) patients are found to have pulmonary hypertension and among females 6 (27.3%) patients had pulmonary hypertension. There were no significant association of pulmonary hypertension among male and female, since the p value was 0.503.

In the table 3 we analysed significance of association of diabetic mellitus with pulmonary hypertension. In total of 50 patients, 31(62%) patients were found to have DM, and among them 7(22.6%) patients were found to have PH. P value was 0.595, hence there was no significance of DM association with PH.

In the table 4 we analysed significance of association of systemic hypertension with pulmonary hypertension. In total of 50 patients, 46(92%) patients were found to have SHTN, and among them 9(19.6%) patients were found to have PH. P value was 0.206, hence there was no significance of SHTN association with PH.

In the table 5 we analysed significance of association of AVF with pulmonary hypertension. In total of 50 patients, 49(98%) patients were on AVF and one patient was on peritoneal dialysis, and among patients on arteriovenous fistula 11(22.4%) patients were found to have PH, and patient with peritoneal dialysis had no PH and P value was 0.780,which is not significance of AVF association with PH.

In the table 6 we analysed significance of association of super imposed infection with pulmonary hypertension. In total of 50 patients, 21(42%) patients were found to have super imposed infection, and among them 7(33.3%) patients were found to have PH. P value was 0.166, which also no significance of super imposed infection association with PH.

In the table 7 we analysed significance of association of volume overload with pulmonary hypertension. In total of 50 patients, 26(52%) patients were found to have volume overload, and among them 6(23.1%) patients were found to have PH. P value was 0.560, hence there was no significance of volume overload association with PH.

In the table 8 we analysed significance of association of anaemia with pulmonary hypertension. In total of 50 patients, 49(98%) patients were found to have anaemia, and among them 11(22.4%) patients were found to have PH. P value was 0.780, hence there was no significance of anaemia association with PH.

In the table 9 we analysed significance of association of LVDD with pulmonary hypertension. In total of 50 patients,

41(82%) patients were found to have LVDD, and among them 10(24.4%) patients were found to have PH. P value was 0.662, hence there was no significance of LVDD association with PH.

In the table 10 we analysed the pulmonary hypertension distribution and significance of association among the patients with varying range of creatinine clearance. In our study group 6(12%), 33(66%), 9(18%), 2(4%) patients were found to have creatinine clearance between 0-5%, 5-10%, 10-15%, 15-30% respectively and among them pulmonary hypertension was found in 1(16.7%), 7(21.2%), 3(33.3%), 0(0%) respectively. P value is 0.717 insignificant.

In the table 11 we analysed significance of association of duration of dialysis with pulmonary hypertension. In total of 50 patients, 15(30%), 30(60%), 5(10%), 15(30%) patients were found to be between 0-5, 5-10,10-15 years of dialysis respectively, and among them 0(0%), 6(20%), 5(100%), 11(22%) patients were found to have PH respectively. P value was 0.00, hence association of duration of dialysis with pulmonary hypertension is statistically significant.

DISCUSSION

There is no availability of epidemiological data in many developing countries including India for cause of pulmonary hypertension, but in India most common causes of PH are due to rheumatic heart disease, obstructive airway disease and congenital heart disease unlike western countries where idiopathic pulmonary artery hypertension and PH due to right heart disease are common.

Craddock et al say that exposure of dialysis membrane to blood leads to activation of neutrophils which leads to sequestration of neutrophils in the lungs. This phenomenon, is more common if cellulose membranes are used and it causes worsening of lung disease in HD patients.[23]

Presence of connective tissue disease, super imposed infections, haematological and liver diseases can cause pulmonary hypertension in patients with CKD. These conditions cause PH mainly by affecting micro vascular tone in lungs. Endothelial dysfunction has association with pulmonary hypertension in patients with CKD on HD, Main mechanism behind that includes imbalance between vasoconstrictors and vasodilators and high endothelin-1 and low nitric oxide levels affect vascular tone leading to PH.[24,25,26]

The prevalence of PH in CKD in our study was 22%, and the maximum affected age group was 51-60 years.In the study by Qian Zhang et al[27], the total prevalence of PH in CKD was 47.38% with the maximum number of patients seen in age 46.44(±14.63) years. Similarly another study from Iraq[28], showed maximum patients in 50 to 60 years and 60 to 70 years age group (35.3% in both groups).Male and female patients had prevalence of 55.32% and 44.68% respectively and their total number of patients compared to ours was large (n=705) while we had male and female prevalence of 17.95 and 27.3% respectively.

As noted by Qian Zhang et al[27], multivariate odds ratio(with 95%CI) for prevalence of PH in CKD showed that gender, diabetes, systemic hypertension had no significant correlation with PH while eGFR was contributing significantly to it. But, in our study all these parameters were insignificant for PH. Similarly, Ali Abdul Majid Dyab Allawi et al[28] and Thenappan T[29] also found no association between PH in CKD and hypertension even though hypertension is an established risk factor in for PH. Chronic volume overload leads to increased venous return in CKD patients may induce PH but as such we did not get any association between them. Severe anaemia is a well-known cardiovascular risk factor in CKD patients as low haemoglobin leads to hypoxic injury in tissues including pulmonary vasculature.[30] In our study we found no significant association of PH with anaemia while In a retrospective study low haemoglobin had significant impact on PH(P-value-0.000).[27]

In our study, we did not find a correlation between Left ventricular diastolic dysfunction and PH although LV end - diastolic pressure is taken as gold standard for its definition. Measuring LVDD in cases where pulmonary systolic pressure may not be estimated may help in predicting a relation with PH.[31]

According to Yigla M et al, pulmonary hypertension (PH) is a progressive, fatal pulmonary circulatory disease that accompanies many conditions (including left to right side shunt) with compensatory elevated cardiac output. PH also complicates chronic haemodialysis (HD) therapy immediately after the creation of an arteriovenous (AV) access, even before starting HD therapy. It tends to regress after temporary AV access closure and after successful kidney transplantation. This syndrome is associated with a statistically significant survival disadvantage. The laboratory hallmark of this syndrome is reduced basal and stimulatory nitric oxide (NO) levels. It appears that patients with end-stage renal disease (ESRD) acquire endothelial dysfunction that reduces the ability of their pulmonary vessels to accommodate the AV access-mediated elevated cardiac output, exacerbating the PH.[32]

We found 22.4% patients with AV fistula who had PH but this was not significant(p-value>0.780) while flow dependent significance of AV fistula was seen by Magdy M Emara et al.[33] In our study we have not measured AVF flow rate so could not assess its significance.

Comparing our study with Domenici et al[34], who noticed PH in 58.9% cases on HD and 22.2% on PD, we found 22.2% patients on HD having PH but no PH in patient on PD. Similarly another study by Yigla et al[35], found PH 39.7% in patients on HD but none on PD. An study in Iran, based on echocardiographic evaluations, found PH in 30-40% patients on chronic dialysis.[36]

Duration of dialysis significantly added to the development of PH which is evident from our study. This is well supported by Magdy et al[33], who reported duration of dialysis to be quite significantly associated with PH(P-value<0.001 and Pearson correlation 0.780).

Compared with previous studies, risk factors like age, sex, diabetes, systemic hypertension, AVF, superimposed infection, volume overload, anaemia, LVDD are not

associated with pulmonary hypertension in our study. But we found that the longer the duration of dialysis, the higher the possibility of pulmonary hypertension.

Limitations

A larger population based study may provide better data and correlations of above mentioned risk factors.

We have excluded secondary causes of PH in those who are known cases of chronic illness from available information only but have not investigated completely.

CONCLUSION

Prevalence of pulmonary hypertension in our study is 22 percentages. The risk factors like age, sex, diabetes, systemic hypertension, AVF, superimposed infection, volume overload, anaemia, LVDD has no influence on PH in our study. only association that we have in our study population in patients with PH is longer duration of dialysis.

ABBREVIATIONS

PH - Pulmonary hypertension, CKD - Chronic kidney disease, AVF - Arteriovenous fistula, LVDD - Left ventricular diastolic dysfunction, EF - Ejection fraction, ESRD - End stage renal disease, HD - Haemodialysis, PD - Peritoneal dialysis, GFR - Glomerular filtration rate, DM - Diabetes mellitus, SHTN - Systemic hypertension

Is Serum Uric Acid an Added Risk Factor for Micro-Vascular Complications of Diabetes Mellitus? – A Prospective Study

Santni Manickam[1], Prashanth Arun[2], Velammal Petchiappan[3], Sujaya Menon[4]

ABSTRACT

Introduction: Diabetes is the leading cause of adult blindness due to retinopathy, end stage renal disease due to nephropathy and foot ulcers and lower limb amputation due to neuropathy. Serum uric acid levels independently predict the development of micro vascular complications. In this study, we analyse the association of serum uric acid with the micro vascular complications of diabetes.

Material and methods: In this hospital based observational study, hundred diabetic patients were included; of which fifty had micro vascular complications, the remaining fifty had no complications. Blood investigations including fasting(FBS) and post prandial blood sugars(PPBS), glycosylated haemoglobin (HbA1C), and serum creatinine and serum uric acid were done in all patients. All the parameters were compared between the two groups.

Results: Females presented with significantly higher complications as compared to males. The mean age of the patients presented with and without complications was 56.4 ± 9.3 and 59.9 ± 10.3 respectively. HbA1C had a positive correlation with the serum uric acid (SUA) (r=0.327, *P* = 0.001). Mean uric acid levels were higher among patients with complications (5.96 ± 2.16) compared to patients without complications (4.95 ± 2.04) which was statistically significant (*P* value =0.021). Patients with nephropathy and neuropathy had significant elevation in serum uric acid levels than those without; however this significance was not noted in those with retinopathy.

Conclusion: Patients with micro vascular complications had higher levels of serum uric acid compared to those without complications. Also there was positive correlation between HbA1C and serum uric acid levels.

Keywords: Serum Uric Acid, Micro Vascular Complications, Diabetic Retinopathy, Diabetic Neuropathy, Diabetic Nephropathy, Glycosylated Haemoglobin.

INTRODUCTION

Diabetes mellitus is the most challenging health problem in this century. Diabetes is the leading cause of adult blindness due to retinopathy, end stage renal disease due to nephropathy and foot ulcers and lower limb amputation due to neuropathy.[1]

Uric acid (UA) is primarily a purine metabolic waste product. About 70% of it gets excreted by the kidneys. Hyperuricemia has gained importance as many studies have reported that it not only has an important role in the development of metabolic syndrome but also micro vascular risk factor.[2-5] Elevated serum uric acid is a feature of hyperinsulinemia or insulin resistance.[6]

Many studies have suggested that inflammation and oxidative stress results from the metabolism of uric acid, leading to vascular injury. The rate limiting step of uric acid production is an enzymatic reaction of the xanthine oxidase (XO) enzyme that oxidises hypoxanthine – xanthine into uric acid. UA synthesis is accompanied by the generation of reactive oxygen species (ROS). XO in the vascular endothelium is associated with ischemia reperfusion injury. It has also been suggested that XO inhibitors improve endothelium-dependent vascular relaxation in blood vessels of hyperlipidemic rabbits.[7] XO as the source of ROS in ischemia/reperfusion injury has been discovered 30 years ago.[8,9]

In recent years there has been a debate regarding the association of hyperuricemia with diabetic complications. If this association is conclusively established, therapeutic interventions aiming to reduce uric acid synthesis might help to retard the progression of micro vascular complications of diabetes. Hence this study was conducted aiming to show the association of uric acid levels with diabetic complications.

MATERIAL AND METHODS

This is a hospital based observational study conducted in a tertiary care centre at Coimbatore from April 2015 to April 2016. Patients with Type 2 Diabetes Mellitus of the age group of 20 to 80 years admitted in the medical wards were included in the study. Patients admitted with acute complications like diabetic ketoacidosis and hyperosmolar coma and patients with gestational diabetes were excluded

from the study. Informed consent was obtained from the patients. Before commencement of the study, approval was obtained from the Institutional Ethics Committee.

A detailed history and physical examination was done. Baseline investigations including fasting and post prandial blood sugars, HbA1c and serum creatinine were done. The diagnosis of diabetes was based on American Diabetic Association criteria. The presence of micro vascular complications was established by fundus examination by an ophthalmologist to assess retinopathy, Urine spot Protein/ creatinine ratio (PCR) to assess nephropathy and nylon monofilament test to assess neuropathy. Serum uric acid was done in all patients. Hyperuricemia was defined as serum uric acid greater than 7 mg/dl.

The study population was divided into two groups: group I patients with diabetes and without any vascular complications; group II patients with diabetes and any one or more of vascular complications.

STATISTICAL ANALYSIS

Descriptive statistics were reported as mean and standard deviation; categorical variables were presented with number and percentages. Chi-square test was used to test the association between the variables. Independent t test was used to compare the blood parameters between diabetes with complications and without complications. P value less than 0.05 was considered statistically significant.

RESULTS

Among the 100 diabetic patients studied, there were 62 males and 28 females; 50 had presented with complications and 50 had no complications in the study group. Out of 50 with diabetes related micro-vascular complications, there were 24 males and 26 females. There was a significant difference in the presence of complications and sex; Females presented with significantly higher complications as compared to males (P= 0.004). The mean age of the patients presented with and without complications was 56.4 ± 9.3 and 59.9 ± 10.3 years respectively; although not significant (P= 0.084), patients who presented with complications were younger than those without complications.

	Present (%)	Absent (%)
Diabetic Retinopathy	19(38)	31(62)
Diabetic Neuropathy	16(32)	34(68)
Diabetic Nephropathy	19(38)	31(62)

Table-1: Distribution of Micro vascular complications

	Diabetes with complications	Diabetes without complications	P value
Sex Male Female	 24 (39) 26 (68)	 38 (61) 12 (32)	0.004*
Age	56.4 ± 9.3	59.9 ± 10.3	0.084
HbA1c	8.28 ± 2.00	7.55 ± 1.50	0.044*
FBS	137.8 ± 44.5	133.5 ± 46.6	0.644
PPBS	210.1 ± 60.3	187.7± 52.7	0.028*
Uric acid	5.96 ± 2.16	4.95 ± 2.04	0.021*

Table-2: Comparison of age, sex, HbA1c and uric acid levels in diabetic patients with and without micro-vascular complications.

Microvascular complication		Serum uric acid level (mg/dL)	P value
Diabetic retinopathy	Present	5.97 ± 2.14	0.97
	Absent	5.95 ±2.20	
Diabetic neuropathy	Present	6.56 ± 2.30	0.004
	Absent	4.73 ± 1.10	
Diabetic nephropathy	Present	7.05 ± 2.13	0.006
	Absent	5.33 ± 1.94	

Table-3: Serum uric acid levels in micro vascular complications

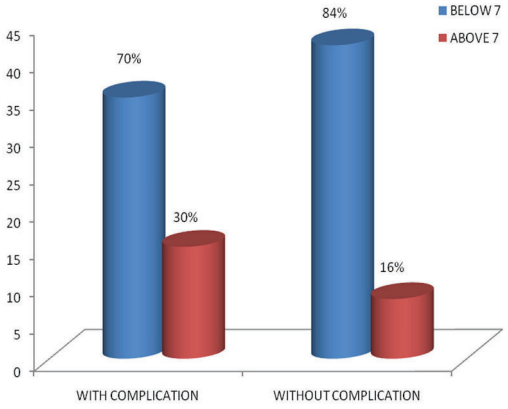

Figure-1: Frequency distribution of serm uric acid(mg/dl) in Diabetes mellitus with and without complications.

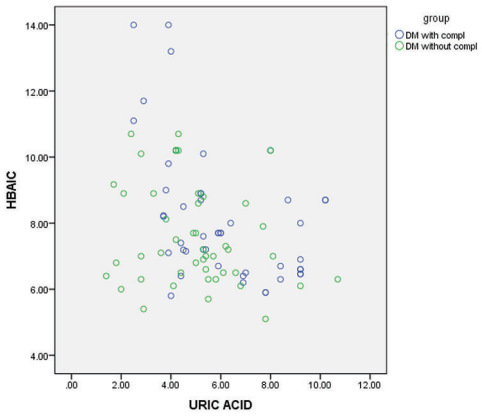

Figure-2: Co-relation of HbA1C with the Serum uric acid levels

The distribution of micro vascular complications is shown in Table 1. Both retinopathy and nephropathy were equally prevalent and slightly more than neuropathy.

Hyperuricemia (Serum uric acid >7 mg/dl) was more prevalent among patients with complications (30%) compared to patients without complications (Fig 1). As shown in Table 2, mean uric acid levels were higher among patients with complications (5.96 ± 2.16 mg/dl) compared to patients without complications (4.95 ± 2.04 mg/dl) which was statistically significant (*P* value = 0.021). HbA1C had a positive correlation with the serum uric acid levels (r=0.327, *P* = 0.001) as shown in Fig 2.

Table 3 represents the prevalence of hyperuricemia in patients with retinopathy, neuropathy and nephropathy, as compared to those without these complications. It can be seen that nephropathy and neuropathy patients had significantly more hyperuricemia than those without. However there was no statistically significant difference seen in the group with retinopathy. This suggests that high uric acid levels are associated with microangiopathies in Type 2 Diabetes.

DISCUSSION

Increasing amounts of uric acid in the serum causes Gout and this is the most significant cause of lifestyle-related disorder. Uric acid is primarily a product of purine metabolism. Serum uric acid (UA) levels are determined by a balance between Uric acid production and excretion. The rate-limiting step of UA production is an enzymatic reaction of the xanthine dehydrogenase/xanthine oxidase (XDH/XO) enzyme that oxidizes hypoxanthine-xanthine into UA. It is expressed in the liver and small intestine of XDH/XO-rich parenchyma cells[10] and is thought to be the major source for UA. The enzyme is also expressed in adipose tissue, the vascular endothelium, and macrophages, all of which are implicated in lifestyle-related diseases.[11] The UA production rate is based on the amount of substrate and/or XO activity. Since the generation of reactive oxygen species (ROS) depends on XO activity, XO is one of the major sources of oxidative stress in cells along with nicotinamide adenine dinucleotide phosphate oxidase, myeloperoxidase, lipoxygenase, and nitric oxide synthase.[12]

The kidney is an important regulator of circulating UA levels and is responsible for 60%-70% of total body UA excretion.[13] The remaining UA is secreted into the intestine, followed by bacterial uricolysis.[13] UA excretion in the kidney consists of urate secretion and reabsorption, and earlier research suggests the involvement of hyperfiltration.[6] Ninety percent of UA filtered by the kidney is reabsorbed.[13]

In patients with diabetes, the SUA level is low due to increased urate clearance.[14] In these patients, hypouricemia is associated with glycosuria[15], decreased metabolic control, hyperfiltration, and a late onset of disease, while elevated SUA is a feature of hyperinsulinemia or insulin resistance.[6]

Development of vascular complications was predicted independently by serum uric acid.[16] In a study conducted by Poonam Agrawal et al., it was concluded that the Uric acid levels are raised in patients with diabetic retinopathy when compared to those without retinopathy.[17] A study conducted by Ching-Chao Liang et al., concluded that there were increased serum uric acid levels which correlated with the severity of diabetic Retinopathy in patients with type 2 DM.[18] Vitreous UA and glucose concentrations were higher in proliferative than in non-proliferative DR. Focal UA production in the vitreous is thought to be involved in the pathogenesis and progression of DR.[19]

UA is lowered in Diabetes mellitus (DM) due to hyperfiltration[20], but decreased UA excretion during renal dysfunction raises SUA levels. Nazir Shah et al.[21] conducted a study in 2013 in 163 patients of diabetes mellitus (type 2) and proposed that elevation in the levels of uric acid was more in the diabetic patients with nephropathy (50%). In a study conducted in 60 diabetic patients by Nasri et al.[22], it was proved that there was a significant association between diabetic nephropathy and the levels of uric acid in the patient's serum. Petter Bjornstadet al[23] stated that there is a relation between the uric acid level elevation and development of diabetic nephropathy. Su-Mi Kim et al.[24] demonstrated that high UA contributes to the development of nephropathy in diabetic patients.

Several recent studies have been investigating therapeutic interventions to delay nephropathy progression.[25-27] Allopurinol therapy significantly decreases serum UA levels in hyperuricemic patients with mild to moderate CKD. Its use is safe and has been shown to help preserve kidney function when used for a duration of 12 months.[25] Febuxostat has a higher renoprotective effect than allopurinol, inhibits oxidative stress, has anti-atherogenic activity, reduces blood pressure, and decreases pulse wave velocity and left ventricular mass index, most likely due to a strong serum UA lowering effect.[27] In animal diabetic nephropathy model, allopurinol attenuated transforming growth factor-beta1-induced Smad pathway activation in tubular cells.[28]

The prevalence of diabetic peripheral neuropathy shows a significant correlation with increased UA levels.[29] Several studies demonstrated that, when controlled for confounding factors such as age, gender, BMI, renal function, and/or diabetic duration, Serum UA levels were high in patients with diabetic polyneuropathy and sudomotor dysfunction.[30,32]

The pathophysiology of diabetic neuropathy is not completely understood, and multiple metabolic imbalances underlie the development of diabetic neuropathy.[33] Hyperglycemia, dyslipidemia, and cardiovascular dysfunction are all independent risk factors for neuropathy. Probable etiologic factors include the polyol pathway, non-enzymatic glycation, free radicals, oxidative stress, and inflammation. Oxidative stress and inflammation are involved in XDH/XO activity. It is therefore speculated that UA generation by XDH/XO plays a role in diabetic neuropathy.

In a study conducted by Yili Xu et al., it was concluded that the patients with vascular complications had increased serum uric acid levels. He also said that this could be an independent predictor of vascular complications.[34] We found similar results in our study.

CONCLUSION

Diabetic patients with micro vascular complications have higher serum uric acid levels than those without complications. Also there was positive correlation between HbA1C and serum uric acid levels.

ABSTRACT

Background: Poorly controlled diabetes mellitus as indicated by elevated glycated haemoglobin (HbA1c) levels is associated with increased cardiovascular risk. C–reactive protein (CRP), an important cardiovascular risk factor, is elevated in diabetics with poor glycaemic control than those with good control. The present study assessed the correlation between HbA1c and CRP levels.
Methods: A prospective study was conducted in thirty type 2 diabetic patients irrespective of the disease duration and treatment; those with established target organ damage were excluded. HbA1c and hsCRP levels were measured at baseline; sugars were monitored monthly and medications optimised; at the end of six months HbA1c and hsCRP levels were measured.
Results: Mean age of the study subjects was 58.7±8.6 years; At the baseline, all had poor glycaemic control (HbA1c >7%); 15 had hsCRP >3 mg/L. At the end of 6 months, 5 achieved good glycaemic control (HbA1c <7%); 10 had hsCRP >3 mg/L. Baseline median hsCRP was 3.33 mg/L (0.68, 15.9) and at the end of 6 months it was 2.08 mg/L (0.48, 9.12). Mean HbA1c at baseline and end line was 10.6±1.55% and 8.43±1.84% respectively. There was significant reduction in both the mean HbA1c and median hsCRP at the end of 6 months (p <0.001). Positive correlation was observed between HbA1c and CRP at baseline (r=0.32, p=0.10). However, this was not observed at the end of 6 months.
Conclusions: There is positive correlation between the level of glycaemic control (HbA1c) and CRP levels; Better glycaemic control results in significant reduction in the hsCRP levels.

Keywords: C-reactive protein, Correlation, Glycaemic control, hsCRP, HbA1c

INTRODUCTION

Diabetes mellitus is a metabolic disorder characterised by the defects in insulin secretion or action; chronic hyperglycaemia can lead to microvascular and macrovascular complications if the blood sugars are not under optimal control. The glycaemic control is assessed by the measurement of glycated haemoglobin (HbA1c) which has its own advantages and disadvantages.[1] Till date HbA1c is the widely used tool to assess the glycaemic status. Poor glycaemic control as indicated by elevated HbA1c levels accelerates the atherosclerosis process and significantly increases the risk of cardiovascular events.[2] C-reactive protein measured by highly sensitive assays (hsCRP), is a very sensitive marker of the inflammatory activity in the arterial wall.[3,4] It is an important predictor of cardiovascular risk apart from the traditional risk factors.[5,6] It is interesting to note that chronic hyperglycaemia stimulates the release of various inflammatory cytokines (IL 6; TNF α) and induces the secretion of acute phase reactants by liver, which in turn results in elevation of CRP in association

with elevated fasting plasma glucose.[7] Studies had shown that elevated CRP levels is associated with an increased risk of future development of diabetes mellitus.[8] Also, people with diabetes mellitus had elevated levels of CRP than non -diabetics.[9,10] We understand that both chronic systemic inflammation and hyperglycaemia contribute to the development and progression of atherosclerotic cardiovascular disease. Experimental and clinical studies have confirmed the inter-relationship between CRP, hyperglycaemia and atherosclerosis.[11,12] In states of elevated CRP, hyperglycaemia exaggerates the pro-atherogenic effects of CRP.[12,13] Few studies which had assessed the relationship between CRP levels and the level of glycaemic status showed conflicting results; some studies had proven the positive co-relation between glycaemic control and CRP levels.[14-16] while some failed to do so.[6] Also, the effect of good glycaemic control on CRP levels is not clear. The aim of this study is to determine the co-relation of glycaemic control as measured by HbA1c levels with hsCRP in patients with type 2 diabetes mellitus and to determine if better glycaemic control reduces CRP levels.

METHODS

The study was conducted in the Department of Medicine, PSG Institute of Medical Sciences, Coimbatore. Patients with type 2 diabetes mellitus diagnosed on the basis of WHO criteria were prospectively enrolled in the study from September 2014 to May 2015 irrespective of disease duration and treatment. Patients with established cardiovascular disease, chronic kidney disease, infections, haemolytic anaemia, on drug therapy with statins and non-steroidal anti -inflammatory drugs were excluded from the study. The study was approved by the Institutional Ethics Committee (approval number: 14/184); informed consent was obtained from all the study participants.

At the time of enrolment in the study, blood samples were collected from the participants for measurement of HbA1c and hsCRP levels. HbA1c was measured by high pressure liquid chromatography (Variant II Turbo - HbA1c kit - 2.0). High sensitive CRP was measured by particle enhanced turbidometry assay (Cobas Integra 400 plus). They were followed up on a monthly basis, clinical evaluation was done; fasting and postprandial blood sugars were monitored and adjustment of anti-diabetic medications done on an individual basis in addition to re-enforcement on life style modification (diet and exercise). At 6 months, blood samples were collected for HbA1c and CRP levels.

Statistical analysis

Descriptive statistics were reported as mean ± SD for normally distributed data, median with 25th and 75th for the non-normal data. Paired t test or Wilcoxon Signed rank test was used to test the significance for the change in HBA1c and CRP after 6 months from baseline. Spearman's Rank correlation is used to assess the correlation between the variables. P value less than 5% was considered statistically significant. All the analyses were done using SPSS version 23.0.

RESULTS

Among the 30 subjects studied, 70% of people were between the age group of 50-70 years; the mean age of the study subjects was 58.7±8.6 years; there were 17 females (57%) and 13 males (43%).

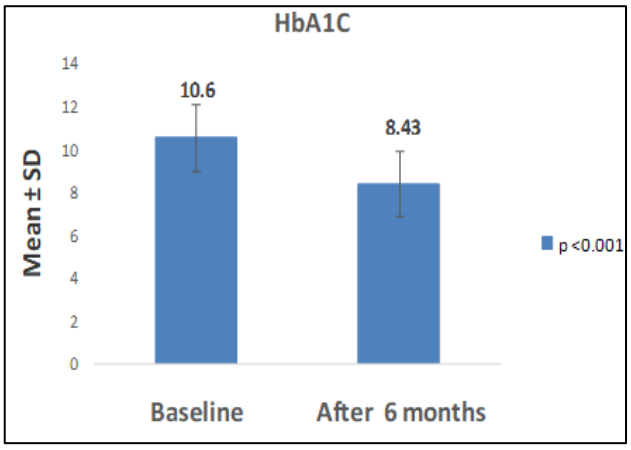

Figure 1: Mean HbA1c levels in % at baseline and at the end of 6 months.

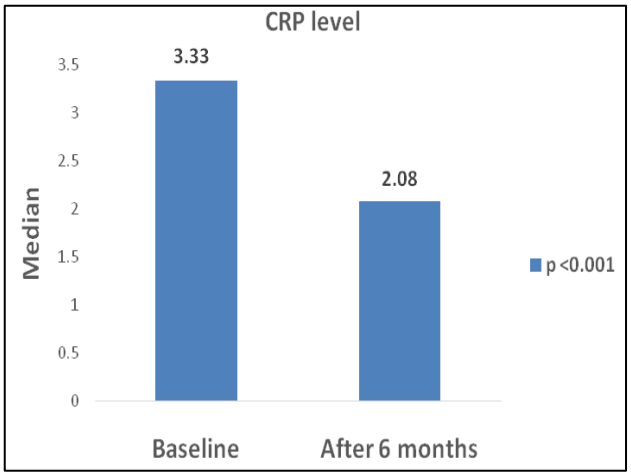

Figure 2: Median CRP levels in mg/L at baseline and at the end of 6 months.

At the baseline, all of them had poor glycaemic control (HbA1c >7%); 15 had hs CRP >3 mg/L. At the end of 6 months, 6 patients lost to follow up; HbA1c and hsCRP levels were measured for the remaining subjects; 5 achieved good glycaemic control (HbA1c <7%); 10 had hs CRP >3 mg/L. The mean hsCRP at baseline and at the end of 6 months was 7.85±9.75 and 4.88 ±5.41 mg/L respectively. Baseline median hsCRP was 3.33 (0.68, 15.9) and at the end of 6 months it was 2.08 (0.48, 9.12). The mean HbA1c at baseline and end line was

10.6±1.55% and 8.43±1.84% respectively. There was statistically significant reduction in both the mean HbA1c and median hsCRP values at the end of 6 months with effective individual based anti-diabetic treatment (p <0.001). The results are depicted in Figure 1 and 2. Positive co-relation was observed between HbA1c and CRP at baseline (r=0.32, p=0.10) although it was not statistically significant. However, this correlation was not observed at the end of 6 months.

DISCUSSION

The role of chronic low-grade inflammation contributing to the pathogenesis of diabetes and its related complications is well known. Chronic hyperglycaemia induces oxidative stress and chronic inflammatory state, which jointly contribute to the pathogenesis of atherosclerosis. C-reactive protein levels more than 3.0 mg/L is associated with worse cardiovascular outcome.[17] Various studies had demonstrated significantly elevated serum hsCRP levels in diabetics than non-diabetics.[15,16,18] Also, significant elevation was noted in those with poor glycaemic control compared to those with good glycaemic control.[15] Recent research has shown that HbA1c and CRP jointly contribute to the increased cardiovascular risk in patients with advanced cardiovascular disease.[19]

The mean hsCRP levels in the study population at baseline was 7.85±9.75 mg/l which is in accordance to that observed in another Indian study conducted in Bangalore (6.9±9.3 mg/l); while Saudi Arabian and Bangladesh studies had shown mean hsCRP levels lower than that observed in the present study, 1.13 and 2.3 mg/L respectively.[6,18] The reason for this difference in CRP levels is unclear; further studies are needed to assess the differences in ethnic groups; standardisation of the techniques used for measurement of hsCRP.

A positive co-relation was observed between HbA1c and hsCRP levels at the baseline in the present study indicating that the change in HbA1c affects hsCRP levels in the same direction. There are other studies which support our results. In a cross-sectional study conducted by Gohel et al, a significant positive linear relationship was observed between hsCRP and HbA1c.[15] Li et al, Khan DA et al, and Sarinnapakorn V et al, also had made similar observation in their studies.[20-22] Kashinakunti et al, in their case control study noted significantly high hsCRP levels in diabetics than controls; also noted positive co-relation between hsCRP and HbA1c, although non-significant.[16] Low HbA1c levels strongly related to negative hs-CRP levels as observed by Amanullah S et al.[23] Another study conducted in Sudan showed significant correlation between CRP levels with fasting plasma glucose and HbA1c.[24] All the above-mentioned studies were cross-sectional observational studies which assessed the relationship between Hba1c and CRP.

On literature search authors could find only one study conducted in Mexico which had assessed prospectively the effects of good glycaemic control on the CRP levels. The study was conducted on newly diagnosed type 2 diabetes patients; they were followed up for 6 months by intensive blood sugar management. There was significant reduction in HbA1c from baseline value of 13.0±4.9 to 8.9±2.9% at the end of 6 months, p <0.00001 which resulted in significant reduction in hsCRP levels (9.6±6.2 to 6.3±3.0 mg/l, p <0.00001). The present study also had shown similar results; significant reduction in hsCRP levels at the end of 6 months compared to baseline was observed following better glycaemic control and reduction in HbA1c levels. In that study, although glycaemic control was achieved in 71 patients at the end of 6 months, only 29 (40.8%) of them showed a reduction in CRP levels to 3 mg/l or less and the remaining 42 (59.2%) maintained a high CRP level. The study concluded that CRP is moderately influenced by glycaemic control.[25] Similar to that observation, the present study also showed that only 41.6% of the study subjects achieved CRP levels <3 mg/L by 6 months.

The positive co-relation observed between HbA1c and CRP at the baseline was not observed at 6 months; this may be because CRP is moderately influenced by glycaemic control.25 There are other variables which affect CRP levels like age, gender, body weight, LDL cholesterol levels. The present study did not take into considerations those variables which is a limitation of the present study.

CONCLUSION

There is positive correlation between the level of glycemic control (HbA1c) and CRP levels; Better glycemic control results in significant reduction in the hsCRP levels.

A Study of Serum Albumin Levels in Acute Ischemic Stroke and its Correlation with Clinical Outcome

Santni Manickam[1], Joel Franklin[2], Velammal Petchiappan[3], Sujaya Menon[4]

ABSTRACT

Introduction:: Stroke is a global health problem. Studies have shown that serum albumin level is an independent predictor of ischemic stroke outcome. In the present study we compared the serum albumin and the volume of infarct with the clinical outcome.

Material and methods: Fifty patients of age more than 18 years with clinical and radiological evidence of acute ischemic stroke were included in the study. The severity of stroke at admission was assessed by National Institute of Health stroke scale (NIHSS). Serum albumin levels were measured at admission within 36 hours after stroke onset. Functional outcome was measured 1 week post admission and after 3 months during follow up using modified Rankin scale (mRs). A score of mRs >3 or death was taken as poor outcome. Statistical analysis and interpretation of the data was done. *P* value of <0.05 was taken as statistically significant.

Results: The mean age group of the study population was 53 years, male patients had more severe stroke compared to female patients. Most common risk factors were diabetes mellitus and systemic hypertension. Patients with a good outcome had lower NIHSS score, low mRS score, high albumin and low volume of infarct. Those with worst outcome had higher NIHSS, high mRS and high volume of infarct.

Conclusion: Relatively high serum albumin level in acute stroke patients decreases the risk of poor outcome. It is not only serum albumin but volume of infarct also does play a role in the final outcome of the patient.

Keywords: Acute Ischemic Stroke, Serum Albumin, Volume of Infarct, Functional Outcome

INTRODUCTION

Stroke is a global health problem. Around 20 million people suffer from stroke every year and about 5 million people among them do not survive.[1,2] It is the second most common cause of death and fourth leading cause of disability worldwide.[3] Stroke is also a predisposing factor for epilepsy, falls and depression in developed countries.[4] It is a leading cause of functional impairments, with 20% of survivors requiring institutional care after 3 months and 15% - 30% being permanently disabled.[5]

It is a well known fact that if stroke patients have associated protein energy malnutrition they tend to have poor outcome.[6] Studies have shown that serum albumin level is an independent predictor of ischemic stroke outcome.[7,8] Experimental studies have shown that human albumin infusion after stroke onset significantly improves the neurological function and reduces the infarct volume.[9] Although low serum albumin is associated with poor neurological outcome, albumin therapy in acute stroke patients is not beneficial as shown by the ALIAS (Albumin in Acute Ischemic Stroke) part 1 and 2 trials which evaluated the efficacy and safety of human albumin therapy in acute ischemic stroke.[10,11] The volume of infarct and its co-relation with the serum albumin was not studied in any of the previous studies. In the present study we compared the serum albumin and also the volume of infarct with the clinical outcome.

MATERIAL AND METHODS

The study was a Hospital based prospective study which included a total of fifty patients of age more than 18 years with clinical and radiological evidence of acute ischemic stroke admitted to the department of General Medicine and Neurology in a tertiary care centre in South India. Patients with Cerebral haemorrhage of any aetiology, Liver disease; Cardiac failure, Nephrotic syndrome, Diabetic nephropathy, Protein losing enteropathies and Malignancies were excluded from the study. Diagnosis of ischemic stroke is based on clinical observation confirmed by radiological imaging.

Prior to the commencement of the study, ethical clearance was obtained from Institutional Human Ethical Committee. The selected patients were briefed about the nature of the study and written informed consent was obtained from them in regional language. Patients were examined clinically in detail and the severity of stroke was assessed by National Institute of Health stroke scale (NIHSS) at baseline. Blood samples for assessment of albumin were collected at admission within 36 hours after stroke onset. Serum albumin estimation was done using Bromo Cresol Green (BCG) end point method. Functional outcome was measured 1 week post admission and after 3 months during follow up using

modified Rankin scale (mRs). This scale runs from 0-6, running from perfect health without symptoms to death. A score of mRs: 0-3 was taken as favourable score and mRs: 4-6 was taken as unfavourable score. Serum albumin level <3.5 g% is considered as low.

The data were reported as the mean +/- SD or the median, depending on their distribution. The differences in quantitative variables between groups were assessed by means of the unpaired t test. Comparison between groups was made by the non-parametric Mann- Whitney test. ANOVA was used to assess the variables. The chi square test was used to assess the difference in categoric variables between groups.

Statistical analysis and interpretation of the data was done by using SPSS version 20. *P* value of <0.05 using two tailed test was taken as being of significance for all statistical tests

Serum albumin g/dl	NIHSS score		Total	*P* value
	≤10	>10		
3-3.4	0	1	1	0.124
3.5-3.9	10	3	13	
4-4.4	24	3	27	
>4.4	7	2	9	
Total	41	9	50	

Table-1: Serum Albumin with NIHSS Score

RESULTS

Among the study population of 50 patients, 44(88%) were males and 6(12%) were females. Out of 50 patients, 3 patients (1 male, 2 females) lost to follow-up. Number of patients with NIHSS score less than or equal to 10 was 41 and more than 10 was 9. Among those with NIHSS more than 10, there were seven males and two females. NIHSS score of 10 or less than 10 was seen in high numbers in 56-65 and >65 years age group. The risk factors of the study population and the nature of the ischemic stroke were tabulated in Figure 1and Figure 2 respectively.

Among the 47 patients, number of patients who had significant disability was 15. Among them 6 were in the age group of 56 to 65. Number of patients who had mild disability was 32.Among them about 11 patients were in the age group more than 65. After 3 months, number of patients with significant disability were 4 and number of patients with mild disability were 43.Significant improvement was seen in the age group of 56 to 65 (9 to 13).

Out of the 43 male patients, 14 patients had significant disability (mRs >3) and 29 patients had mild disability (mRs ≤3). Among the 14 with significant disability, 3 had death as outcome. Out of the 4 female patients, 1 had significant disability and died during the first week. Remaining 3

patients had mild disability. At 3 months follow-up, among the male patients, number of patients with significant disability dropped from 14 to 4. In the female group, the 3 patients with mild disability had improvement in the mRS score and didn't worsen.

Among 50 patients, only one patient in the age group of 46 - 55 had low serum albumin levels (<3.4 g/dl)). Mean albumin was 3.8. Majority of patients had albumin levels between 4 and 4.4. Both males and females showed similarity in this.

Table 1 showed that out of 9 patients with NIHSS score >10, only one patient had low serum albumin level<3.5 g/dl. The remaining 41 patients with a NIHSS score of less than 10 had serum albumin level above 3.5 g/dl.

On co-relating serum albumin level with mRS score at 1 week after stroke onset, while all the 32 patients with mRS ≤3 had serum albumin levels ≥3.5 g/dl, only one out of 15 with mRS > 3 had low serum albumin levels, the rest had serum albumin levels ≥3.5 g/dl. *P* value was 0.319. Hence there was no significant correlation. (Table 2) On co-relating serum albumin level with mRS score at 3 months after stroke, it was noted that out of 14 patients with high albumin levels who initially had mRS > 3 at 1 week, 9 had clinical improvement and the remaining 5 persisted to have mRS > 3 at 3 months post stroke. Also, a single patient with serum albumin <3.5 had an improvement in mRS score from baseline.

Out of 47 patients, volume of infarct could not be calculated for one patient. In the rest, the mean volume of infarct is significantly higher in those with mRs >3 than those ≤3 score at 1 week after stroke. (*P* value was 0.001) The results are tabulated in Table 3

The volume of infarct and mRS scale was compared during 3rd month using ANOVA method. *P* value was 0.146. This showed there was no correlation between volume of infarct and outcome during 3rd month. (Table 4)

DISCUSSION

It is well known that serum albumin plays a major role in the clinical outcome of vascular diseases. The neuroprotective effect of albumin is due to its various properties like anti-inflammatory and anti-oxidant effects, inhibition of thrombosis in microcirculation.[12-14] It reduces hematocrit level and also plays a vital role in aggregation of erythrocytes[15] by increasing low shear viscosity and decreasing erythrocyte sedimentation under no-flow conditions. Albumin has a good antioxidant property. Other neuroprotective effect of albumin in stroke includes Prevention of thrombosis and Prevention of leukocyte adhesion within post capillary microcirculation in the early reperfusion phase.

Albumin captures the oxygen free radicals and slows the production of reactive hydroxyl radical species. Albumin has a peculiar property of binding to copper ions by doing so it inhibits the process of copper ion dependent lipid per oxidation at cell membrane. It has also been postulated that albumin exerts neuroprotection by binding to lysophosphatidylcholine. Free lysophosphatidylcholine increases leukocyte adhesion molecules which lead to inflammatory mediated damage on vascular endothelium. It also causes apoptosis when it is present in high concentration. Based on the above said properties it was postulated that albumin infusion post ischemic stroke may be beneficial in long term outcome.

Experimental studies in rats done by Belayev et al. showed that high-dose human albumin therapy, if administered within 2 to 4 hours after stroke onset, is highly effective in improving neurological status and in reducing infarction volume and extent of brain swelling.[16]

Based on all the evidences human trial known as ALIAS (Albumin In Acute Ischemic Stroke) was conducted. It showed that treatment with intravenous albumin 25% at 2 g/kg was not associated with improved outcome at 90 days and was associated with increased incidence of intracerebral haemorrhage and pulmonary oedema. Further research is required to come to conclusive evidence that human albumin infusion can improve the clinical outcome of stroke patients as there were good results in rat models of stroke.

The mean age group of the study population was 53 years, predominantly middle aged group which is a decade lower than the peak age group of stroke in western countries.[17] In the present study, male patients had more severe stroke compared to female patients. Most common risk factors noticed in this study were diabetes mellitus and systemic hypertension.

Around 42 patients had good outcome in this study and only 5 patients had poor outcome. Most of the previous studies showed that patients with good outcome had lower NIHSS

score and high serum albumin level on admission and those with worst outcome showed high NIHSS score and low serum albumin level. In our study also patient with low NIHSS and high albumin had good neurological outcome. Only one patient had low albumin and high NIHSS score had unfavourable mRs score after 1 week; however his mRs score improved after 3 months

The studies which were done earlier didn't take volume of infarct into account. The patients with poor outcomes had a mean volume of infarct of around 26.51 and those with good outcome had a mean volume of infarct of around 5.59. Even though there was significant correlation between volume of infarct and mRS score at 1 week there was no significant correlation between them at 3 months

In this study, most patients with a good outcome had lower NIHSS score, low mRS score, high albumin and low volume of infarct. Those with worst outcome had higher NIHSS, high mRS and high volume of infarct. The one patient with low serum albumin also had a good outcome in 3 months. It is not only serum albumin but volume of infarct also do play a role in the final outcome of the patient which was not considered in other studies. Those who had poor outcome had a mean volume of infarct of around 25 cm^3 and also there was statistical significance between volume of infarct and mRS at 1 week. Even though clinically most of the patients had good outcome after 3 months based on mRS score, statistically *P* value was not significant. Hence this study is contrary to the evidence that serum albumin is a long term predictor of ischemic stroke outcome. The disadvantage of this study was that not enough number of patients could be obtained with low serum albumin levels.

CONCLUSION

Though the risk of stroke increases with age, our patients were predominantly in the middle aged group. Male patients had more severe stroke compared to female patients. Most common risk factors noticed in this study were diabetes mellitus and systemic hypertension. Most patients with a good outcome had lower NIHSS score, low mRS score, high albumin and low volume of infarct. Those with worst outcome had higher NIHSS, high mRS and high volume of infarct. The one patient with low serum albumin also had a good outcome in 3 months. It is not only serum albumin but volume of infarct also does play a role in the final outcome of the patient.

ACKNOWLEDGEMENT

We would like to acknowledge the patients who participated in the study.

ABSTRACT

Background: Metabolic syndrome (MS) is associated with premature coronary artery disease (CAD). The aim of this study was to evaluate the prevalence of MS and its association with severity of CAD proven by coronary angiogram (CAG) in young patients.
Methods: We included patients, aged 45 years or less, admitted with acute coronary syndrome (ACS), who had CAD confirmed by coronary angiography. They were divided into two groups according to the presence or absence of MS based on International Diabetes Federation (IDF) criteria. CAD was classified into single, double and triple vessel disease (TVD). The prevalence of MS and its individual parameters was calculated.
Results: Among 90 young patients who presented with ACS, MS was present in 67 patients (74.44%). Among those with MS, the prevalence of each individual criterion was statistically significant in MS group (P <0.05). Prevalence of pre-existing hypertension and diabetes was significantly higher in MS group (p <0.01). Smoking, alcohol consumption and family history of CAD were not statistically significant in patients with and without MS. Fifteen out of 90 patients (14 in MS group) who presented with ACS had TVD in CAG, but this was not statistically significant (p 0.06).
Conclusions: This study confirms a very high prevalence of MS in young Indian patients with premature CAD. MS was more prevalent than the conventional risk factor smoking in young CAD patients. We could not find significant difference in severity of CAD based on CAG between MS and non-MS group.

Keywords: Coronary angiogram, Coronary artery disease, Metabolic syndrome, Young patients

INTRODUCTION

Coronary artery disease (CAD) affecting younger individuals has reached enormous proportions. There is no doubt that it will become a major public health problem in the future unless we concentrate on reversible causes and prevention, through research studies. CAD is increasing in developing and transitional countries because of urbanization, demographic and lifestyle changes, whereas it is decreasing in many developed countries.[1] Studies have suggested that the risk of myocardial infarction is mostly due to modifiable risk factors like smoking, physical inactivity, poor diet, psychosocial stress, hypertension ,diabetes mellitus, dyslipidemia and increased waist-hip ratio.[2,3] Many of these risk factors are grouped or are seen at the onset of metabolic syndrome (MS).

Metabolic syndrome, a cluster of glucose intolerance, hypertension, dyslipidemia and abdominal obesity, has

been recognized as a major predeterminant of type 2 diabetes mellitus and CAD.[4,5] MS was associated with a 1.5 fold increase in all-cause mortality and a two fold increase in cardiovascular outcomes in a recent metaanalysis.[6] Presence of MS with or without diabetes was found to be an independent determinant of premature CAD.[7] CAD in younger population is an area of increasing interest because of its potential for long-term disability and premature death.

Few studies have reported MS and its association with CAD in the young.[7-9] We found only very limited studies in an Indian setting analyzing the association of MS with premature CAD.[10] The prevalence of MS in young patients with angiographically proven premature CAD has not been studied in Indians, to our knowledge. Understanding the impact of MS on CAD in younger age group is important for developing public health policy towards prevention and management. Hence this study was undertaken to know the prevalence of metabolic syndrome using International Diabetes Federation (IDF) criteria in patients with premature coronary artery disease proven by coronary angiogram (CAG). We also tried to evaluate any association between the presence of metabolic syndrome and severity of CAD.

METHODS

This cross-sectional study was conducted at our centre, a large tertiary care teaching hospital in South India. The study was done after obtaining institutional ethical committee clearance and informed consent. All patients, aged 45 years or less, admitted with acute coronary syndrome (ACS) [ST-elevation myocardial infarction (STEMI)/non-ST-elevation myocardial infarction (NSTEMI) and unstable Angina as per standard definition], in our hospital during the period March 2014-August 2014 were included in the study. We excluded patients younger than 18 years or older than 45 years of age and patients who did not undergo coronary angiogram for various reasons.

ACS was diagnosed in patients with symptoms compatible with myocardial infarction (MI), based on electrocardiogram (ECG) changes and cardiac enzymes. Ejection fraction (EF) and left ventricular systolic dysfunction (LVD) was assessed by echocardiography. CAG was done in all subjects either at admission for primary Percutaneous Coronary Intervention (PCI) or electively after initial medical stabilization with thrombolysis or conservative treatment, depending on the clinical circumstances and consent from the patient. CAD was diagnosed as a 50% or greater stenosis in one of the three major coronary arteries and classified as single vessel disease (SVD), double vessel disease (DVD) and triple vessel disease (TVD) based on the number of arteries involved. The IDF criteria were used for a diagnosis of MS, which is suitable for Indian population.[4] MS was defined as the presence of abdominal obesity (defined by waist circumference ≥ 90 cm for men and ≥ 80 cm for women) plus two or more of the following factors

- Triglycerides ≥150 mg/dL or specific treatment for this lipid abnormality,
- High density lipoprotein (HDL) cholesterol <40 mg/dL for men or <50 mg/dL for women or specific treatment for this lipid abnormality,
- Blood pressure ≥130/85 mm Hg or treatment of previously diagnosed hypertension,
- Fasting plasma glucose ≥ 100 mg/d L or previously diagnosed type 2 diabetes.

Detailed history was taken including presenting symptoms, history of diabetes/systemic hypertension/ history of CAD in the family/usage of alcohol and smoking. A careful physical examination was done with reference to waist circumference (WC) and blood pressure. About ≥3 measurements of BP at the time of entry with values greater than or equal to 130/85mmHg on an average or any medications for hypertension was considered significant. WC was recorded according to the national health and nutritional survey. Peripheral venous blood samples were drawn at the time of admission, the following morning after an overnight fast for lipid profile (total cholesterol, high density lipoprotein cholesterol (HDL-C), low density lipoprotein cholesterol (LDL-C) and triglycerides) and at day 5 for fasting plasma glucose.

Statistical analysis

The data were analyzed using Statistical Package for Social Science (SPSS) Version 19.0, and Microsoft Excel 2010. Continuous variables were expressed as mean/SD and compared with independent sample t-test. Categorical variables were expressed as percentage and compared with chi-square test. A predictive value of less than 0.05 was taken as statistically significant.

RESULTS

A total of 90 young patients with ACS, who underwent CAG were studied. The key demographics of the study group are summarized in Table 1. Patients ranged from 26 to 45yrs. The mean age of the patients was 39.7 yrs. Among 90 patients, 82 were male and eight were female. Out of 90 cases, 67 (74.44%) had MS according to IDF criteria and 23 (25.55%) did not. Of these 67 patients with MS, 29 (43.28%) met three, 24 (35.82%) met four and 14 (20.89%) met all five criteria for MS. MS was found in 60 men out of 82 (73.17%) and seven women out of eight (87.5%), thus a greater percentage of young women had MS than men, but this was not statistically significant.

The distribution of MS criteria as defined by IDF in those 67 patients was as follows (Figure 1).

Table 1: Baseline demographic characteristics.

Variable value	Ms		P
	Yes (n=67)	No (n=23)	
Blood pressure ≥130/85mmhg	44 (65.67%)	6 (26.08)	<0.01
Fasting blood glucose ≥100mg/dl	43 (64.17%)	9 (39.13%)	<0.05
Triglycerides (mg/dl)	179.14	115.86	<0.01
HDL-C (mg/dl)	32.36	36.78	<0.05
WC (in cms)	95.64	87.23	<0.001
Age	40.49	37.39	<0.01
Sex			
Male	60	22	0.674
Female	7	1	
Diabetes mellitus	37 (55.22%)	5 (21.73%)	<0.01
Pre-existing hypertension	31 (46.26%)	3 (13.04%)	<0.01
Family history of CAD	10 (14.92%)	2 (8.69%)	0.448
Smoking	42 (62.68%)	15 (65.21%)	0.825
Alcohol consumption	32 (47.76%)	13 (56.52%)	0.468
Dyslipidemia	15 (22.3%)	2 (8.69%)	0.148
STEMI	36 (53.7%)	18 (78.26%)	<0.05
LVD	23 (34.32%)	11 (47.82%)	0.24

MS: Metabolic syndrome, HDL-C: High density lipoprotein cholesterol, WC: Waist circumference, CAD: Coronary artery disease, STEMI: ST-elevation myocardial infarction, LVD: Left ventricular systolic dysfunction.

All (100%) had abdominal obesity, 60 (89.55%) had low HDL or treatment for lipid abnormality, 45 (67.16%) had BP≥130/85 mmHg or treatment for hypertension, 43 (64.17%) had elevated triglycerides or treatment for lipid abnormality and 43 (64.17%) had raised FBS or DM. All these criteria were statistically significant in MS group.

Table 2: Angiography results in MS/non- MS.

Angiogram result	MS		Non-MS		P value
	N= 67	%	N=23	%	
SVD	39	58.2	16	69.56	0.335
DVD	14	20.89	6	26.08	0.605
TVD	14	20.89	1	4.34	0.066

MS: Metabolic syndrome, SVD: Single vessel disease, DVD: Double vessel disease, TVD: Triple vessel disease.

MS patients had significantly higher prevalence of pre-existing hypertension and diabetes (p<0.01). Alcohol consumption, smoking status, patients receiving treatment for dyslipidemia and family history of CAD were not statistically significant in patients with and without MS (Table 1).

Thirty-six patients (53.7%) out of 67 in MS and 18(78.26%) out of 23 in non-MS cohort presented with ST elevation MI, which was statistically significant (p <0.05). Twenty-three patients (34.32%) in MS and 11(47.82%) in non-MS group had LVD with the p value of 0.24, which was not significant.

Majority of patients in both MS and non-MS groups had SVD, 58.2 % and 69.56 % respectively; it was not significant (p 0.33). Fifteen out of 90 patients who presented with ACS had TVD. Fourteen patients with TVD had MS, whereas only one patient in non-MS group had TVD, even though TVD was more common in MS, it was not statistically significant (p 0.06) (Table 2).

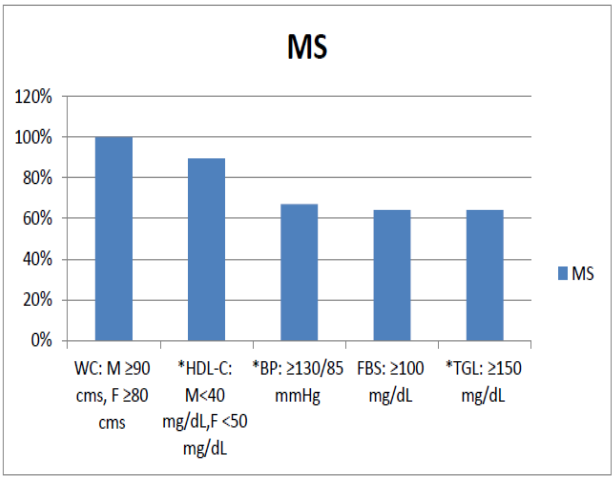

Figure 1: Prevalence of each criterion in MS group. MS: metabolic syndrome, WC: waist circumference, HDL-C: high density lipoprotein cholesterol, BP: blood pressure, FBS: fasting blood glucose or known type 2 diabetic, TGL: triglycerides. M: male, f: female, * or on treatment.

DISCUSSION

MS is characterized by a constellation of risk factors such as raised triglyceride, low HDL, glucose intolerance, hypertension and abdominal obesity that may lead to the development of CAD. Asian Indians are more prone to

diabetes and premature CAD, which is attributed to increased insulin resistance and characteristic abdominal obesity. Asian Indians have a different distribution of body fat, with abdominal obesity or a higher body fat content, even in the presence of normal body mass index.[11] Increased visceral fat is a dependable indicator of hyperinsulinemia and insulin resistance, which are risk factors for diabetes, dyslipidemia, hypertension and CAD.[12]

Hence, we have applied IDF criteria which has lower ethnic-specific waist circumference cut-offs for obesity, in our study.

We found that the prevalence of MS among patients presenting with young CAD was alarmingly high (74.44%). The prevalence of MS in young patients with CAD was similarly high in studies done by Hassanin et al. (66.39%) and Ranjith et al. (57%).[9,13] However, other studies have shown lower prevalence of MS in similar groups of patients ranging from 26% to 37%.[8,10,14]

Various studies in young CAD patients have shown a higher prevalence of MS in young women than in men.[9,10,14] In our study too the prevalence of MS was more common in women than men (87.5% versus 73.17%), but the difference was not statistically significant. This is important because Morraquin et al. have shown that women with CAD and MS have significantly higher risk of cardiovascular events and decreased survival than women without MS.[15]

Cigarette smoking was found to be the most common risk factor for premature CAD in earlier studies.[9,10,14,16] This was in contrast to our study, where we found MS was dominating with 74.44% versus smoking (63.33%), as a risk factor for premature CAD. This finding could suggest that MS may play a significantly more important role than smoking in the development of cardiovascular disease in younger age group.

While assessing the various components of MS in patients with the syndrome, we found that all patients had abdominal obesity, low HDL was the next most frequently seen risk factor (89.55%). A similar pattern of the individual components of MS in young patients with CAD was seen in a study done by Sadeghian et al.[17] Another study done in young Indians also showed a higher prevalence of low HDL (78.8%) in MS patients.[10] Higher percentage of low HDL in Indians was seen in a study conducted by Goswami et al. in MS patients with CAD.[18]

Studies have shown the predominance of dysfunctional HDL in MS patients and this proinflammatory HDL can further worsen metabolic dysfunction and hence increase the cardiovascular risk.[19] We also noted in our study that all eight women with premature CAD had low HDL. Hence, our study confirms higher prevalence of abdominal obesity and low HDL, which are well recognized risk factors for CAD.[20-23]

We also found a higher incidence of STEMI in non-MS group (78.26%) than MS (53.7%). This was unlike the results of Danciu et al. and Chung et al., where MS patients had more STEMI.[8,24] Danciu et al. found that STEMI in MS patients was statistically significant, whereas Chung et al. did not.

Although TVD was more common in the MS cohort than non-MS (14 patients versus one patient), this was not statistically significant. Thus, no significant difference in disease severity in terms of number of vessels stenosed, based on CAG, was found in our study. Goswami et al. in an Indian study found that the prevalence of MS increased significantly in patients with TVD, but they had included patients of all age groups.[18] Marroquin et al. showed that women with MS had increased risk of cardiovascular events in angiographically significant CAD patients, but again patients ranged from 21 to 86 years.[15]

There are a few limitations to our study. Those patients who met four out of five criteria for MS without the principal criteria (waist circumference more than 80 in women and more than 90 in men) were excluded from the MS group. We had only few female patients in our study. The strength of our study is that we describe the prevalence of MS in angiographically proven premature CAD, which is the gold standard to diagnose CAD.

CONCLUSION

To conclude, this study clearly indicates a very high prevalence of MS in Indian patients with premature CAD. Our study is important because we found that MS was more prevalent than the conventional risk factor of smoking in young patients with CAD. We could not find significant difference in severity of CAD between MS and non-MS group in young patients, but larger and more studies in a similar age group are required to confirm this finding.

Family physicians have an important role in identifying MS in young healthy individuals and thus, may help find people at risk for premature CAD. Healthcare professionals should routinely measure waist circumference and screen for low HDL, which is usually ignored in practice. The presence of MS or any of its components in young people should trigger an aggressive approach toward patient education and implementation of primary and secondary measures to help reduce the prevalence of premature CAD.

ABSTRACT

Background: The causes of megaloblastic anemia may vary in different geographical regions. The aim of the present study is to evaluate the utilization of bone marrow examination and upper gastrointestinal endoscopy (UGIE) in megaloblastic anemia.
Methods: This was a cross-sectional descriptive study done on 50 patients (age ≥15years) of macrocytic anemia after applying inclusion and exclusion criteria. A bone marrow aspiration with biopsy and an UGIE with duodenal biopsy were performed in consented patients with evidence of megaloblastic anemia in the peripheral smear or Vitamin B12 deficiency or folate deficiency or both.
Results: Out of 50 cases, 38 patients had pure Vitamin B12 deficiency, 2 patients had pure folate deficiency and 5 patients had combined deficiency. Among 43 patients with vitamin B12 deficiency, only four (9.3%) were vegetarians and remaining 39 (90.7%) were having non-vegetarian diet. Bone marrow study was done in 29 patients (out of 50) and all of them were found to have megaloblastic erythropoiesis in the bone marrow. Thirty three out of 50 consented for UGIE and duodenal biopsy. Out of 33, 17 patients (51.5%) had features of tropical sprue in biopsy.
Conclusions: We found a high prevalence of tropical sprue in megaloblastic anemia due to Vitamin B12 and/or folate deficiency. We recommend that UGIE with deep duodenal biopsy should be considered in all patients with megaloblastic anemia to rule out tropical sprue in India.

Keywords: Bone marrow study, Duodenal biopsy, Megaloblastic anemia, Tropical sprue, Upper gastrointestinal endoscopy

INTRODUCTION

Megaloblastic anemia is characterized by macrocytic anemia and abnormally large erythrocyte precursor cells (megaloblasts) in the bone marrow. Disorders that affect the synthesis of DNA in the precursors of erythrocytes in the bone marrow lead to megaloblastic anemia. Vitamin B12 and folate deficiencies are the most common causes of megaloblastic anemia.

The causes of megaloblastic anemia may vary in different geographical areas. Pernicious anemia is a major cause of megaloblastic anemia in western countries, but nutritional deficiencies and malabsorption could be the leading cause of megaloblastic anemia in India.[1] Studies have shown that vitamin B12 deficiency is more common in vegetarians.[2,3]

The main cause of folate deficiency is less intake of green leafy vegetables and legumes. There have been hardly any studies on the role of bone marrow and upper gastrointestinal endoscopy (UGIE) in the evaluation of megaloblastic anemia. The objective of the present study is to evaluate the utilization of bone marrow examination and UGIE in megaloblastic anemia.

METHODS

This was a cross-sectional descriptive study carried over a period of 12 months from July 2013 to June 2014 on 50 patients (age ≥15years) of macrocytic anemia treated in a tertiary care hospital of South India. Macrocytic anemia was identified when:

- A mean red blood corpuscular volume >95 fL
- Anemia with hemoglobin of
  a) <13 g/dL in male
  b) <12 g/dL in female.

Inclusion criteria

Patients above the age of 15 years with macrocytic anemia.

Exclusion criteria

Patients with liver disease, chronic kidney disease, hypothyroidism, hemolytic anemia, hemorrhagic disease, post splenectomy and pregnant patients.

The history was taken in detail; a complete and thorough physical examination was carried out in all patients. Detailed information was sought on alcohol consumption, drug intake, thyroid disorder and other comorbid illness. All patients were investigated with a hemogram that included estimation of hemoglobin level, red cell indices (MCV, MCH and MCHC), red cell distribution width, total leucocyte count, differential leucocyte count, platelet count, reticulocyte count, and peripheral smear examination.

All patients were subjected to fasting serum Vitamin B12, fasting serum folic acid, serum TSH, creatinine, liver function test and lactate dehydrogenase. A bone marrow aspiration with biopsy and an UGIE with deep duodenal biopsy were performed in patients with evidence of megaloblastic anemia in the peripheral smear or Vitamin B12 deficiency or folate deficiency or both, who gave consent for the same.

Statistical analysis

The data were analyzed using Microsoft Excel 2010 and Statistical Package for Social Science (SPSS) Version 19.0. Continuous variables were expressed as mean/SD and categorical variables were expressed as percentage. Independent student T test and Anova tests were used as described below. A predictive value of less than 0.05 was taken as statistically significant.

RESULTS

In current study population of fifty patients presenting with macrocytic anemia, 34 were male comprising about 68% and 16 were female comprising about 32%. The mean age of male and female were 53.15±15.89 and 54.37±16.58 respectively. Majority of the population belong to the age group above 40 years, both in males and females. Six patients in this study group were vegetarians. Five patients gave history of consuming alcohol. Three patients gave history of drug exposure and were on phenytoin/ sodium valproate.

The major symptom at presentation was fatigability (58%, n=29), 16% (n=8) presented with chronic diarrhea and 26% (n=13) with other symptoms like short pyrexia etc. No patient had bleeding tendencies or features of nervous system involvement.

On clinical examination, pallor was noticed in all patients in various degrees from mild to severe. Icterus was seen in 10 patients, hyperpigmentation of the knuckles in 7 patients. Organomegaly was noticed in 2 patients, among them one had hepato-splenomegaly and one had splenomegaly.

Out of 50 cases, 38 patients had low Vitamin B12, 5 patients had low levels of both folate and Vitamin B12 and 2 patients had low folate level alone. Vitamin B12 and folate levels were normal in the remaining five patients (Table1). Among 43 patients with Vitamin B12 deficiency, only four (9.3%) were vegetarians and remaining 39 (90.7%) were having non- vegetarian diet.

Table 1: Vitamin B12 and folate status in the study group.

Vitamin status	n=50	Percentage (%)
Pure vitamin B12 deficiency	38	76
Pure folate deficiency	2	4
Combined deficiency	5	10
Both normal	5	10

Table 2 shows hematological parameters of our patients. Out of 50 patients, 24 patients presented with anemia alone, 6 patients with bicytopenia (low hemoglobin and low platelets) and the remaining 20 patients with pancytopenia.

Table 2: Hematological parameters.

Hematological parameter	Mean ± SD
Hemoglobin (g%)	7.1 ± 2.5
MCV (fL)	115.1 ± 10.3
Red cell distribution width	22.71 ± 6.2
Total WBC count	4775 ± 2643
Platelet count	123686 ± 100097

Table 3: Comparison of severity of anemia with macrocytosis.

Hemoglobin (g%)	MCV(fL) Mean ± SD	n =50	P value
< 6	113.56 ± 7.83	18	>0.05
> 6	115.96 ± 11.39	32	

Study found no statistical significance (p=0.4) between the severity of anemia and the degree of macrocytosis, when the values of MCV were compared with the degree of anemia using independent student T test (Table 3). There was no statistical significance (p=>0.5) between the mean of MCV and levels of serum Vitamin B12 using Anova test (Table 4).

Table 4: Comparison of serum Vitamin B12 level and MCV.

Vitamin B12 level (pg/mL)	n=50	MCV (fL) Mean ± SD	P value
< 100	n = 28	116.69±10.89	>0.05
101-190	n = 15	112.20±6.83	
> 190	n = 7	114.92±12.50	

Out of 24 patients with anemia, 21 had low serum Vitamin B12 and 16 of 20 patients with pancytopenia had low serum Vitamin B12. All 6 patients with bicytopenia had low serum Vitamin B12. When the various levels of low serum Vitamin B12 were compared with presentation of patient with anemia, bicytopenia or pancytopenia using Anova test there was no significance (p=>0.5) (Table 5).

Table 5: Comparison of serum Vitamin B12 level and hematological presentation.

Presentation	n=50	Vitamin B-12 level (pg/mL) Mean ± SD	P value
Pancytopenia	20	64.37±31.41	>0.05
Bicytopenia	6	76.83±33.36	
Anemia	24	98.24±44.88	

The peripheral smear examination showed neutrophilic hyper segmentation and / or macro-ovalocytosis in 25 patients suggesting megaloblastic erythropoiesis. These patients and another four (Vitamin B12/folate/or both deficient) who gave consent were subjected to a bone marrow examination. Among 50 patients, bone marrow examination was done in 29 and all of them were found to have megaloblastic erythropoiesis in the bone marrow.

Thirty three out of 50 consented for UGIE and deep duodenal biopsy. Twenty-six of them showed duodenal finding of either scalloped duodenal folds or folded duodenal margins. Others showed features of erosive gastritis, atrophic gastritis or antral gastritis. One had external gastric impression and the other had gastric polyp (Table 6).

Among twenty-six patients who had abnormal duodenal features in endoscopy, fifteen showed features suggestive of tropical sprue in duodenal biopsy (Table 6). Two patients who had normal duodenal findings also had features of tropical sprue in biopsy. Hence 17 patients out of 33 (51.5%), who gave consent for endoscopy and biopsy had tropical sprue. Among 17 patients with tropical sprue, 15 had low Vitamin B12 level, one had both low vitamin B12 and folate levels and one had both normal.

Table 6: Upper gastrointestinal endoscopy and duodenal biopsy findings.

Endoscopy findings	n =33
Scalloped duodenal folds / flattened duodenal margins	26
Erosive gastritis	2
Atrophic gastritis	2
Antral gastritis	1
Others	2
Duodenal biopsy findings	**n =33**
Tropical sprue	17
Intraepithelial lymphocytosis	2
Non-specific	3
Brunner's gland hyperplasia	3
Peptic duodenitis	1
No specific pathology	7

DISCUSSION

Megaloblastic anemia has variable etiological factors. In current study population 76% had Vitamin B12 deficiency, 10% had deficiency of both Vitamin B12 and folate and 4% had pure folate deficiency. Our findings were consistent with a study by Khanduri and Sharma, who have reported Vitamin B12 deficiency to be 65% in 120 patients of megaloblastic anemia, combined Vitamin B12 and folate deficiency in 12% and folate deficiency in 6% .[4] A similar high prevalence of Vitamin B12 deficiency was reported by Sarode et al, in 102 cases (76%) of nutritional megaloblastic anaemia.[5] In contrast to this finding, Haq et al, found that folic acid deficiency was the commonest cause (62.5%) of megaloblastic anemia in her patients.[6]

The predominant symptoms in this study were fatigability (58%) and chronic diarrhea (16%). No patient presented with bleeding manifestation or had neurological symptoms. Unnikrishnan et al, found 91.7% of their patients presenting with fatigability, but in contrast to present study, 36.7% had bleeding manifestation and 10% presented with neurological symptoms.[7] In another study by Haq et al, in a population of 80 patients, 84% had fatigability and 27.5% had bleeding tendency.[6] Bleeding manifestations in thrombocytopenia due to Vitamin B12 or folate deficiency are typically mild and this may be the reason why no patient presented with bleeding tendency in the study.

In the present study, clinical examination revealed pallor in 100%, icterus in 20%, skin hyperpigmentation in 14% and organomegaly in 4%. Haq et al, found pallor in 84% and splenomegaly in 48%.[6] In a study by Unnikrishnan et al, 35% had jaundice, 31.7% had splenomegaly, 28.3% had hepatomegaly and 23.3% had skin changes.[7] Thus

when compared to the above studies we found lesser percentage of patients with organomegaly and skin changes.

Among 43 patients with Vitamin B12 deficiency, only four (9.3%) were vegetarians and remaining 39 (90.7%) were having non-vegetarian diet. 39 out of 44 (88.6%) non-vegetarians had Vitamin B12 deficiency in present study group. In concordance with present study, Unnikrishnan et al, and Iqbal et al, also reported a higher proportion of non-vegetarians having megaloblastic anemia and Vitamin B12 deficiency.[7,8] In contrast to our finding, Liggy et al and Kankonkar et al, showed Vitamin B12 deficiency higher in vegetarians than non-vegetarian. But the study cohort was different, Liggy et al, included all the patients and not only anemic patients, Kankonkar studied B12 deficiency in different diseases.[9,10] In current study 40% of patients had pancytopenia. Other studies have also found that megaloblastic anemia can present with pancytopenia.[5,11]

Bone marrow study was done in 29 out of 50 patients by us. All patients had megaloblastic erythropoiesis in the bone marrow. Khanduri and Sharma have suggested that bone marrow study should be done in selected patients when myelodysplasia is a differential diagnosis.[4] We also agree with them that bone marrow examination need not be done in all patients initially with megaloblastic anemia or Vitamin B12/folate deficiency, as it did not contribute to identifying a different etiology. In present study population of 50 patients, 33 (66%) underwent endoscopy and biopsy. 17 patients out of 33 (51.5%) had tropical sprue (TS). Among 17 patients with TS, 15 had low Vitamin B12 level, one had both low Vitamin B12 and folate levels and one had both normal.

An interesting observation in this study was that tropical sprue was more prevalent in megaloblastic anemia due to Vitamin B12 and/or folate deficiency. This may be because of endemic nature of TS in India. We found that Vitamin B12 deficiency was more in non-vegetarians and this may be due to underlying TS associated malabsorption.

TS is a malabsorption syndrome of unknown etiology or due to a probable persistent infection. TS cause malabsorption of folic acid and Vitamin B12 leading to megaloblastic anemia. A study done in West India in 1968 has reported that majority of patients with TS have Vitamin B12 deficiency.[12] After extensive literature search, we could not find many studies of endoscopic biopsy in megaloblastic anemia. There are few studies in malabsorption syndrome. Dutta et al. in a south Indian study and Ranjan et al. in a north Indian study found that TS was the commonest cause of malabsorption syndrome.[13,14]

There are a few limitations to current study. The sample size was small and we could not do complete work up for megaloblastic anemia and malabsorption due to cost factor.

CONCLUSION

To conclude, we found a high prevalence of TS in megaloblastic anemia due to Vitamin B12 and/or folate deficiency. We observed in thisstudy that being a non-vegetarian does not protect against Vitamin B12 deficiency, hence we recommend that all patients with megaloblastic anemia (including vegetarians) in India should be subjected to UGIE with deep duodenal biopsy to rule out TS, as the prevalence is high and treatment is different.

Study also found that bone marrow study did not yield added information and hence need not be considered in all patients with megaloblastic anemia or Vitamin B12/folate deficiency at the time of presentation, unless clinically indicated. We need larger and more studies to confirm our finding.

A Prospective Study of Correlatio of Magnetic Resonance Imaging of Brain Including MR Angiogram and Carotid Vertebral Arterial Doppler Study with the Clinical Features in Ischemic Stroke

Santni Manickam[1], Srinivasan T V[2], Velammal Petchiappan[3], Sujith Kumar S[4]

ABSTRACT

Introduction: Stroke is a global health problem. In this study we evaluated the risk factors, clinical features and their correlation with Magnetic Resonance Imaging (MRI) brain including Magnetic Resonance Angiogram (MRA) and Carotid Verteberal (CV) Doppler findings in patients presenting with acute ischemic stroke.

Material and methods: Seventy five patients of the age group 20 to 80 years admitted with acute ischemic stroke were enrolled for the study. A detailed history, clinical examination and blood investigations were done. MRI, MRA and CV Doppler were done in all patients. Serum Homocysteine levels and Anti-nuclear antibody assay (ANA) by Immunofluorescence (IF) were done in selected patients. Statistical analysis was done using SSPS version 16.0 for microsoft windows.

Results: In this study, there were more males than females. The mean age was 59 years. Young stroke population (<40 years) was 5%. Anterior circulation was predominantly involved than posterior circulation. Right Middle Cerebral Artery was the most common artery involved. There was positive correlation for clinical presentation and area of infarct and for areas of infarct and the vessels involved. Most common clinical presentations were weakness and slurring of speech. There were 3% intracranial anomalies. 56% had significantly elevated levels of homocysteine. 24% had ANA- IF positivity. Recurrence of stroke was seen in 17%; National Institute of Health Stroke Scale (NIHSS) score was higher in patients with recurrent stroke and right hemisphere infarcts.

Conclusion: There was positive correlation for clinical presentation and area of infarct and for areas of infarct and the vessels involved.

Keywords: Stroke, Anterior Circulation, Clinical co-relation, MRI, MRA Brain, Homocysteine, Area of Infarct.

INTRODUCTION

Stroke is a worldwide concern. Approximately two hundred lakh people every year suffer from stroke and of these fifty lakh do not survive.[1,2] In the developed nations, stroke is the leading cause for disability, second cause of dementia and third cause of death. Stroke is the second common cause of death and fourth leading cause of disability globally.[3] Stroke is an important cause for epilepsy, falls and depression in developed nations.[4] It is the leading cause of functional impairments, with 20% of survivors required hospital and nursing care for a prolonged period of more than 3 months duration and 15% - 30% of patient develop permanent disability.[5] Stroke is a life-changing event both financially and physically.

Stroke is caused by acute interruption of blood supply to the brain region it supplies, usually because of the blockade of a cerebral artery by a thrombus or emboli or by rupture of a vessel. This cuts off the supply of vital oxygen and nutrients to the brain, accumulation of free radicals causing damage to the brain tissue. An acute total occlusion of the vessels to the brain can cause death of the brain tissue within four to ten minutes. WHO clinically defines stroke as the rapid development of clinical signs and symptoms of a focal neurological disturbance lasting more than 24 hours or leading to death with no apparent cause other than vascular origin.[6] Among CVA, ischemic stroke constitutes 50%–85%[6,7] Hemorrhagic strokes - Subarachnoid hemorrhage and intra-cerebral hemorrhage, account for 1%-7% and 7%-27% respectively of all strokes worldwide.[8,9] In a study done, hemorrhagic stroke has significantly higher mortality when compared with ischemic stroke.

This study was conducted to evaluate various parameters like the risk factors of stroke, areas of brain involvement including the vessels involved and their clinical correlation in patients with acute ischemic stroke.

MATERIAL AND METHODS

This is a prospective observational study conducted in a tertiary hospital at Coimbatore between June 2015 and June 2016. A total of 75 patients in the age group of 20 to

DOI: http://dx.doi.org/10.21276/ijcmr.2019.6.6.60

80 years admitted with acute ischemic stroke to the medical and neurology wards were enrolled in the study. The study was initiated after obtaining clearance from the Institutional Ethical Committee. After obtaining informed consent, a detailed history attributable to the risk factors of stroke was obtained. A detailed clinical examination including baseline NIHSS score was obtained.

Investigations like complete hemogram, urine analysis, blood sugar, serum electrolytes, serum creatinine, blood urea, chest X-ray, fasting lipid profile, echocardiogram, electrocardiogram, MRI brain with MRA intracranium, CV Doppler were done in all patients. HbA1C was done if patient was found to be Diabetic based on random blood sugars. Investigations like ANA- IF and serum Homocysteine were done in selected patients.

STATISTICAL ANALYSIS

The data was reported as the mean +/- SD or the median, depending on their distribution. Frequencies were reported in percentages. The differences in quantitiative variables between groups were assessed by means of the unpaired t test. Non parametric test Wilcoxon signed test was used to assess the qualitative variables. To assess the difference in categoric variables between groups chi square test was used. Two tailed test was considered significant for all statistical tests when *P* value is <0.05. All data were analysed with a statistical software package (SSPS version 16.0 for microsoft windows).

Table-1: Clinical Presentation

RESULTS

Among the study population of 75 patients, 62 (83%) were males and 13 (17%) were females. 77% of total patients were aged more than 50 years. The mean age in the study population was 59 years. The young stroke population (<40 years) in this study was 5%.

The percentage of smokers, alcoholics and both was 17%, 5% and 24% respectively. In the study population the percentage of Type 2 Diabetes mellitus, Systemic hypertension, Dyslipidemia and combined was 11%, 9%, 35% and 41% respectively.

The most common symptoms were weakness, slurring of speech, deviation of angle of mouth as listed in Table 1.

In the study population, 47 patients (63%) had anterior circulation stroke and rest twenty eight patients (37%) had posterior circulation involvement. The most commonly involved arteries in the present study were Middle Cerebral Artery (MCA). Forty three out of seventy five patients (57%) had MCA involvement. Among the 43 patients with MCA involvement, right MCA was involved in 24 patients and 19 patients had diseased left MCA. Anterior cerebral artery (ACA) was involved in 4 patients. Posterior cerebral artery (PCA) was involved in twenty eight patients (Figure 1)

31% of the patients had intracranial obstruction due to atherothrombotic process which was classically seen in MRA intracraium. 11% of the patients had only extracranial occlusion which was seen in CV doppler studies. Twenty one percentage of the study population had both intracranial and extracranial leisions and 37% had normal IC & EC studies, probably related to small vessel ischemia.

Forty five patients (60%) had positive correlation of location of the infarct in the brain with either MRA or CV Doppler findings *P* <0.001. 37% had normal MRA & CV Doppler findings. Only in 3% of the study population there was no

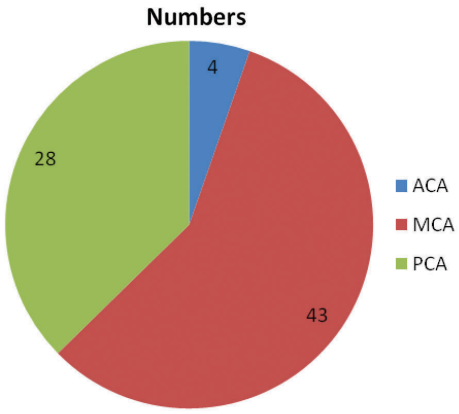

Figure-1: Most commonly involved arteries

			95% CI of mean				
	Mean	SD	Lower	Upper	Minimum	Maximum	Sig
Right	5.5	2.9	4.5	6.5	1	11	<0.05
Left	5.2	2.3	4.4	6.0	1	10

Total	5.3	2.7	4.7	5.9	1	12	

Table-2: Mean NIHSS score with Laterality

correlation of the same.

The clinical presentation was correlating with infarct in MRI in seventy patients (93%) P <0.05. There was no correlation in 7% of the study population due to bilateral involvement.

In this study population, recurrent CVA was seen in thirteen patients (17%). The mean age of recurrent CVA was 62 yrs and average NIHSS was 6.5 which were significantly higher than patients who had CVA for the first time. NIHSS was more in those with right hemisphere involvement when compared with left and bilateral involvement. The average NIHSS for right, left, bilateral involvement was 5.5, 5.2, and 4.8 respectively (Table 2). The maximum NIHSS in this study population was 12 which were noted with bi-hemisphere involvement.

Fasting serum Homocysteine levels and ANA –IF was done in 46 patients. Elevated homocysteine and ANA –IF positivity was noted in 56% and 24% respectively. Serum homocystiene was elevated in 36% of the alcoholics and 64% of non alcoholics. The highest value was 160 against <12 of the normal reference range.

In the study population, 2 (3%) had congenital anomalies. They were Frontal arteriovenous malformation and fetal PCA. None of the patients in the study population underwent thrombolysis.

DISCUSSION

Stroke among adults is rapidly increasing in the recent times. A systematic approach with good clinical history and examiantion, evaluation of risk factors, investigations and proper management of stroke is the need of the hour for acute ischemic stroke (AIS) patients.

In this study, males were more when compared with females. The male: female sex ratio among affected individuals is 7:1 in India. Among the females high risk groups are those taking oral contraceptives and pregnancy.[10,11]

The mean age was 59 years. In our study young stroke population (<40 years) was 5%. In a study at All India Institute of Medical Sciences (AIIMS), out of the 2,634 patients admitted with AIS, 440 patients (16.7%) were in the age group of 18-45 years and majority (83.4%) were male.[12] Smoking, alcoholism and dyslipidemia have been found to be significantly associated with stroke and its recurrence. Poor control of Diabetes Mellitus and systemic hypertension were associated with stroke recurrence.

Anterior circulation was predominantly involved than posterior circulation. Right MCA was the most common artery involved. There was positive correlation for clinical presentation and area of infarct and for areas of infarct and the vessels involved. Most common clinical presentation was weakness and slurring of speech. There were 3% intracranial anomalies

Eleven percent of patients had only extracranial occlusion. Extracranial occlusion that is carotid artery disease constitutes 10-20% of the strokes; stroke risk is directly proportional to the degree of occlusion. Carotid endarterectomy should be considered within 2 weeks if carotid stenosis of more than 70% involvement. There is less benefit of end carotidectomy and carotid stenting in patients with stenosis of carotids 50 to 69% and in asymptomatic patients, and there is literally no benefit in patients with stenosis of less than 50%

Hyperhomo-cysteinemia emerged as an important independent risk factor for ischemic stroke.[13] 56% had significantly elevated levels of homocystiene. The levels ideally have to be assessed 6 weeks later, for ideally diagnosing hyperhomocystinemia. Vitamins such as B12, B6 and folate play a vital role in the Homocysteine - methionine cycle[14], thus alcoholics are at risk of developing lower levels of folate and hence the increased Homocysteine levels. In contrary the proportion of elevated levels of Homocysteine was more in the non alcoholics when compared with alcoholics. There is correlation made in few studies that higher the Homocysteine values higher the mortality and recurrence of stroke.

24% had ANA- IF positivity but none of them had history of connective tissue disease. Incidental ANA- IF positivity in 24% of the study population raises concern whether it should be done routinely in all stroke patients and the same should be repeated to confirm the autoimmune etiology 6 weeks later.

Recurrence of stroke though was seen in 17%, but no mortality was observed among these patients. Relapse of alcohol, hard to kickoff smoking, poor adherence of medications was prime important in the stroke recurrence. NIHSS score was comparatively higher in these patients than in patients who had stroke for the first time. Similarly Right sided infarcts had higher NIHSS

None of the patients was thrombolysed due to varied reasons like exclusion criteria, after explaining the risks involved and mainly the time lapse in reaching the hospital. None of the patients was treated surgically.

CONCLUSION

There was positive correlation for the clinical presentation with area of infarct and for areas of infarct with the vessels involved. Elevated serum homocystiene levels and incidental positivity of ANA-IF noted in the present study raises concern; further studies are needed which will throw light in this area and indicate their significance in patients with acute ischemic stroke.

ACKNOWLEDGEMENT

I would like to thank all the patients who rendered their support for this study.

Association of N-terminal-Pro-B-type Natriuretic Peptide with Localization of Thrombus and Clinical Outcome in Acute Pulmonary Embolism

Santni Manickam[1], Yoganathan Chidambaram[2], Jayachandran Kuppusamy[3], Clement Jenil Dhas[4], Sujith Kumar[5]

ABSTRACT

Introduction: Pulmonary Embolism is a major health problem which is associated with significant mortality and morbidity. It is a common and lethal condition. This study was undertaken to find the association between NT-Pro-BNP levels and the localisation of thrombus in acute Pulmonary Embolism and to prognosticate the patients.

Material and methods: Prospective study conducted at a tertiary care hospital.Thirty patients with Pulmonary Embolism of various etiologies, confirmed with clinical features, laboratory investigations and imaging and fulfilling the inclusion and exclusion criteria were included. After getting informed consent, Blood samples for assessment of NT-Pro-BNP levels were collected within 24 hours of admission.

Results: In 19 patients, the thrombus was located centrally (in main pulmonary artery) whereas in 11 patients, the thrombus was located in the peripherally (in segmental and subsegmental pulmonary arteries). 22 participants of the study had normal clinical outcome. 5 patients were morbid (oxygen dependant/ heart failure) whereas 3 patients died. Patients with central pulmonary embolus had higher NT-Pro-BNP levels whereas patients with pulmonary embolus in the segmental or subsegmental pulmonary arteries had relatively less NTPro-BNP levels. Patients with high NT-Pro-BNP levels had complicated in-hospital course/ mortality whereas, patients with relatively lower NT-Pro-BNP had uncomplicated in-hospital course.

Conclusion: This study shows that higher NT-Pro-BNP levels indicate higher probability of a more central location of thrombus in pulmonary embolism and also right ventricular overload. Also patients with higher NT-Pro-BNP levels had a complicated in hospital course.

Key words: Pulmonary Embolism, Pulmonary Arteries, Right Heart Failure, NT Pro-BNP

INTRODUCTION

Pulmonary Embolism (PE) is a major health problem which is associated with significant mortality and morbidity. It is a common and lethal condition. Pulmonary Thrombo Embolism (PTE) and deep vein thrombosis (DVT) collectively known as venous thromboembolism (VTE) encompass one disease entity. Among cardiovascular diseases, VTE along with stroke and myocardial infarction rank as three big cardiovascular killers. PTE implies partial or complete occlusion of pulmonary arterial circulation by the clot formed elsewhere usually in deep veins of the leg. Less than 5% of venous thrombosis occurs in other sites. The incidence of PE in non-hospitalised patients is 3.5 per 10,000 person years while the incidence rate in hospitalised in-patients can be above 500 per 10,000 person years.[1] In India, VTE is a common cause of mortality and morbidity in patients hospitalized for medical or surgical illnesses. It is often misdiagnosed and not intervened in time. Though the exact magnitude of problem is not known in India, the clinical relevance and incidence is not expected to be different from Western countries. Acute PE has high early mortality rates. Despite the advances in diagnosis and treatment, the early mortality rates have not changed significantly. Due to the embolus obstructing the pulmonary bed, PE can result in a life threatening condition, acute right ventricular (RV) failure.[2] Early diagnosis is of paramount importance since most patients die within the first hours of presentation. Timely management is usually highly effective in reversing RV failure. The diagnosis of acute PE is based on the assessment of clinical likelihood, ECG, CXR, echocardiography, laboratory investigations, mainly D-dimer and cardiac biomarkers and imaging techniques (CT pulmonary angiogram). Several cardiac biomarkers have emerged as indicator of right ventricular dysfunction and clinical outcome predictor in patients with acute PE. Brain type natiuretic peptide (BNP) is a marker of ventricular dysfunction. Following cardiac myocyte stretch, this compound is released into the circulation. It is synthesized as an inactive pro hormone (Pro-BNP) which is split into active hormone BNP and an inactive N-terminal fragment (NT-Pro-BNP).[3] This study was undertaken to find the association between NT-Pro-BNP levels and the localisation

Association of N-terminal-Pro-B-type natriuretic peptide with localization of thrombus and clinical outcome in acute pulmonary embolism. International Journal of Contemporary Medical Research 2020;7(4):D19-D22.

DOI: http://dx.doi.org/10.21276/ijcmr.2020.7.4.11

BY-NC-ND

of thrombus in acute PE, to monitor and prognosticate the patients closely.

Primary objectives of the study were to study the association of N-terminal-Pro-B-Type Natriuretic Peptide with localisation of thrombus in Acute Pulmonary Embolism and to study the association between NT-Pro-BNP levels and clinical outcome in patients with Acute Pulmonary Embolism and secondary objectives were to study on the various risk factors in patients diagnosed with acute pulmonary thrombo embolism and to follow up the patients at the end of 1 month to know the clinical outcome.

MATERIAL AND METHODS

Prospective study was conducted at a tertiary care hospital, PSG Hospitals, Coimbatore. Thirty consecutive patients diagnosed to have pulmonary embolism were included in this study with the following criteria.

Inclusion criteria

All patients of age more than 18 years with clinical and radiological evidence of acute PE will be included in the study.

1) Clinical evidence

Patients presenting with dyspnoea, hemoptysis and chest pain with no acute ischemic changes in ECG and with normal Ejection fraction. ECG in acute pulmonary embolism will shows S1Q3T3 pattern.

2) Radiological evidence

CT pulmonary angiogram showing filling defects within the pulmonary vasculature.

Exclusion criteria

Patients with COPD, known case of Congestive cardiac failure and chronic kidney disease are excluded from this study.

After getting informed consent, Blood samples for assessment of NT-Pro-BNP levels were collected within 24 hours of admission. Risk factors for pulmonary thrombo embolism were noted such as prolonged bed rest, hypertension, malignancy etc. Thrombi located in main/ right/left pulmonary artery were classified as central while the others at segmental/sub-segmental levels were classified as peripheral. Echocardiographic findings such as ejection fraction, functions of right and left ventricle, pulmonary artery pressure were noted. Clinical course of the patient and clinical outcome were also noted. Clinical outcome of the patient at the end of one month was recorded by following up. Then descriptive and statistical analysis of location of thrombus and clinical outcome in relation with NT-Pro-BNP levels was done.

Risk factors	Frequency (n)	Percent (%)
Prolonged immobilization	13	43.3
Carcinoma	4	13.3
Unprovoked	13	43.3
Total	30	100.0

Table-1: Risk factors of the study participants

Clinical Outcome	Frequency (n)	Percent (%)
Normal	22	73.3
Morbid	5	16.7
Death	3	10.0
Total	30	100.0

Table-2: Clinical Outcome after 30 Days

STATISTICAL ANALYSIS

The data collected from the patients was tabulated using Microsoft excel. The data are reported as mean +/- SD depending on their distribution. Risk factors will be described in numbers and percentage. Any association will be analysed using chi-square test. Correlation will be analysed by Pearsman correlation. A p value of <0.05 using two tailed test was taken as being significant for all statistical tests. All data were analysed with statistical software package (SPSS version 24.0)

RESULTS

In our study, we included 30 patients diagnosed with acute pulmonary thromboembolism. The mean age of study population is 57.6 years. 11 patients belonged to the group of 51 to 60 years. Only 2 patients were younger adults and 2 patients were old adults. Among the study group 17 patients were male (56.7%) and 13 patients were female (43.3%).In our study population following were the risk factors noted. Thirteen patients had prolonged immobilisation following road traffic accident or following major orthopaedic surgeries. 4 patients had underlying malignancy such as Ca lung or Ca breast. 13 patients had unprovoked PTE.(Table 1) The thrombus was located unilaterally in 19 patients whereas 11 patients have bilateral thrombus. In 19 patients, the thrombus was located centrally (that is, in main pulmonary artery) whereas in 11 patients, the thrombus is located in the peripherally (segmental and sub segmental pulmonary arteries).22 participants of the study had normal clinical outcome. 5 patients were morbid (oxygen dependant/ heart failure) whereas 3 patients died.(Table 2)

Patients with central pulmonary embolus have higher NT-Pro-BNP levels whereas patients with pulmonary embolus in the segmental or subsegmental pulmonary arteries have relatively less NT-Pro-BNP levels. And the difference between the two was statistically significant. (P= 0.02)(Table 3)

Patients with high NT-Pro-BNP levels had complicated in-hospital course/mortality whereas, patients with relatively

	Localisation	N	Mean	Std. Deviation	P value
PROBNP	Central	19	6196.27	4377.75	.02*
	Peripheral	11	1529.10	2636.40	

Table-3: Association of PROBNP with localization

	Clinical Outcome	N	Mean	Std. Deviation	P value
PROBNP	Normal	22	3814.15	3860.52	.005*
	Morbid	5	3009.16	4033.77	
	Death	3	11864.00	1417.83	

Table-4: Association of PROBNP with Clinical Outcome

lower NT-Pro-BNP had uncomplicated in-hospital course. (P = 0.005)(Table 4)

DISCUSSION

Acute PE shows wide variations in clinical presentation from asymptomatic course to a massive pulmonary embolism that may be fatal. When planning treatment for this condition, risk stratification is important. In this study 30 patients diagnosed with pulmonary embolism were included. The mean age of study population is 57.6 years.17 patients were male(56.7%) and 13 patients were female (43.3%). The thrombus was located unilaterally in 19 patients whereas 11 patients had bilateral thrombus. In 19 patients, the thrombus was located centrally (main pulmonary artery) whereas in 11 patients the thrombus was located in the peripheral pulmonary artery (segmental and subsegmental pulmonary arteries). 22 participants of the study had normal clinical outcome. 5 patients were morbid (oxygen dependant/ heart failure) whereas 3 patients died. Patients with central pulmonary embolus have higher NT-Pro-BNP levels whereas patients with pulmonary embolus in the segmental or subsegmental pulmonary arteries have relatively less NTPro-BNP levels. And the difference between the two is statistically significant. (P= 0.02).

Patients with high NT-Pro-BNP levels had complicated in-hospital course/ mortality whereas, patients with relatively lower NT-Pro-BNP had uncomplicated in hospital course. (P = 0.005).From this study, it is evident that patients with higher NT-Pro-BNP levels have more central thrombus, have complicated in-hospital course and also cause morbidity and mortality. Whereas patients with comparatively lower NT-Pro-BNP levels have thrombus in segmental or subsegmental pulmonary arteries and they have an uncomplicated course.

The findings of our study were consistent with many other similar studies.

In a prospective study conducted by Akpinar et.al in turkey in Forty-nine patients concluded that higher pro bnp levels indicate higher probability of a more central location of thrombus in pulmonary embolism, resulting a more adverse clinical course and also leading to right ventricular overload..

In a prospective study done by Pruszcyk et.al in Poland in 79 patients found NT-Pro-BNP to be a prognostic marker in acute pulmonary embolism.[5]

An Egyptian prospective study by A.Selem et al conducted in 64 patients concluded elevated NT pro-BNP in PE was associated with worse short term prognosis in terms of higher morbidity and mortality.[6] Another study, Heleder Dores et al a retrospective study also had similar results as that of our study which concluded that elevated NT pro-BNP in PE identified worse short term prognosis and also had excellent power to predict 30 day all cause mortality.[7]

In a meta analysis conducted by Frederikus et.al, in the Netherlands, they found that higher concentrations of NT-Pro-BNP distinguish patients with pulmonary embolism at higher risk of complicated in-hospital course and death from those with low NT-Pro-BNP levels.[8] In another meta analysis conducted by Cavallazzi et.al in USA, they found that NT-Pro-BNP levels are significant predictors of all cause in hospital or short term mortality.[9] A meta analysis by Guillaume Coutance et al concluded while elevated BNP levels can help to identify high risk of death and adverse outcome, the high negative predictive value of normal BNP levels is certainly more useful.[10]

From our study it is evident that NT-Pro-BNP levels are significant predictor of all cause in- hospital mortality in patients with acute PE. The potential outcome of our study is that patients with normal levels of NT-Pro-BNP have a high negative predictive value for unfavourable outcome. Patients with normal NT-Pro-BNP levels have low risk of death as well as for hemodynamic collapse.This was consistant with a study conducted by Nils Kucher in 73 patients which predicted that lower the pro-BNP levels, lower would be the hospital stay.[11]

Our study have a few limitations. First, the sample size is limited. Further studies including larger number of patients are necessary to clarify this point. Secondly, NT-pro-BNP is a precursor of BNP. The conversion of BNP to NT-Pro-BNP may take several minutes after myocardial stretch which may lead to false negative results in patients who present early. Serial monitoring of NT-Pro-BNP (eg. At admission and 6 hours later) may overcome this limitation.

CONCLUSION

This study shows that higher NT-Pro-BNP levels indicate higher probability of a more central location of thrombus in pulmonary embolism and also leading to right ventricular overload.Also patients with higher NT-Pro-BNP levels had a complicated in-hospital course.Further studies with large number of patients were undertaken to determine the exact cut off levels of NT-Pro-BNP to help in treatment decisions.

Ethical approval

The study was approved by the Institutional Ethics Committee

Venous leg ulcers are the most common form of non-healing leg ulcers. They are subjected to treatments such as topical medications, dressings, and compression therapies. This can lead to exposure to a number of allergens with subsequent sensitisation and contact dermatitis of the regional skin. This may contribute to the poor ulcer healing. To detect the various contact sensitisers in patients with venous leg ulcers through patch testing, patients from 6 centres across India with venous leg ulcers of longer than 6 weeks duration were enrolled for the study. They were patch tested using a special parch test kit with 27 antigens. A total of 172 patients were included in the study; 82 (48.2%) tested positive for at least 1 antigen. Among them, polyvalent sensitisation was noted in 71% of patients. Wood tar mix (10.4%) and the framycetin (8.7%) were the most common allergens. There is a high frequency of allergic sensitisation to various ingredients of topical therapies used in the venous ulcer management, which may interfere with wound healing. Avoiding them can help obtain a better therapeutic outcome.

KEYWORDS
contact dermatitis, patch test, venous ulcer

1 | INTRODUCTION

Venous ulcers are an important sequel of chronic venous insufficiency (CVI). They are known for protracted course and refractory healing. A multidisciplinary approach is required for their assessment and treatment, including proper wound management, compression, and surgical interventions. Persistence of the ulcer for a longer duration leads to exposure to numerous topical applicants and medicament-incorporated dressings. Contact with these medicaments by the barrier-disrupted skin and occlusive wound dressings can lead to contact sensitisation. This allergic contact dermatitis of the skin surrounding the leg ulcers is undesirable because it delays wound healing.

Contact sensitisation in leg ulcer patients is very frequently reported in published studies.[1–7] The spectrum of allergens causing contact dermatitis in chronic leg ulcer patients depends on the wound care practices in a given area. In the majority of studies, a major group of sensitisers include fragrances, lanolin, antimicrobial agents, and rubber-related allergens. There is a high probability of polyvalent sensitisation, especially in ulcers of a longer duration. Patients with chronic leg ulcers, with or without associated dermatitis, should hence be patch tested to detect sensitisation to various allergens. This is an Indian study on the pattern of contact sensitisation in patients with chronic leg ulcers using special patch test series.

2 | METHODS

This is a prospective, multicentre, cross-sectional study conducted in 6 centres across India. Approval to conduct study was obtained from the respective institutional ethics committees. Consecutive patients who presented with chronic venous ulcers due to CVI persisting for 6 weeks and who consented to participate in the study were recruited. Patients with and without dermatitis of the surrounding skin were recruited for the study. Relevant clinical and demographic details were obtained. Local examination, including the morphology of ulceration, presence of dermatitis or other signs of CVI, and other relevant clinical findings, were also recorded. Those who were on immunosuppressive drugs, a steroid dose of 20 mg of prednisolone or equivalent, and those with dermatitis involving the back were excluded from the study. The study was conducted for a period of 1 year.

All patients included were patch tested using patch test series for leg ulcers obtained from the Chemotechnique Diagnostics, Modemgatan 9, SE-235 39, Vellinge, Sweden, which includes 27 allergens consisting of medicaments, preservatives, steroids, etc. Application of patch test series and patch test reading was performed according to the guidelines of the International Contact Dermatitis Research Group. The Finn chamber method was used to apply the allergens. Test patches were removed at 48 hours, and a patch test reading was performed. Readings were also taken at 72 to 96 hours and on the 7th day. Readings were recorded as negative (−), doubtful (?), weak/non-vesicular reaction (+), strong reaction (oedematous or vesicular) (++) and extreme reaction (bulla or ulceration) (+++). Patch testing was considered positive when recorded as (+), (++), or (+++) reactions during any reading. Findings from all 6 centres were obtained and tabulated. Univariate analysis was the statistical method followed.

3 | RESULTS

A total of 172 subjects participated in the study. Details of the subjects from various centres are given in Table 1. Most patients were middle aged or elderly; almost half of the patients were aged between 50 and 70 years (Table 2). Majority of the patients were males (142 out of 172). A total of 52% of our patients had an ulcer duration of less than a year (Table 3). Of 172 patients, 83 (48.2%) showed positive patch test reactions to 1 or more antigens (Table 3). Almost 50% of those showing positive reactions had disease duration of less than 1 year. A total of 29 % of the subjects demonstrated positive reaction to only 1 antigen and 27% to 2 antigens (Figure 1). One patient had positive reactions to 7 antigens.

Table 4 shows the various antigens that were patch tested. There were 183 positive reactions. Clinical relevance of the positive patch test reactions in these cases often remains questionable, but most positive reactions included antibiotics, antiseptics, solvents, and emulsifiers, which are components of the topical applicants. The most common allergen in our study was wood tar mix (19 patients). This was followed by framycetin sulphate (17 patients) and thiomersal and eosin (13 patients each). Twelve patients each

Key Messages

- venous leg ulcers therapies, such as topical medications, dressings, and compressions, expose the patients to allergens, followed by sensitisation and contact dermatitis; patch testing them can identify these allergens, and avoiding these allergens is an integral part of successful wound healing
- venous leg ulcer therapies, such as topical medications, dressings, and compressions, expose the patients to various allergens leading to contact dermatitis; it can contribute to poor wound healing
- patch testing patients can identify these allergens; avoiding these allergens is an integral part of successful wound healing

showed positive patch test reactions to benzalkonium chloride and p-CHLORO-m-CRESOL (PCMC). All allergens except tixocortol pivolate showed at least 1 positive test reaction.

4 | DISCUSSION

Chronic venous ulcers are 1 of the common problems, with prevalence rates for open ulcers ranging from 0.12% to 1.1% of the population.[8] Venous disease is the most frequent aetiology of leg ulcers, followed by arterial disease and other causes, such as diabetes.[9] Prevalence of venous ulcers has reduced due to better management of CVI, but it continues to be a major health problem. Chronic course of the ulcers, local inflammation, skin barrier disruption, use of topical medicaments including "over the counter" preparations, and the use of occlusive bandages are the reasons patients get sensitised to many antigens.[10] This leads to the onset of dermatitis, maceration of the surrounding skin, delayed wound healing, and bacterial infection. Allergic contact dermatitis may develop at distant sites other than the legs due to allergen exposure, dissemination from the ulcer site, or systemic spread.[11] Apart from poor wound healing, the presence of contact dermatitis of the surrounding skin will reduce the choices of therapy and local wound care.

Eczema was the most frequent manifestation of CVI, followed by leg ulceration.[12] Ulceration is an important determinant of the poor quality of life in venous disease. Our study included all patients presenting with leg ulcers irrespective of the presence of eczema. We used the leg ulcer series commercially supplied by the Chemotechnique Diagnostics.

Our study included 172 patients; 83 (48.2%) patients demonstrated positive patch test reactions to at least 1 allergen (Table 3). Our study results are almost at par with the results of Smart et al, who reported positive patch test results in 46% of their patients.[6] Higher positive results have been reported by Tavadia et al (68%), Saap et al (63%), Machet et al (75%), Lim et al (61.4%), and Jasmina et al (75%).[1–5] Some of these studies tested a larger number of antigens, which could be the reason for higher positive reactions. For example, in the study by Saap et al, a standard North American Contact Dermatitis Group series and 54 supplemental antigens were used.[2] Contact sensitivity to various allergens was higher in their general population, thus yielding higher results. Artüz et al. recently reported their findings in a study involving 40 patients and 20 controls; reported patch test positivity in these groups was 77.5% and 50%, respectively.[13] Management practices in our population may expose our patients to a lesser number of allergens, and this could have led to a lower percentage of positive reactions. In spite of all these factors, 48% positivity appears to be a high value and could play a role in the non-healing nature of the ulcers.

Among the 172 patients, 60% belonged to the age group of 30 to 60 years; another 30% were aged over 60 years. According to a population survey, 22% of the leg ulcers began before 40 years of age.[14] Only 30 (17.4%) of our patients were females, which may be due to decreased hospital reporting by women. In a population-based study, women outnumbered men by a ratio of 2.8:1.[15]

The duration of the leg ulcer is an important factor in the development of contact sensitisation. Venous ulcers are usually chronic; 33% to 60% of the ulcers can persist beyond 6 weeks;[16] 40 % of the ulcers may remain open for over 1 year.[17] One can predict that there will be more patch test-positive reactions with increased duration of the ulcer. In our study, 48% of those who tested positive had an ulcer duration of 2 years or more (Table 3). Polyvalent sensitisation and higher mean number of allergen sensitisations were found more frequently in ulcers with a duration of more than 5 years.[5]

Polyvalent sensitisation has been reported consistently with leg ulcers.[1–3,5] Studies have proven that the common sensitisers are the various ingredients of topical applicants, dressings, and bandages.[18] Lanolin, antibiotics, antiseptics, preservatives, emulsifiers, resins, and latex were the principal sensitisers. A total of 71% of our patients were positive for more than 1 allergen (Table 4). One patient was found to have positive reactions to 11 allergens. A total of 183 positive reactions were found in our study (Table 4). The most common allergen in our patients was the wood tar mix, with 19 patients (10.4% of all positive reactions) showing

positive reactions. This was followed by framycetin (16 patients, 9%), eosin (13 patients, 7.5%), *p*-CHLORO-*m*-CRESOL or PCMC (12, 7%), and benzalkonium chloride (12 patients, 7%). Other important allergens include propylene glycol, triethanolamine, chloramphenicol, imidazolidinyl urea, and phenyl mercuric acetate (Table 4). The majority of these reactions were relevant. There was no sensitisation to tixocortol pivolate. A venous eczema study utilising Indian standard series has been published by Jindal et al; they found 50% of positive results, with fragrance mix, *p*-phenylene diamine, wool alcohol, and nickel being the other common detected allergens.[19]

Wood tar mix was 1 of the most frequent (20%) allergens also found in the study by Saap et al.[2] In their study, sensitivity to balsum of Peru and bacitracin were the most frequent. Wood tar sensitisation was also 1 of the common sensitisers in a large study involving 1883 patients with allergic contact dermatitis.[20] Wood tar is used in the flavouring of certain food. A high degree of cross-allergy between wood tars and fragrance mix can occur. Framycetin is a common antibacterial agent used for ulcer care in India; hence, sensitisation to this agent is highly relevant. In spite of lack of evidences of the efficacy of framycetin or other antibiotics, the practice of topical antibiotic usage widely prevails in wound care.[21] We have known about very high framycetin sensitisation in leg ulcer patients for decade.[22,23] A number of antibiotic- and antiseptic-impregnated dressings are also used in ulcer management.[24] Eosin sensitisation has been reported in 2 studies.[25,26] In one of those studies, a very high rate of contact sensitivity (82.5%) has been reported, with eosin being positive in 5%. Eosin is an acid red dye used in lipsticks, nail polish, textiles, and antiseptics. Patch test positivity is thus relevant in patients with leg ulcers. PCMC and benzalkonium chloride are compounds used as an antiseptic and disinfectant. Both are known for their potential for allergic contact dermatitis.[27,28-] Saap et al. have reported 13% patch test positivity to benzalkonium chloride in their study.[2] We detected many other allergens with low frequency, and the relevance of such positive reactions cannot be determined.

Compression therapy using various bandages and stockings is an integral part of management and prevention of venous ulcers.[29,30] Allergic contact dermatitis to synthetic rubber, neoprene, in compression stockings has been reported.[32,33] Modern dressing-related contact dermatitis is infrequent but has also been reported.[31–34] Usage of these modern dressings is infrequent in Indian patients, and hence, sensitisation may be a rare occurrence. Many indigenous and traditional home remedies are used, and their sensitisation potential has also been explored in a few studies.[10,35]

The most important limitation of this study was the noninclusion of a control group. Inclusion of a control group with healthy volunteers was not considered in order to avoid the discomfort involved in patch testing. There was no uniformity in the number of patients recruited from the various centres. Indian standard series patch testing could have been performed in addition to the leg ulcer series.

Venous insufficiency and ulcers are problems Indian patients experience because of occupations that involve prolonged standing. There may be a genetic predisposition to varicose veins in many patients. It affects people during their prime of life as our study inferred. It is more common in men, who are the breadwinners in most Indian households, thus causing health as well as economic burden. The pattern of sensitisation appears to be related to treatment practices. Allergens and their frequencies in Indian patients with venous disease were almost similar to those reported from other parts of the world.[1–4,19] Common allergens in many of those studies were the fragrance mix, antibacterials, wood tar mix, and lanolins. Sensitisation to fragrance mix was very high, and a significant number were sensitive to topical corticosteroids in the study by Tavadia et al. We found wood tar mix and the antibacterials (framycetin) among the common allergens, and we found no sensitisation to corticosteroids.

Studies have inferred that patients with chronic wounds of the lower extremity experience functional disability and

emotional distress, with negative influences on quality of life. Apart from physical and psychosocial functioning, treatment-related issues also can have an impact.[36,37] A review of the literature and calculated sensitisation rates of a pool of 3043 patients extracted from 24 series, and their own, has shown a significant increase in sensitisation in recent times.[3] Contact allergy to the various topical treatments employed in leg ulcer management can contribute to or worsen eczema and can impede ulcer healing. Thus, it can be a major reason of poor quality of life. Modern dressings with lower allergenic potential may be used as wound dressing. It is better to avoid antiseptics and antibiotics in the absence of infection, and it should be used for a limited period. This should be known by all health care personnel involved in managing venous leg ulcers.

COVID-19 Presenting as Enanthem and Itchy Exanthem

Reena Rai[1], Harish Nagarajan[2]
[1]Professor and HOD of Dermatology, [2]Postgraduate, PSGIMSR, Coimbatore, Tamil Nadu

Sir,

Dermatologists can play a very important role in coronavirus disease 2019 (COVID-19) pandemic as early recognition of skin lesions are important in diagnosing severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) infection. The various cutaneous lesions that have been described so far with COVID-19 falls into four categories: exanthema (varicella-like, papulo-vesicular and morbilliform rash), vascular (chilblain-like, purpuric /petechial and livedoid lesions), urticarial and acro-papular eruption.[1]

A 36 year old male, known case of decompensated chronic liver disease (ethanol related cirrhosis) came to the emergency department with history of itchy rash in the trunk and limbs for 7 days. There was no history of fever, cough, sore throat, loose stools or drug intake. Cutaneous examination revealed multiple maculopapular exanthematous rash with excoritation over chest, abdomen, back, arms, thighs and both lower legs. Examination of the oral cavity revealed multiple tiny erythematous macules and pinpoint enanthems over soft palate and the tongue showed evidence of candidiasis. Since endoscopy was suggested by the gastroenterologist, swabs were taken from the nasopharynx and oropharynx for COVID-19. Real-time reverse transcriptase–polymerase chain reaction for SARS-CoV-2 turned out to be positive. Most of the skin manifestations reported in literature coexist with other symptoms of COVID-19. Many patients who are confirmed or suspected to have

COVID-19 do not have their oral cavity examined due to safety concerns. In our patient, we did not suspect, as the patient did not have symptoms suggestive of COVID-19. Exanthem can occur in patients with viral infections and drug reactions. Usually, exanthem presenting as pustules and dusky lesions suggest drug etiology, whereas, petechial or vascular pattern with enanthem point towards an infectious etiology.[2]

In a study done by Dr Jimenez-Cauhe et al, oral cavity of 21 patients with COVID-19 and skin rash were examined, among which 6 patients had enanthem. The mean duration between onset of COVID-19 symptoms and appearance of enanthem is 12.3 days.[3] Enanthem can present as petechial, macular, macular with petechiae, or erythematovesicular. Our patient had macular enanthem and itchy exanthem without other symptoms of COVID-19.

Physicians should have a high degree of suspicion when patients present with skin manifestation of exanthematous rash and oral enanthem as it may be a presenting feature of COVID-19.

Effectiveness of Dual Sequential Wavelength Laser in the Treatment of Portwine Stains – A Retrospective Study

Mohan Kumar Periyasamy, Shanmuga Sekar C, Reena Rai

Department of Dermatology, PSG Hospitals, Coimbatore, Tamil Nadu, India

Abstract

Background: Port Wine Stain (PWS) is only partially and superficially treated with the Pulsed dye laser (PDL) because of its limited depth of penetration. The 1064-nm long pulsed Nd:YAG laser has greater depth of penetration and is used to treat deeper vessels. The dual sequential wavelength laser (DSWL) which combines PDL/Nd:YAG (595/1064 nm) can be more effective for the treatment of deeper, nodular portwine stains due to its synergistic effect. The purpose of this study is to evaluate the efficacy and safety of DSWL in the treatment of portwine stains after five treatment sessions. **Materials and Methods:** A total of 11 patients with PWS lesions on the head and neck, who were treated with DSWL for at least five sittings at monthly interval were included in this study. The assessment of the therapeutic response and grading of improvement was done with a scale of 0 to 4 by comparing the photographs taken before treatment and after 5 sittings of laser treatment. **Results:** Out of the 11 patients, 5 patients (45.45%) had more than 70% improvement. Six out of eleven patients (54.54%) had 40 to 70% improvement at the end of five sittings with no adverse effects including purpura. **Conclusion:** Dual Sequential Wavelength Laser is a good modality of treatment for portwine stains. It has enhanced penetration and effective clearance of thicker, nodular, recalcitrant lesions of PWS. DSWL is safe and efficacious and it can be recommended as a therapeutic modality for portwine stains.

Keywords: *Dual sequential wavelength laser Nd:YAG laser, PDL, portwine stains, vascular lasers*

Introduction

Pulsed dye laser (PDL) is the "gold standard" for treating portwine stains (PWS).[1] PDL is used for many years to treat vascular lesions. It destroys the target tissues by the principle of selective photothermolysis.[2] Nearly 25–50% of the lesions treated with PDL alone do not demonstrate a significant improvement even after many sessions of treatment. The 1064 nm-long pulsed Nd:YAG laser has greater depth of penetration of upto 5 to 6 mm and greater affinity for deeper large vessels.[3] Vascular lesions of varying size, density, color, flow and depth may not respond to either PDL or Nd:YAG alone.[4] The dual sequential wavelength laser (DSWL) which combines PDL/Nd:YAG with 595/1064 nm has been proposed as an alternative treatment for PWS. DSWL is effective for the treatment of portwine stains. It produces two widely separated laser wavelengths in a single device[5] and at a lower fluence, it gives good therapeutic response with lesser side effects.[6]

Materials and Methods

This is a retrospective study conducted in our department of dermatology after getting approval from our institutional ethics committee. Eleven patients with PWS lesions on the head and neck, who were treated with DSWL (Cynergy system, Cynosure Corp, Westford, MA, USA) for at least five sittings at monthly interval were included in this study.

All the patients had been treated with a fluence ranging from 4 to 10 J/cm^2 and pulse duration between 0.5 and 40 ms for PDL and a fluence ranging from 20 to 50 J/cm^2 with pulse duration between 15 and 40 ms for Nd:YAG. The spot size of 7 or 10 mm were used with inter-pulse delay of 1 second for sufficient cooling. The air cooling device (Cynosure smart cool, USA) was attached to the laser hand piece for epidermal cooling. The assessment of the therapeutic response and grading of improvement was done with a scale of 0 to 4 by comparing the photographs taken before treatment and after five sittings of

laser treatment. Grade 0 is less than 20% improvement, grade 1 is 21 to 40% improvement, grade 2 is 41 to 60% improvement, grade 3 is 61 to 80% improvement, grade 4 is more than 80% of improvement.

Results

Of the 11 patients, 8 were females and 3 were male patients with age groups ranging from 18 to 44 years. One patient had lesions over the neck, 10 patients had facial lesions [Figure 1a]. The improvement of lesions after five laser sittings is shown in Table 1. Out of the 11 patients, 5 patients (45.45%) had more than 70% improvement, i.e., 1 patient had 90% improvement [Figure 1b], 2 patients had 80% improvement, 2 patients had 70% improvement. Totally, 6 out of 11 patients (54.54%) had 40–70% improvement i.e., 4 patients had 50% improvement and 2 patients had 40% improvement.

Out of the 11 patients, seven patients had flat reddish lesions and four patients had thick, elevated lesions of PWS over face [Figure 2a] and neck. Of the four patients who had thick, elevated lesions, 1 patient had 80% improvement [Figure 2b], 1 patient had 70% improvement**,** 2 patients had 50% improvement. One patient who had thick nodular lesions over the neck [Figure 3a] had 70% improvement [Figure 3b] after 5 sittings of laser treatment at monthly intervals. No adverse effects were recorded including purpura after DSWL treatment.

Discussion

Portwine stains (PWS) present as light pink macules due to progressive vessel ectasia and can progress into dark purple lesions. PWS are usually located in the papillary and reticular dermis. If hypertrophy of soft tissues occurs, it can become thicker and more nodular over a period of time. Various modalities of treatment are available for portwine stains, including Pulse Dye Laser, Nd:YAG lasers and Intense Pulsed Light (IPL). Several vascular lasers like argon, tunable dye, copper vapor, krypton lasers, which were also used in the past with the risk of dyschromia and scarring.[7]

Table 1: Percentage of improvement after 5 sittings

Age/Sex	Site of the lesion	Improvement (%)
23 yrs/M	Right side of the scalp and face	80
18 yrs/F	Right side of the face	90
34 yrs/M	Left side of the face	40
20 yrs/F	Right side of the face	50
33 yrs/F	Right side of the forehead and upper eyelid	40
21 yrs/F	Left side of the cheek and upper lip	70
28 yrs/M	Left side of the face	50
18 yrs/F	Left side of the cheek and upper lip	50
22 yrs/F	Left side of the face	80
44 yrs/F	Left side of the face	50
42 yrs/F	Right side of the neck	70

DSWL works under the principle of selective photothermolysis. It is the process by which a target tissue absorbs photons, becoming heated and destroyed totally, while structures surrounding it are relatively spared. In case of PWS, the desired targets are 10–500 μm dilated capillaries and postcapillary venules in the superficial and deep dermis.[8] PDL has shallow depth of penetration and hence it is not effective for treating deeper, nodular lesions of PWS. Over the years, modifications to the original PDL system have been made in order to overcome these disadvantages. Usually PWS lesions extend 3 to 5 mm into the dermis and the PDL is effective only up to

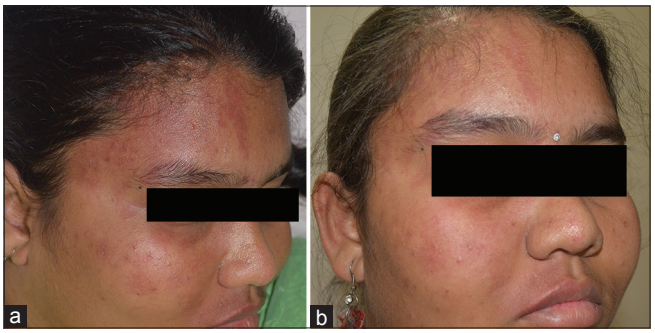

Figure 1: PWS lesions over the right half of face. (a) Before treatment. (b) After five sessions of treatment with DSWL at monthly intervals, she had 90% improvement

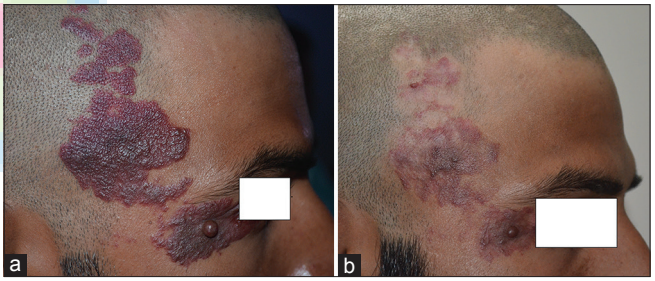

Figure 2: PWS lesions over the right side of scalp and face. (a) Before treatment. (b) After five sessions of treatment with DSWL at monthly intervals, he had 80% improvement

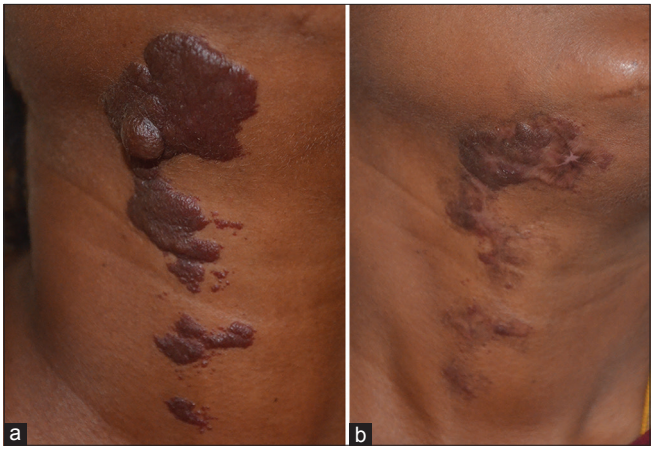

Figure 3: PWS lesions over the right side of neck. (a) Before treatment. (b) After five sessions of treatment with DSWL at monthly intervals, she had 70% improvement

[Downloaded free from http://www.idoj.in on Friday, June 28, 2019, IP: 201.17.106.59]

2 mm depth. Deeper vessels that are not damaged fully with PDL therapy may recover in future. High energy is required to thermo-coagulate the deep vessels and hence, epidermis should be protected to minimize the damage to keratinocytes and melanocytes by means of epidermal cooling. Cooling is therefore an integral part of all vascular lasers.[8]

DSWL is a new concept that sequentially emits two wavelengths from the same delivery fiber with a pre-selected delay between the two pulses. The PDL energy emits first, converts oxy-hemoglobin to met-hemoglobin. Met-hemoglobin has three times higher absorption co-efficient to Nd:YAG wavelength than oxy-hemoglobin. Pre-selected delay will allow the met-hemoglobin to penetrate deep into the blood vessels. Nd:YAG laser emits few milliseconds later following PDL, allows the reduction of treatment fluence and thereby reduces the adverse effects.[1]

Usually PWS appears pink during infancy period, which becomes red during adulthood. Without treatment, PWS typically darkens as age increases and may develop nodular thickened lesions. Early treatment gives more optimal results in all patients. Much quicker results can be visualized when the laser treatment is begun at an earlier age.[8]

Zoran Barcot *et al*. stated that, after PDL treatment nearly 65% of patients achieved between 50% and 90% lightening of their lesions and 15% achieved greater than 90% lightening with individual treatment sessions spaced 2 to 3 months apart; 8 to 10 serial treatments were needed to achieve significant lightening of the lesions.[9] Tina Alster *et al*. proved that the use of dual 595/1,064-nm wavelength laser provided continued improvement of PWS that were previously recalcitrant to PDL therapy. Moderate clinical improvement was observed in 12 out of 25 subjects (48%), and mild improvement was observed in 13/25 subjects (52%). The total number of treatments ranged from 2 to 7 sessions. Side effects were limited to erythema, edema, and purpura. Rarely vesicle formation was observed, with no scarring or pigmentary changes.[10]

Badawi *et al*. conducted a study with 20 patients of nodular and thick port wine stains, stated that the average improvement was 70% following 4 treatment sessions at 3–4 weeks interval.[11] Barton *et al*. has demonstrated that the sequential application of lasers at 532- and 1,064-nm wavelength caused permanent vessel damage at which the two pulses individually had little or no effect.[12]

Alster *et al*. stated that the DSWL is best used for darker, thicker, nodular, recalcitrant PWS, whereas the PDL can be used alone for superficial, early, pink lesions of PWS, and the Nd:YAG laser can be used alone in patients with darker skin tones. The frequency of laser treatments in the literature showed more variations, ranged between few weeks to few months. Patients with dark skin types have increased risk for hypo or hyper-pigmentation, may benefit more from this DSWL technology.[13]

Koster *et al*. demonstrated that studies show 50–90% overall clearance of PWS, with approximately 10% improvement per treatment session. Superior results had been observed with the DSWL approach when compared to PDL alone in PWS cases which was resistant to other treatment modalities.[14] In this study, out of the 11 patients 5 patients (45.45%) had more than 70% improvement, 6 patients (54.54%) had 40–70% improvement at the end of 5 sittings and there was a progressive lesional lightening noted after each laser treatment in all patients without any adverse effects.

Conclusion

Dual sequential wavelength laser (DSWL) is a good modality of treatment for portwine stains. It has enhanced penetration and effective clearance of thicker, nodular, recalcitrant lesions of PWS. DSWL is safe and efficacious and it can be recommended as a therapeutic modality for portwine stains.

Declaration of patient consent

The authors certify that they have obtained all appropriate patient consent forms. In the form the patient(s) has/have given his/her/their consent for his/her/their images and other clinical information to be reported in the journal. The patients understand that their names and initials will not be published and due efforts will be made to conceal their identity, but anonymity cannot be guaranteed.

Efficacy of Topical Timolol versus Saline in Chronic Venous Ulcers: A Randomized Controlled Trial

Abhay K. Rai, Janani K, Reena Rai

Department of Dermatology, PSG Institute of Medical Sciences and Research (PSGIMSR), Coimbatore, Tamil Nadu, India.

Abstract

Background: Chronic venous ulcers sometimes fail to heal in spite of adequate treatment. Nonhealing is possibly because of chronic activation of β-2 adrenergic receptor (B2-AR) in the keratinocytes by endogenously generated catecholamines, which inhibits keratinocyte migration. Blocking of B2-AR using β-blockers has been reported to promote wound healing through keratinocyte migration, angiogenesis, and fibroblast migration. Topical timolol, a B2-AR antagonist, is used to promote wound healing. **Aims and Objectives:** The aim of this study was to compare the efficacy of topical timolol versus saline in chronic venous leg ulcers and to compare the mean reduction in ulcer area at the end of 4 weeks. **Materials and Methods:** Twenty patients were randomized into two groups. Patients in Group 1 were treated with one drop of 0.5% topical timolol every alternate days for 4 weeks. Ulcer margins were measured and ulcer area calculated every week for 4 weeks. Similar dressing and measurement were carried out for patients with saline for 4 weeks. Healing rate was assessed by the percentage of reduction of ulcer area of both groups at week 4. **Results:** The mean reduction in the ulcer size in timolol group was 86.80%, and in saline group 43.82% at the end of 4 weeks. **Conclusion:** Topical timolol is an easy, noninvasive therapy that can be recommended for chronic ulcer.

Keywords: Healing, timolol, venous leg ulcer

Introduction

Venous stasis ulcers account for 80%–90% of all leg ulcers. The current treatment for venous ulcers is compression and wound care with dressings. All of which have not showed any significant improvement in healing. Keratinocyte migration is a key component in wound healing and it is required for skin reepithelization and complete wound repair. β-2 adrenergic receptor (B2-AR) is expressed primarily on human keratinocytes.[1] Activation of this receptor inhibits keratinocyte migration. Blocking of B2-AR pathway using B2-AR antagonists (β-blockers) has been reported to promote wound healing through different mechanisms, including keratinocyte migration, promotion of angiogenesis, increased dermal fibroblast migration, and epidermal differentiation.[2] Timolol, a commercially available B2-AR antagonist, used as an intraocular glaucoma medication has been shown to promote wound healing when instilled in chronic leg ulcers. The purpose of this study was to assess the efficacy of topical timolol in wound healing.

Materials and Methods

Twenty patients diagnosed with chronic venous ulcer of lower extremities, presenting to the OPD over the study period and satisfying the inclusion and exclusion criteria, were included in the study after obtaining informed consent.

The inclusion criteria of the study included patients who were over 18 years old, venous ulcers lasting for at least 4 weeks with no improvement with good wound care, dressings, and compression stockings.

The exclusion criteria of the study included infected ulcers, patients on systemic β-blockers, patients with asthma and COPD, and patients with venous leg ulcers on systemic

treatment. Each patient after randomization was allotted into treatment or control group.

Group 1 (treatment group). Ten patients with chronic venous leg ulcer receiving topical timolol

Group 2 (control group). Ten patients with chronic venous ulcer receiving saline dressing.

All patients were advised to continue compression stockings.

Group 1. One milliliter of timolol contains 5 mg of the drug. Each milliliter contains 20 drops. Hence, each drop contains 0.25 mg of the drug. To each patient, one drop was instilled every 2 cm^2 of wound edge and then covered with sterile dressing. This was repeated every alternate days.

Group 2. One drop of saline was instilled every 2 cm^2 of wound and then covered with sterile dressing every alternate days.

Ulcer margin was measured by measuring the greatest length and the greatest width, perpendicular to the greatest length every week for a maximum period of 4 weeks. Digital photographs were taken during each visit.

The primary end point is to evaluate the ulcer reduction rate at the end of 4 weeks. The improvement was also evaluated with photography and the ulcer reduction rate in both groups was calculated at the end of 1 month after beginning the treatment. The healing rate between the study and control group was compared statistically using Satistical Package for Social Sciences Software Version 24.0. Armonk, NY: IBM Corp.

Results

A total of 20 patients meeting the inclusion and exclusion criteria were enrolled in the study. All the patients were suffering from chronic venous ulcers. The result was assessed on the basis of ulcer area reduction. The mean ulcer area reduction after 1 week in the timolol group was 23.06%, after 2 weeks it was 36.57%, at 3 weeks it was 67.18%, and after 4 weeks it was 86.80% [Table 1]. However in the saline group, it was 11.01%, 17.53%, 31.78%, and 43.82%, respectively [Table 2]. The overall mean reduction

in the ulcer area was 86.80% in the patients with timolol dressing as compared to 43.82% in the patients treated with saline dressing [Figure 5]. There was a complete closure of the ulcer in five patients (50%) in the timolol group [Figures 1 and 2]. There was no case of complete closure of the ulcer in the saline group [Figures 3 and 4].

Although there was a reduction in the ulcer size in the timolol group as compared to the saline group at the end of 4weeks, it was not statistically significant at $P = 0.104$ [Table 3].

There were no local or systemic side effects noted.

Discussion

Chronic ulcers are a common problem, particularly in older people resulting in repeated admissions. The treatment of chronic ulcer presents a therapeutic challenge and includes good wound care, dressings, compression therapy, and lifestyle modifications. Dressings often used for chronic ulcers include hydrocolloid, hydrogel foams, pastes, silver impregnated dressings, and simple nonadherent dressings. A meta-analysis of 42 randomized controlled trials with more than 1000 patients showed no significant difference among dressing types.[3] Hydrocolloid dressings that are expensive are not shown to have a healing benefit over simple nonadherent dressings. There is no clear evidence to support the use of one dressing over the other and so the choice of dressing depends on the cost and ease of application.[3]

B2-AR receptors are present on cells in multiple organ systems, including the skin. Within skin, receptors are present on keratinocytes, fibroblasts, and melanocytes. B2-AR is the dominant subtype expressed on keratinocyte surfaces.[1] The influence of this receptor has been studied by observing the effects of agonist and antagonist at the receptor. In addition, the epidermis contains the full range of enzymes necessary to synthesize catecholamines such as norepinephrine and epinephrine to bind to various adrenergic receptors and delay wound healing.[4] B2-AR antagonists have been reported to promote wound healing, and one potential mechanism of action via keratinocyte migration. Keratinocyte migration occurs by the facilitation of chemotaxis, the polarization of cells, and activation of extracellular signal-related kinases essential in the signaling of promigratory pathways. The B2-AR activation inhibits keratinocyte migration by activating the serine/threonine phosphatase 2A, which downregulates phosphorylation of extracellular signal-related kinases necessary for migration.[5] Therefore, B2-AR antagonists prevent the phosphorylation of phosphatase 2A and downstream extracellular signal-related kinase promotion, inducing a promigratory pathway in keratinocytes. The B2-AR antagonists improve the ability of keratinocytes to respond to such migratory signals, whereas the B2-AR agonists decrease keratinocytes ability to respond.[6] Angiogenesis and dermal fibroblast proliferation are also regulated by B2-AR. The B2-AR antagonists have been found to promote angiogenesis in chick chorioallantoic membrane assays and *in vivo* murine wound models. Dermal fibroblast migration is also increased when exposed to B2-AR antagonists, and epidermal differentiation is improved with B2-AR antagonists.[7,8] Catecholamines, such as epinephrine and norepinephrine, are endogenously generated agonists, and these are also generated by the wound epithelium. Therefore, it is possible that one pathogenic mechanism contributing to nonhealing skin wounds is the chronic activation of B2-AR by endogenously generated catecholamines.[9] Blocking of B2-AR pathway using pharmacological antagonists promotes keratinocyte migration and re-epithelization *in vitro*, in human skin, in an *ex vivo* skin wound model, and *in vivo* in animal preclinical studies.[10,11]

People with burns have been treated with systemic B2-AR antagonist proponalol to diminish the effect of excessive catecholamine response after burn injury. Mohammadi *et al.*[12] carried out a randomized double-blind trial in burn patients. They included 79 burn patients, 37 in the study group and 42 in the control group. The participants in the study group who received oral propranolol had better wound healing.

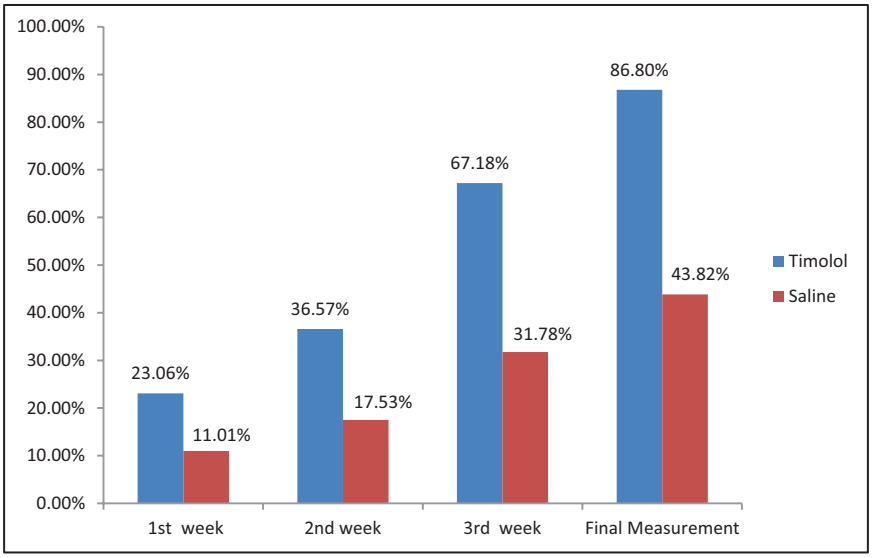

Figure 5: Bar diagram showing the comparison of the mean improvement in timolol group and saline group after every week and also after the treatment for 4 weeks

A case report by Tang *et al.*[13] showed that topical timolol application produced complete wound healing in a refractory wound on the mid back.

A cohort study by Chakkittakandiyil *et al.*[14] showed the efficacy, tolerability, and safety of timolol maleate 0.5% solution in treating infantile hemangiomas. Thus, Manahan *et al.*[15] used topical timolol as a safe and inexpensive drug to treat chronic ulcer. Braun *et al.*[16] used topical timolol in five patients with recalcitrant wounds; 0.5% topical timolol was instilled in chronic, recalcitrant wounds of these five patients, and improvement was noted in all five, including three patients who had complete healing. The mean reduction in wound size after 7 weeks was 78.2%. Lev-Tov *et al.*[17] successfully treated chronic venous leg ulcer with topical timolol.

A study by Thomas *et al.*[18] showed that the patients treated with topical timolol had a significantly higher ulcer healing rate of 61.79% in the study group and 29.62% in the control group at the end of 12 weeks. Analysis showed that there were significant differences in percentage change in ulcer of the study and control groups. Thus, treatment using topical application of timolol resulted in faster healing rate compared with conventional treatment.

Our study showed that patients in timolol group (86.80%) had significant reduction in the size of the ulcer as compared to the saline group (43.82%) after 4 weeks of treatment. There was no side effects and the treatment was well tolerated.

Our research attempts to study the efficacy of topical timolol on healing of chronic venous leg ulcer. Topical timolol is cost-effective, easily available as a 0.5% solution, and is therefore a treatment option in chronic ulcers. This is the first randomized controlled study comparing timolol and saline on healing rate of chronic venous ulcers. The limitation of our study is the sample size. However, more studies are needed.

Declaration of patient consent

The authors certify that they have obtained all appropriate patient consent forms. In the form the patient(s) has/have given his/her/their consent for his/her/their images and other clinical information to be reported in the journal.

Case Report

Erythrokeratoderma En Cocardes – A Rare Phenotype

P Arunprasath, Reena Rai, G Umamaheswari[1]

Departments of Dermatology and [1]Pathology, PSG Institute of Medical Sciences and Research, Coimbatore, Tamil Nadu, India

Abstract

Erythrokeratodermas are disorders of keratinization with two major types, namely erythrokeratodermia variabilis and symmetrical progressive erythrokeratoderma. Apart from the two main types, rare variants include erythrokeratoderma en cocardes (EEC), erythokeratoderma with erythema gyratum repens-like lesions, erythema annulare centrifugum-like lesions, and reticulate erythrokeratoderma. Herein, we report a rare case of EEC with associated palmoplantar keratoderma, the association which has not been described in previous reports.

Keywords: *En cocardes, erythrokeratoderma, palmoplantar keratoderma*

Introduction

Erythrokeratodermas are disorders of keratinization which encompass two main subtypes, namely erythrokeratodermia variabilis (EKV) and symmetric progressive erythrokeratoderma (SPEK) and other atypical rare variants.[1] Erythrokeratoderma en cocardes (EEC) is a rare variant characterized by polycyclic, concentric, and targetoid lesions along with erythematous plaques.[2]

Case Report

A 4-year-old boy born out of third-degree consanguineous marriage presented with multiple hyperpigmented scaly lesions involving the arms, forearms, back, gluteal region, thighs, and legs since 6 months of his age. There was a history of aggravation of lesions during cold season and improvement during summer. There was no history of atopy and other systemic symptoms. Milestones were achieved normally. There was no history of similar skin lesions in siblings or other family members.

Cutaneous examination revealed multiple scaly plaques with polycyclic borders involving the arms, forearms, thighs, and legs [Figures 1a,b and 2]. In the posterior aspect of the thigh, there were scaly plaques with polycyclic borders sparing of the popliteal fossa [Figure 3]. There were multiple discrete annular scaly plaques with concentric rings involving the forearms and thighs. Anterior aspect of legs showed diffuse ichthyosis extending to the dorsum of the feet [Figure 4]. Palms and soles revealed diffuse keratoderma with fissuring and scaling [Figure 5]. Examination of hair, nails, and teeth was normal. Systemic examination was essentially normal. Hematological examination did not reveal any abnormality. Scrapings of skin for potassium hydroxide mount were negative for fungal elements.

Histopathology revealed hyperkeratosis, focal mild parakeratosis, conspicuous granular layer, and irregular acanthosis. There were mild spongiosis and lymphocytic exocytosis. The papillary and upper dermis showed pigment incontinence, prominent capillaries, and a mild perivascular lymphohistiocytic infiltrate, a picture compatible with erythokeratoderma [Figure 6].

Owing to the distinct clinical morphology with annular lesions, polycyclic borders, and histopathological features, a diagnosis of EEC was entertained.

Discussion

Erythrokeratoderma has two variants: SPEK and EKV. SPEK is characterized by well-demarcated, hyperkeratotic plaques distributed symmetrically over the elbows, knees, dorsal aspect of the hands, feet, and buttocks, sparing the trunk. SPEK has its onset in infancy or early childhood.[3] EKV, on the other hand, manifests as two distinct clinical pictures: with generalized, erythematous, hyperkeratotic plaques in one and localized sharply demarcated

hyperkeratotic plaques in the other. EKV has its onset in birth or in neonatal period in 50% of patients and within 1st year of life in 90% of patients.[4]

Rare variants of EKV described include EEC, EKV with erythema gyratum repens-like lesions, EKV with

[Downloaded free from http://www.ijpd.in on Wednesday, July 1, 2020, IP: 157.50.37.87]

erythema annulare centrifugum-like lesions, and reticulate erythrokeratoderma.[4,5] Degos *et al*., in 1947, described EEC in a 13-year-old girl, a rare and atypical variant of EKV with polycyclic plaques, with concentric layers of scaling and erythema giving a targetoid, or "en cocardes" appearance.[6]

The index case described by Degos had an onset at birth, remissions and recurrences, desquamation of palm, similar skin lesions in father and paternal uncle pointing to autosomal-dominant inheritance, and improvement of skin lesions during summer.[7] The present case had onset during 6 months of age, without any family history and improvement during summer. Unlike the index case, the cases reported by Rajagopalan *et al*. and López-Ferrer *et al*. did not show improvement of lesions during the summer.[1,2] Furthermore, the present case showed prominent palmoplantar keratoderma, which has not been described in previous reports.[1,2,8]

Apart from EEC, differential diagnoses considered include annular type of epidermolytic ichthyosis, X-linked recessive ichthyosis, and SPEK. Unlike, in annular epidermolytic ichthyosis, there was no history of blisters and erosions at birth, and histopathology did not revealed any epidermolytic hyperkeratosis. X-linked recessive ichthyosis presents with dark brown ichthyotic scales with sparing of popliteal and antecubital fossa with associated cryptorchidism, autism, and deep stromal corneal opacity.[4] Although the present case had ichthyosis of legs with sparing of popliteal fossa, there were no associated systemic abnormalities. Tinea imbricata can be a morphological differential diagnosis, but the presence of skin lesions since 6 months of age and negative test for skin scrapings for fungus preclude the condition.

Histopathology cannot distinguish between the variants of erythrokeratodermas. Genetic studies show mutation in connexin genes in cases of EKV. Connexins are a family of transmembrane proteins that form gap junctions in the cells. These intercellular channels play an important role in cell growth, homeostasis, and epidermal differentiation.[4] Mutations in genes, namely GJB3, GJB4, and rarely GJA1 encoding the connexins, have been identified as the underlying pathogenesis in EKV.[3,9] In SPEK apart from GJB4 mutation, mutations reported include a frameshift mutation in loricrin gene, homozygous loss of function mutation in KRT83 gene, and mutation in KDSR gene which codes for an enzyme involved in ceramide synthesis.[3] López-Ferrer *et al*. have reported a case of EEC with missense mutation R32W in GJB3 gene.[1] Similar mutation in GJB3 gene had been reported in patients with palmoplantar involvement and deafness.[10] The present case had clinical lesions analogous to EEC and palmoplantar involvement but without any hearing impairment. However, genetic study for mutation analysis was not done due to resource constraints.

Treatment options include topical emollients, retinoids, salicylic acid, and corticosteroids. Systemic retinoid such as acitretin and isotretinoin shows good improvement, but with recurrence of lesions once the treatment is stopped.[8] Improvement with retinoids with psoralen and ultraviolet A therapy has been reported.[11] Since the disease is a genodermatoses, parents should be counseled regarding the chronic nature of the disease and the need for long-term follow-up. Treatment plan with acitretin was considered, but the patient did not report for follow-up.

The present case is highlighted for its distinct clinical picture and its association with palmoplantar keratoderma.

Declaration of patient consent

Author certify that they have obtained all appropriate patient consent forms. In the form the patients/parents have given their images and other clinical informations to be reported in the journal. Case Report

Hemophagocytic Lymphohistiocytosis Complicating Methotrexate Toxicity

Abstract

Hemophagocytic syndrome or hemophagocytic lymphohistiocytosis (HLH) is a rare but potentially fatal disease caused by dysregulated activation of macrophages against one's blood cells. Major pathologic feature of HLH is hemophagocytosis. We present a case of HLH complicating methotrexate toxicity in a 65-year-old psoriatic patient with history of renal disease. Diagnosis of HLH was established as he fulfilled five out of eight HLH diagnostic criteria. This case report is presented to enlighten clinicians about the clinical entity of HLH and to suspect and recognize this rare and generally fatal disease at the earliest.

Departments of Dermatology and [1]Pathology, PSG Institute of Medical Science and Research, Coimbatore, Tamil Nadu, India

Introduction

Hemophagocytic syndrome or hemophagocytic lymphohistiocytosis is a clinical syndrome of hyperinflammation resulting in uncontrolled and ineffective immune response.[1,2] It may be primary or secondary. Primary HLH is a genetic entity. Secondary HLH is associated with infections, malignancies, immune disorders, or drugs.[2-5] In both types, activated macrophages engulf erythrocytes, leukocytes, platelets, and precursor cells in bone marrow, liver, and lymph nodes.[6] Most severe forms of the disease lead to a sepsis like picture and multiorgan dysfunction. HLH is a disease of rapid progression and has high mortality despite treatment.[3,7-9] We report a case of secondary HLH complicating methotrexate toxicity and sepsis.

Case History

A 65-year-old male, a case of chronic plaque psoriasis on intermittent therapy with methotrexate since 15 years and chronic kidney disease since 5 years presented with fever, severe body ache, and ulcerative lesions over lips and trunk. He developed these symptoms 5 days after inadvertent intake of tablet methotrexate 5 mg for 5 consecutive

days. Examination showed tender inguinal and axillary lymphadenopathy, hemorrhagic crusting of lips, and necrotic ulcers over psoriatic plaques and as well as normal skin with severe skin tenderness and positive Nikolsky's sign. Since ulcers were present over psoriatic plaques, methotrexate-induced skin necrosis was suspected. Histopathology findings were skin with detached stratum corneum, large subcorneal pustule [Figure 1a], mild spongiosis, marked regenerative atypia, basal vacuolar degeneration, pigment incontinence, and apoptotic keratinocytes [Figure 1b]. Routine investigations showed bicytopenia with hemoglobin of 9.6 g/dl, WBC of 600 cells/mm^3 with normal platelet count of 120,000 cells/mm^3. His renal function tests were altered with elevated urea (106 mg/dl) and creatinine levels (3.16 mg/dl). The patient was started on antibiotics, leucovorin rescue therapy (folinic acid 10 mg every 6th hourly), and injection Filgrastim (Granulocyte colony-stimulating factor) 300 mg subcutaneously daily. There was worsening pancytopenia and renal function and further developed splenomegaly, features of sepsis. Blood culture was positive for Group B streptococci and methicillin sensitive *staphylococcus aureus* and procalcitonin levels were elevated (24.5 ng/ml). His antibiotics were upgraded and platelet transfusion given in spite of which patient developed fever, tachycardia, hypotension with further decrease in platelet count to 6,000 cells/mm^3 on

Quick Response Code:

5th day. Secondary HLH was suspected and a workup was rapidly initiated based on HLH 2004 diagnostic criteria. Peripheral smear revealed pancytopenia [Figure 2]. Bone marrow aspiration was done which showed megaloblastic erythroid maturation, maturation arrest in the myeloid series, and hemophagocytosis [Figure 3a and b]. Patient had hyperferritinemia (>500 mcg/L) with normal fibrinogen (522 mg/dl) and triglycerides (50 mg/dl) levels. He thus fulfilled 5 out of 8 diagnostic criteria of HLH and was treated as per HLH 2004 protocol with systemic antifungals and injection dexamethasone 10 mg/m^2. Despite all supportive measures, patient developed multiorgan dysfunction and succumbed.

Discussion

HLH is a rare disease characterized by cytokine overproduction and tissue infiltration with cytotoxic lymphocytes and activated macrophages resulting in fever, hepatosplenomegaly, and cytopenias.[1,2,9] A strict diagnostic criteria of HLH was given in 2004 by Histiocyte Society and is as follows.[9,10] Molecular diagnosis consistent with HLH that is the identification of mutations of PRF1, UNC13D, or STX11 or patient should fulfill five out of the eight criteria: fever (>100.4°F), splenomegaly, cytopenia affecting at least two of three lineages: Hb <9 g/dl (in infants <4 weeks: Hb <10 g/100 ml, platelets <100 × 10^9/L, Neutrophils <1 × 10^9/L), hypertriglyceridemia (fasting >265 mg/dl) and or hypofibrinogenemia (≤150 mg/dl), ferritin >500 ng/ml, hemophagocytosis in bone marrow, spleen, or lymph nodes, low or absent NK cell activity, soluble CD25 (soluble IL-2 receptor) >2400 U/ml and in the case of familial HLH there should be no evidence of malignancy.

This patient presented with features of methotrexate toxicity with skin necrosis, bone marrow suppression, and renal failure. His progressive pancytopenia was initially thought to be due to high dose methotrexate. He did not respond to leucovorin rescue therapy or injection Filgrastim and worsened clinically with features suggestive of sepsis due to which antibiotics were upgraded. He was evaluated for HLH as he had progressive pancytopenia unresponsive to treatment and decreased counts in spite of platelet transfusions. The major pathologic feature of HLH is hemophagocytosis as seen in our patient. It is also seen in conditions like sepsis and multiorgan failure.[3] There is considerable clinical and laboratory overlap between sepsis and HLH.[8,9] Diagnosis of HLH was established in our patient as he fulfilled five out of eight diagnostic criteria of HLH. This is a rare presentation of HLH complicating methotrexate toxicity. This case report is presented to enlighten clinicians about HLH inorder to reduce the mortality associated with the disease.

Declaration of patient consent

The authors certify that they have obtained all appropriate patient consent forms. In the form the patient(s) has/have given his/her/their consent for his/her/their images and other clinical information to be reported in the journal. The patients understand that their names and initials will not be published and due efforts will be made to conceal their identity, but anonymity cannot be guaranteed.

Comparison of Direct Immunofluorescence of Plucked Hair and Skin for Evaluation of Immunological Remission in Pemphigus

Reena Rai, Manu V. Harikumar

Department of Dermatology, PSG Institute of Medical Sciences and Research, Coimbatore, Tamil Nadu, India

Abstract

Background: Pemphigus is a chronic autoimmune bullous disorder characterized by autoantibodies directed against desmoglein 3 and/or 1. Demonstration of intercellular deposition of IgG on the cell surface of keratinocytes by direct immunofluorescence (DIF) of the skin is the gold standard in the diagnosis of pemphigus. Recently, DIF of plucked hair demonstrating intercellular deposition of IgG in the outer root sheath (ORS) has shown to be useful. **Objective:** To compare the DIF of plucked hair and skin for the evaluation of immunological remission in pemphigus vulgaris patients in clinical remission. **Materials and Methods:** A total of 30 patients with pemphigus vulgaris with positive DIF of the skin and hair at baseline were included, and DIF of skin and hair was repeated after 6 months or more of clinical remission (with no new/non-healing lesions). Presence of intercellular deposits of IgG and or C3 in skin and ORS of the hair was considered as positive. **Results:** Of the 30 patients, DIF of skin was positive in 10 patients and hair was positive 14 patients. The findings of hair and skin DIF correlated with each other in 22 patients. In 6 (20%) patients DIF of hair was positive even though the DIF of skin was negative. The sensitivity of hair DIF was 80% and specificity was 70%. **Limitations:** Small sample size. **Conclusion:** DIF of hair is a simple, non-invasive, and cost effective procedure and can be used as an additional procedure for the assessment of immunological remission in patients with pemphigus vulgaris.

Keywords: *Hair immunofluorescence, immunological remission, pemphigus*

Introduction

Pemphigus is a chronic autoimmune bullous disorder characterized by autoantibodies directed against desmoglein (Dsg) 3 and/or 1.[1] Direct immunofluorescence (DIF) of the skin or mucosa is considered as the gold standard in the diagnosis of pemphigus. Systemic steroids alone or in combination with other immunosuppressive agents are the main stay of treatment, and long-term administration of the same is associated with significant adverse effects, morbidity, and mortality.

Therefore, a system is required to monitor disease activity to lower the dosage of the drugs and eventually withdraw treatment.Various methods for assessment of immunological remission include DIF, indirect immunofluorescence, and anti-desmoglein enzyme-linked immunosorbent assay (ELISA) titres.[2-7]

DIF of the skin or mucosa is an invasive and expensive procedure and the patient may not be willing for the same. Recently, pemphigus-specific immunofluorescence pattern has been demonstrated in the outer root sheath (ORS) of hair follicles, which is structurally analogous to epidermal keratinocytes, with a sensitivity ranging from 85–100%.[8-11]

Hence, DIF of hair may be an ideal substrate for assessment of immunological remission because it is a simple, non-invasive, and cost effective procedure. We conducted this study to compare the DIF of plucked hair and skin for the evaluation of immunological remission in pemphigus vulgaris patients in clinical remission.

Materials and Methods

After obtaining approval from the institutional ethics committee and consent from the patients, a prospective study was conducted in the Department of Dermatology in the PSG institute of medical sciences and research (PSG IMS&R) over a period of 1 year.

[Downloaded free from http://www.idoj.in on Thursday, December 16, 2021, IP: 103.224.34.2]

A total of 30 patients with pemphigus vulgaris who showed intercellular deposits of IgG antibodies against Dsg3 and/orDsg1 and/or Complement 3 (C3) in the DIF of skin and hair during the active stage of disease fulfilling the following inclusion criteria were included in the study: (a) patients in clinical remission, defined as those who had no new or non-healing skin or mucosal lesions for the past 6 months or more and (b) with or without daily prednisolone dosage equal to or less than 10 mg with or without adjuvant immunosuppressive therapy such as azathioprine 50mg or cyclophosphamide 50 mg daily.

Patients with new or non-healing skin or mucosal lesions in the preceding 6 months and patients with other bullous disorders were excluded from the study.

The presence of lace-like pattern in DIF in the ORS of the hair follicle and in the epidermis was considered as positive [Figure 1].

Skin and hair DIF was performed in all the patients. The skin sample was obtained from the upper trunk. Trichogram was done and anagen hair was collected. The samples were transported in the Michels medium to the Department of Pathology in PSG IMS&R and subjected to DIF staining with fluorescent isothiocyanate (FITC) labeled rabbit anti IgG and C3 antibodies. The samples were washed in PBS three times, each wash taking 10 minutes. Following which they were incubated with FITC labeled anti-IgG and anti-C3 for 1 hour at 37°C and once again washed in PBS three times for 10 minutes each, and then air dried and mounted on slide with PBS-glycerol solution for examination. The PBS contained propidium bromide as a counterstain.

Patients demographic parameters, phenotype of pemphigus vulgaris, history of scalp involvement, duration of disease, duration of remission, and past and current treatment were recorded.

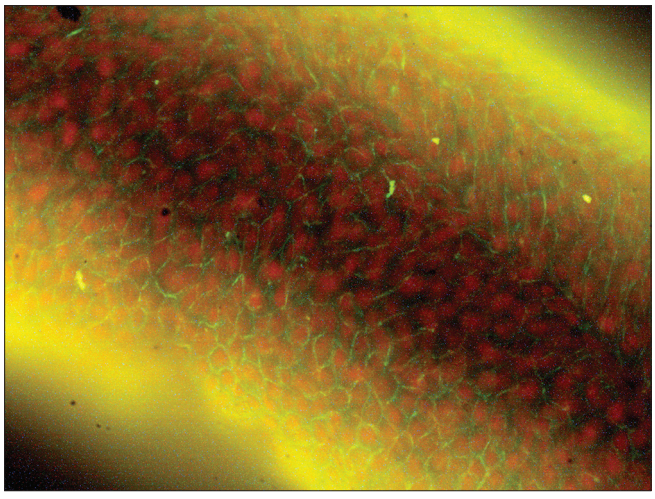

Figure 1: Fish net-like pattern of immunofluorescence in the outer root sheath of hair on DIF

Results

Patient characteristics and hair and skin DIF findings are shown in Tables 1 and 2, respectively. The age of patients in our study ranged from 17–69 years, and majority (33.3%) of the patients were in the age group of 41–50 years. All the 30 patients had a history of scalp involvement. Of the 30 patients, DIF of skin was positive in 10 patients and hair was positive 14 patients. The findings of hair and skin DIF correlated with each other in 22 patients. In 6 patients, DIF of hair was positive and skin was negative. Whereas in 2 patients, DIF of the skin was positive and hair was negative, as seen in Table 2.

The skin DIF was considered as the gold standard, and the sensitivity and specificity of hair DIF was calculated. The sensitivity (true positive/true positive + false negative) of hair DIF was 80% and specificity (true negative/true negative + false positive) was 70%.There was a statistically significant association between skin and hair DIF positivity with a *P* value of 0.010 [Table 2]. Positive predictive value of hair DIF (true positive/true positive + false positive), which refers to the percentage of patients with a positive test who actually have the disease was 57.14%, and negative predictive value (true negative/true negative + false negative), which refers to the percentage of patients with a negative test who do not have the disease was 87.5%.

A total of 18 patients were undergoing treatment in our study. In these patients, the hair and skin DIF was negative in 10 and 13 patients, respectively, which was higher than that in patients not undergoing treatment. However, the findings were not statistically significant. There was no

significant association between hair DIF and duration of disease, remission, and treatment.

Discussion

Desmogleins are the main target antigens in pemphigus. These desmogleins are calcium dependent transmembrane adhesion proteins belonging to the cadherin family. In the epidermis and hair, the distribution of desmogleins correlates with the degree of differentiation. Desmoglein 1 is expressed in the suprabasal cells of the epidermis and inner root sheath as well as the innermost layers of the ORS of the hair follicle.[12] Desmoglein 3 is present in the basal and suprabasal cells of the epidermis and throughout the ORS of the hair follicle except in the areas of epidermal-like keratinization such as in the infundibulum, where its confined to the basal layer of ORS.[12] Desmoglein 3 is also responsible for anchoring the telogen hair in the follicle.[13]

Wilson *et al*. in 1991 demonstrated that the human hair follicle is rich in the target antigens of pemphigus.[14] In 2003, Schaerer and Trueb first reported positive DIF findings in the ORS and the matrix of hair follicle in 100% of pemphigus patients.[8] Subsequently, Rao *et al*. reported 80% positivity and Daneshpazhooh *et al*. reported 91% positivity of DIF in the anagen hair.[9,10] Kumaresan *et al*. and Tanasilovic *et al*. also demonstrated positive DIF findings in 100% of their patients with active pemphigus in ORS of both anagen and telogen hair.[11,15]

David *et al*. in 1989, based on their study suggested that repeated negative DIF in pemphigus patients on clinical remission could be a sign of immunological remission.[16] Similar findings were also reported by Balighi *et al*. and Ratnam *et al*.[6,17]

Ratnam *et al*. also noted that the patients with positive DIF findings during clinical remission had a significantly higher relapse rate after the discontinuation of treatment.[17]

Various studies have shown that the rate of relapse was approximately 44–100% in patients with positive DIF findings during remission and 13–27% in patients with negative DIF.[16,18]

Rao *et al*. in 2012 conducted a study to assess the role of hair DIF in monitoring the disease activity in pemphigus; they suggested that, in patients in clinical remission, DIF of hair could be an ideal substrate for assessment of immunological remission.[19]

Only limited studies are available till date to analyze the role of hair DIF for the assessment of immunological remission. Apart from the study published by Rao *et al*., one study by Daneshpazhooh *et al*.in 2013 demonstrated the usefulness of hair DIF in the assessment of immunological remission in pemphigus patients.[20]

In their study, the sensitivity and specificity of hair DIF was 79% and 48%, respectively. Similarly, our study had a sensitivity of 80%, however, the specificity was 70% which is comparatively higher.

Even though skin or mucosal DIF is considered as the ideal substrate for the assessment of immunological remission, 6 patients in our study had positive hair DIF even though skin DIF was negative, as seen in Table 1. Thus indicating that these patients were not yet in immunological remission. Had the clinician relied only on the DIF of skin, this finding could have been missed. The sensitivity of hair DIF in our study was not high enough to suggest it as an alternative to skin DIF for the assessment of immunological remission. However, hair DIF, being a non-invasive procedure can be used initially for patients in clinical remission to assess immunological status and if it is positive then the DIF of skin could be avoided.

Conclusion

Hence, DIF of hair is a simple, non-invasive, and cost effective procedure, and can be used as an additional procedure for assessment of immunological remission in pemphigus vulgaris. However, further studies are needed to validate the same.

Abstract

Papillon Lefevre syndrome (PLS) manifests with palmoplantar keratoderma, combined with a rapidly progressive periodontitis associated with mutations in Cathepsin C (*CTSC*) gene. This article reports a 15-year old male proband with typical PLS traits having a novel compound heterozygote with p.Q49X mutation in exon 1 and p.Y259C missense mutation in exon 6 of *CTSC* gene respectively. The exon 1 mutation, p.Q49X, (found in proband's mother) was located in exclusion domain and exon 6 mutation, p.Y259C (found in proband's father), was present in peptidase C1A, papain C-terminal domain. Interestingly, missense mutation p.Y259C identified in this study was found to be not reported so far. Upon computational analysis, this missense mutation was found to be lethal. Moreover, our protein modelling approach using mutant protein revealed the presence of monomeric structure on contrary to the tetrameric structure of the wild type protein. In addition, in vitro functional characterization of mutant p.Y259C expressed in HEK293 cells showed a significant reduction in CTSC activity (0.015 ± 0.009 mU/ml) when compared with wild type protein (0.21 ± 0.008 mU/ml). Thus, in this study, we have demonstrated that the pathogenic missense mutant p.Y259C might cause PLS by impaired CTSC function.

Introduction

Papillon–Lefèvre syndrome (PLS) is an autosomal recessive disorder characterized by palmoplantar keratoderma in association with aggressively progressing periodontitis. Keratosis can occur in the knees and elbows [1, 2]. Mutations in *CTSC* gene predisposes to PLS [3] with an increased risk of medical manifestations in consanguineous marriages. Haim munk syndrome and PLS share common features but with supplementing components like arachnodactyly, acroosteolysis and onychogryphosis is found only in the former.

CTSC gene finds its locus on chromosome 11q14-q21 [4, 5] and encodes a lysosomal cysteine protease involved in activation of many serine proteinases within immune cells. It is involved in cell-mediated cytotoxicity, phagocytic destruction of bacteria, local activation or deactivation of cytokines. Many reports on *CTSC* mutation leading to loss of function

Published online: 29 June 2020

Author's personal copy

of CTSC protein and development of PLS has been reported [6, 7].

In our study, the proband suspected to be a PLS case was screened for *CTSC* gene mutation and found to have a compound heterozygous mutation, p.Q49X in exon 1 and p.Y259C in exon 6 of *CTSC* respectively. p.Y259C is a novel missense mutation not reported so far in association with PLS. It is a pathogenic mutation with a monomeric structure and had reduced enzyme activity.

Materials and methods

Patient and family unit

A 15-year old boy who attended the Dermatology outpatient clinic of PSG Hospitals, Coimbatore, India was clinically examined for dermatological, dental and radiological findings. The patient and his parents consented for genetic analysis and therefore, blood samples were drawn from them. Third degree parental consanguinity was documented. The phenotypic characteristics were then compared with the genotype results.

Mutation analysis of *CTSC*

Genomic DNA was isolated using EZ-10 Spin Column Blood Genomic DNA MiniPreps Kit (Bio Basic Canada Inc). The seven exons of *CTSC* gene were amplified using the primer sets reported [6]. The PCR reaction mixture of 20 µl containing 50 ng DNA as the template, 50 nM each of the forward and the reverse primer, 1 mM each of dNTPs, in a 1X PCR buffer (with1.5 mM $MgCl_2$) with 1U of Taq Polymerase (Ampliquon, Germany) was incubated in a thermal cycler (Eppendorf, USA). The cycling parameters included 95 °C for 2 min, 35 cycles of 95 °C for 30 s, 60 °C annealing for 40 s and extension of 72 °C for 1 min. The amplified exons were sequenced by Sanger's sequencing and analysed.

Computational analysis

The CTSC protein was analysed using InterProscan and PROSITE database tools to identify significant domains and functional active sites in the protein respectively. In order to predict the potential pathogenecity of *CTSC* mutations, two bioinformatics tools were used, PolyPhen-2 (Polymorphism Phenotyping v2) in a scale from 0.00 (for benign) to 1.00 (for deleterious) (http://genetics.bwh.harvard.edu/pph2) and Mutation Taster (http://www.mutationtaster.org/). Multiple protein sequence alignments were performed using COBALT (Constraint-based Multiple Alignment Tool). Moreover, the wild type and the mutant proteins were modelled using SWISS MODEL (https://swissmodel.expasy.org) tool to obtain the comparative 3D structure of both the proteins.

Site directed mutagenesis

The Q5 Site-Directed Mutagenesis Kit (NEB, USA) was used to construct the missense mutant, Y259C. The kit manufacturer's instructions were followed to obtain the mutant clones and were confirmed through sequencing.

Cell culture and transfection

HEK293T cell line was cultured in Dulbecco's Modified Eagle's Medium (DMEM) supplemented with 10% fetal bovine serum and 100 U/ml penicillin and 100 µg/ml streptomycin (Sigma Aldrich, USA) at 37 °C in a 5% CO_2 atmosphere. The cells were transiently transfected with the Lipofectamine 3000 reagent (Invitrogen, USA) and Opti-MEM Reduced Serum Medium in 24 well plates. After 48 h, the medium was replaced with complete DMEM with 100 µg Hygromycin to obtain the cells bearing the plasmid (pCMV3) with Hygromycin resistance.

Mutant and wild type CTSC protein expression and purification

The transfected cells were disrupted in 100 µl lysis buffer (10 mM Na_3PO_4, 0.1% Triton X-100) and centrifuged at 2500 g for 5 min at 4 °C. The supernatant (5 µg per lane) was separated on 10% SDS PAGE. Proteins were quantified using the Bradford assay. The His—CTSC protein fractions were selectively purified using Ni-NTA column (Qiagen, Germany). The protein mixture was incubated in the binding buffer (20 mM Tris/HCl, 200 mM NaCl; pH 7.5), washed (20 mM Tris/HCl, 200 mM NaCl, 5 mM imidazole; pH 7.5) and eluted (20 mM Tris/HCl, 200 mM NaCl, 200 mM imidazole; pH 7.5) to obtain pure protein fractions. The protein fractions were allowed to undergo activation by with 20 µg/ml papain at 37 °C, pH 6.5 for 6 h to generate active peptides of CTSC. To inhibit the activity of the mature enzyme, 1 mM iodoacetamide (Sigma Aldrich, USA) was used.

Recombinant CTSC enzyme activity assay

Enzymatic activity was assayed by mixing 20 µl of the purified protein with 30 µl reaction buffer (100 mM Na_3PO_4, 2 mM NaCl, 2 mM DTT), 30 µl dilution buffer (10 mM Na_3PO_4, 0.1% Triton -X-100), and 100 µl of chromogenic CTSC substrate (1.5 mM gly-phe-para-nitroanilide). Absorbencies were measured at 405 nm, samples were incubated at 37 °C for 1 h, and read again. Cathepsin C activity of samples, expressed as para-nitroanilide released (nmol/mg of protein * hour), was determined interpolating

Author's personal copy

the difference between first and second reads in a standard curve (0.0351–2.24 nmoles) of pure 4 para-nitroaniline (4 pNA) (Sigma-Aldrich, USA) [8].

Statistical analyses

Data were expressed as mean ± standard error of the mean (SEM) from three independent experiments. The data were evaluated for statistical significance with unpaired *t* test. $p < 0.05$ was considered statistically significant. All the statistical analyses were carried out using GraphPad Prism software version 5.0 Windows (GraphPad Software, USA).

Results

Clinical manifestations of the patient with PLS

A 15 year old boy, born out of third degree consanguineous marriage, presented to the dermatology OPD with complaints of thickened skin involving the palms and soles since infancy. He had erythematous lesions involving elbows, knees and few areas of trunk. The patient gave history of failure of eruption of lower incisors following the fall of primary teeth. The patient had developed multiple furuncles in the past. On examination, the patient had diffuse palmoplantar keratoderma with multiple erythematous papules and plaques seen involving the dorsum of hands, feet, elbows, knees and few areas of the trunk. On examining the teeth, the lower central incisors were absent (Fig. 1a). The nails showed multiple transverse ridging. Biospy done from the cutaneous lesions showed evidence of psoriasiform hyperplasia of epidermis with dermis being unremarkable. Routine blood investigations and X ray of the hands were normal.

CTSC mutation analysis

The seven exons of the *CTSC* gene from the proband and parents were sequenced using Sanger sequencing method. Further, *CTSC* gene analysis (NCBI reference sequences for mRNA: NM_001814.6, Concensus CDS: CCDS44693.1 and Protein: NP_001805.4) of the proband showed a compound heterozygous mutation, Q49X in exon1 and Y259C in exon 6 (Fig. 1b, c). The parents were heterozygous carriers of the mutations and were unimpacted. The nonsense mutation *c.145C > T* (p.Q49X) in exon 1 was inherited from mother while missense mutation *c.776A > G* (p.Y259C) in exon 6 was from father (ESM_1).

Evolutionary conservation of *CTSC* and in silico analysis

The mutations, p.Q49X and p.Y259C belonged to the exclusion domain (25-142 aminoacids) and Peptidase C1A, papain C-terminal domain (231-458 aminoacids)

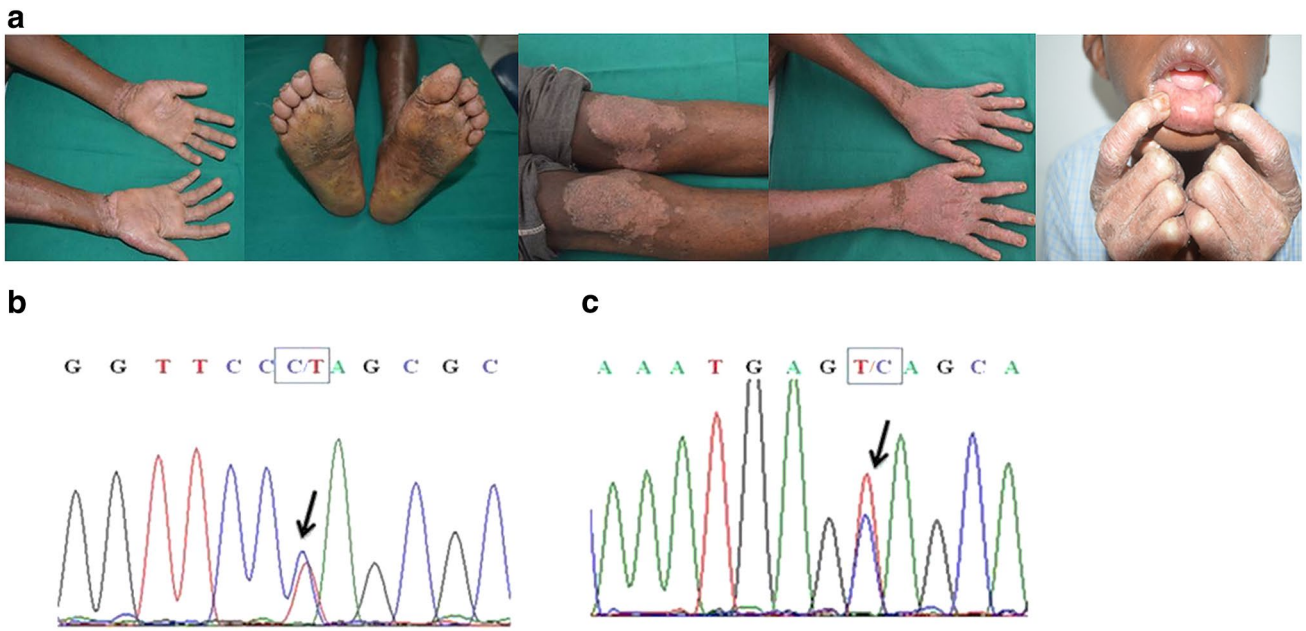

Fig. 1 Clinical observations and sequence results of *CTSC* in the patient. **a** Clinical examinations in the patient revealed multiple erythematous papules and plaques seen involving the dorsum of hands, feet, elbows, knees and few areas of the trunk. The nails showed multiple transverse ridging. The lower central incisor teeth were absent. Compound heterozygous mutation in the *CTSC* gene of the proband revealing **b** heterozygous mutation (*c.145C > T*) in exon 1 and **c** heterozygous mutation (*c.776A > G*) in exon 6

respectively as identified from InterProscan analyses. The PROSITE database search revealed that cathepsin C protein has a thiol (cysteine) protease enzyme whose active sites are composed of Cys258, His405 and Asn427. PolyPhen2 predictions of the functional effect of the missense mutation proved that mutation was predicted to be damaging with a score of 1.00. Another tool, Mutation Taster also predicted this mutation to be disease causing. Moreover, the aminoacid Y (tyrosine) at 259th position was found to be highly conserved among different species like house mouse, rat, zebra fish, dog, cattle, chimpanzee, monkey, chicken and frog (Fig. 2a).

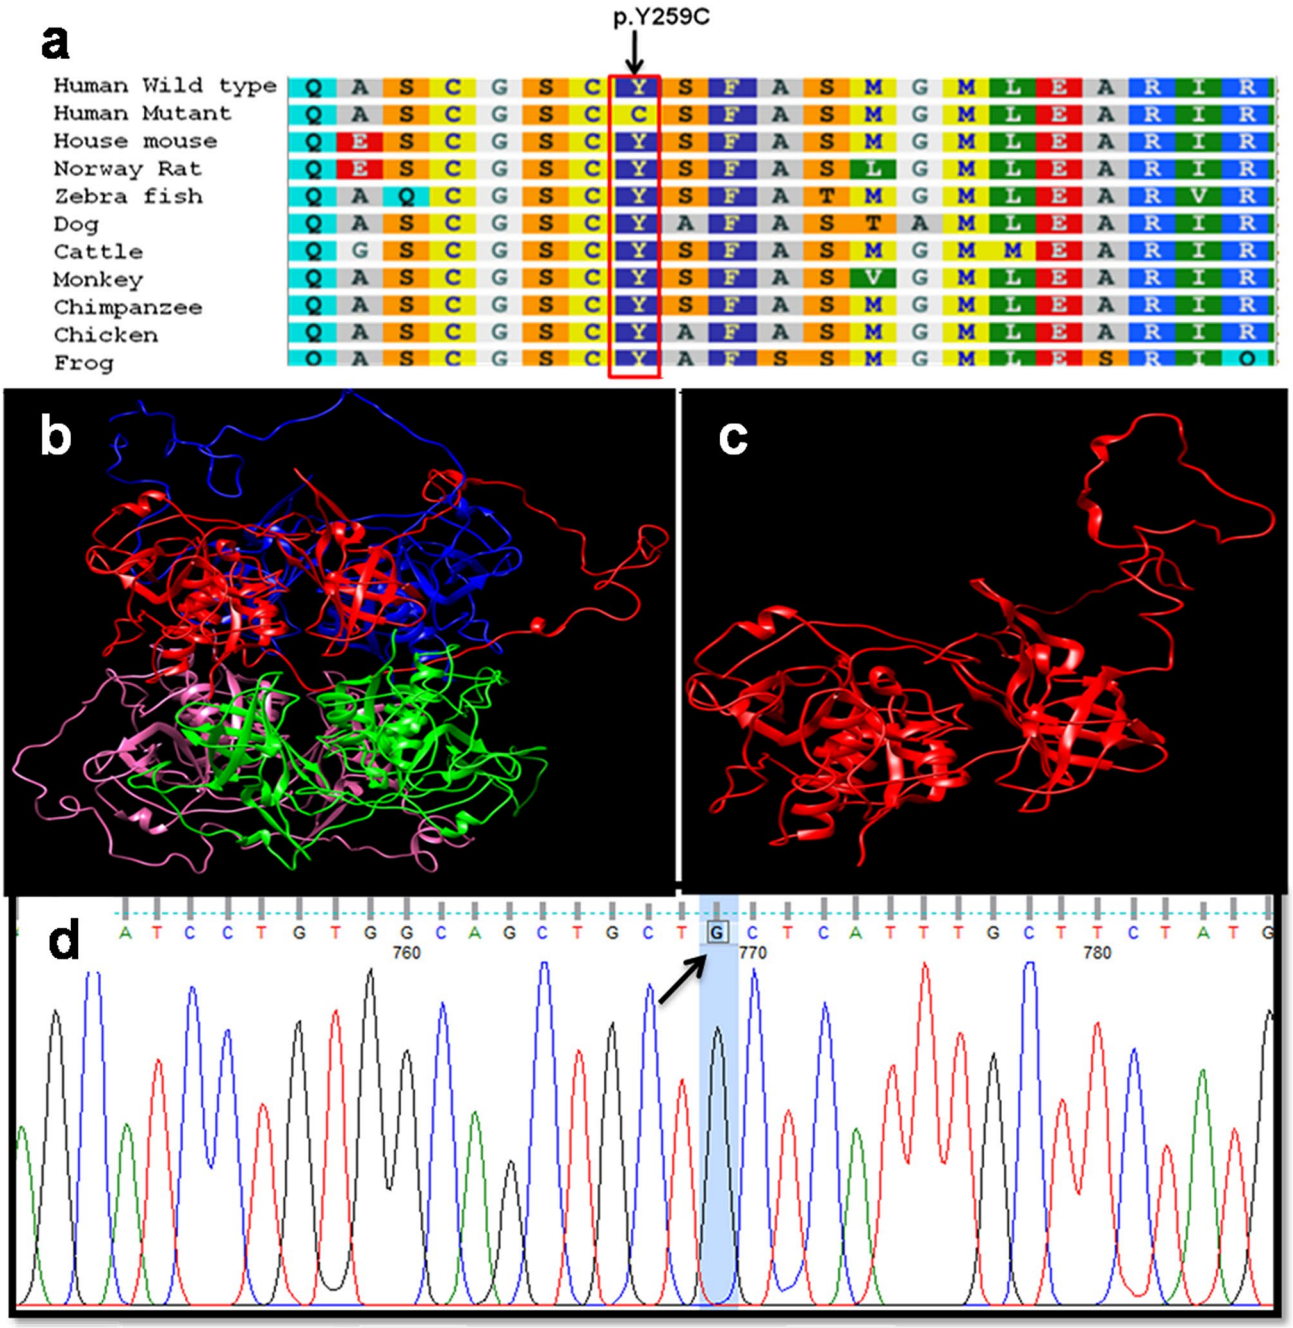

Fig. 2 Confirmation of pathogenecity of p.Y259C mutation of *CTSC* gene. **a** Cross-species multiple sequence alignment showing the high conservation of the aminoacid Y at 259th position. 3D structure of the proteins modelled using SWISS MODEL software showing the **b** tetrameric structure of the wild type protein-A chain (red), B chain (blue), C chain (green), D chain (pink) and **c** monomeric structure of the mutant protein (p.Y259C)-A chain (red) as predicted by the software. **d** Electropherogram of the mutant clone confirming *c.776A > G* mutation in CTSC gene to construct pCMV3-CTSC Y259C vector

Author's personal copy

The protein sequence derived from the wild type and mutant protein (Y259C) were subjected to sequence based structure prediction using SWISS MODEL protein modelling software. The wild type protein was predicted by the SWISS MODEL as a tetramer having A, B, C and D chains (Fig. 2b). On the other hand, the mutant protein carrying the novel mutation p.Y259C was predicted to be only a monomer having the A chain (Fig. 2c).

In vitro expression of mutant p.Y259C CTSC protein

The pCMV3-CTSC vector was subjected to site directed mutagenesis to create a p.Y259C mutation. After mutagenesis, the clones were confirmed by Sanger's sequencing (Fig. 2d). To obtain the rCTSC protein, the following vectors were transfected into HEK 293T cell lines; pCMV3-CTSC, pCMV3-CTSC Y259C and pCMV3 negative control vector. After transfection, the cells bearing hygromycin resistant phenotypes were selectively harvested. DNA was isolated from the harvested cells and *CTSC* gene *was* amplified (Fig. 3a). The cells were lysed to obtain the protein fractions which were purified. The purified protein (inactive) was of size 55 kDa which is a propeptide. It was activated by papain treatment which yielded bands of sizes 25 kDa and 6 kDa (Fig. 3b).

Mutant p.Y259C CTSC shows reduced activity

The mutant p.Y259C CTSC protein showed a statistically significant reduction in its activity (0.015 ± 0.009 mU/ml) when compared to wild type CTSC protein (0.21 ± 0.008 mU/ml). Upon treatment with 1 mM iodoacetamide, a cysteine protease inhibitor, the activity of both mutant and wild type protein was reduced by 10 folds (Fig. 3c).

Discussion

PLS is caused by mutation in cathepsin C (*CTSC*) gene which encodes a lysosomal enzyme expressed predominantly in palms, soles, elbow, knee and gingiva. This explains the disordered keratinization leading to cutaneous lesions in these areas. Cathepsin C also plays an important role in the function of polymorphonuclear cells and macrophages, thus explaining the reason for recurrent pyoderma and gingivitis in PLS [9].

Among the PLS cases, missense mutations predominates nonsense and frameshift mutations in *CTSC* gene. The first compound heterozygous individual with PLS was reported in 2000 [10]. In the current study, a nonsense mutation p.Q49X ($c.145C > T$) and a missense mutation p.Y259C ($c.776A > G$) was present in a compound heterozygous state in the proband. This nonsense mutation truncated the protein to a 49 amino acid polypeptide as a nonfunctional enzyme resulting in PLS phenotype. p.Q49X has been reported in an Indian family coupled with PLS [11] and Haim Munk syndrome [12].

A missense mutation $c.776A > G$ (p.Y259C) observed in the affected patient was located in Peptidase C1A, papain C-terminal domain which is important for the intracellular protein degradation activity of the enzyme as this domain corresponds to the 233 amino acids mature enzyme unit [13] of cathepsin C. Moreover, this mutation Y259C lies next to the active site Cys258, thus, raising a suspicion of any possible Cys-Cys disulfide bond formation between Cys258 and Cys259 in the mutant protein and abolishing the active site availability. The 3D structure prediction results show that the p.Y259C mutant protein lacked the tetrameric structure unlike the wild type protein and

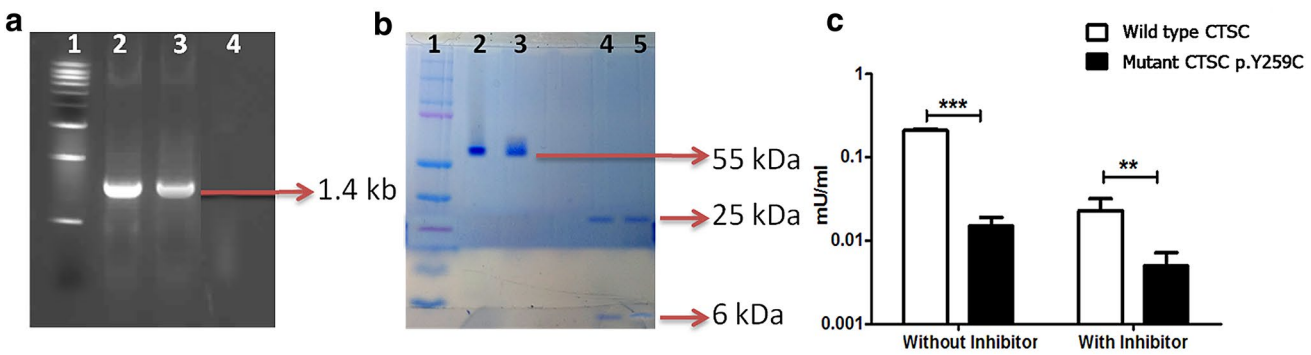

Fig. 3 Cloning, expression and enzyme activity of wild type and p.Y259C mutant CTSC protein. **a** *CTSC* amplified from cells transfected with wild type (lane 2), mutant plasmid (lane 3) and negative control vector (lane 4). **b** The image shows propeptide form of His-CTSC (lane 2) and His-CTSC Y259C (lane 3) purified from the cell lysate of wild type and mutant plasmid transfected HEK 293T cell lines. The active form of His-CTSC (lane 4) and His-CTSC Y259C (lane 5) after papain treatment is also shown. 5 µg of the protein was loaded onto 10% SDS PAGE and followed by Coomassie blue staining. Lane 1: Prestained protein ladder (Biorad, USA). **c** Mutant CTSC (p.Y259C) protein showed a statistically significant 14 fold reduction in the enzyme activity when compared to wild type CTSC protein. 1 mM iodoacetamide inhibited the CTSC enzyme activity proportionally in mutant CTSC (p.Y259C) and wild type CTSC by tenfolds

Author's personal copy

had a monomeric structure (A chain). It is reported that tetramerization is crucial for the enzymatic activity [14]. Therefore, the structure modelled by SWISS MODEL substantiates the fact that this missense mutation has resulted in the development of PLS phenotype by abolishing the formation of tetrameric structure. Similarly, structural effects leading to functional abnormalities were also reported as a result of P35delL and R272P mutations in CTSC gene [15]. The inactive form of CTSC protein was of 55 kDa which after maturation yielded bands of molecular weights of 25 kDa and 6 kDa observed in earlier studies [16].

This missense mutation identified in our study, p.Y259C, was found as a novel pathogenic mutation associated with PLS syndrome In addition, there was a statistically significant 14 fold reduction in CTSC enzyme activity in the mutant protein when compared to the wild type protein. The presence of cysteine protease inhibitor, iodoacetamide further reduced the enzyme activity in both the wild type and the mutant proteins by 10 folds as observed in other studies [17]. Similarly, 85% reduction in the enzyme activity was observed in Mexican patients with PLS in a study [18]. Recently, many reports on requirement of early identification of PLS and proper dental management was emphasized [19–22]. Therefore, our study has helped to broaden the list of reported mutations associated with PLS.

Pirfenidone-Induced Dose-Dependent Phototoxicity – A Distinct Drug Reaction

P Arunprasath, Reena Rai, Chaitra Venkataswamy[1]

Departments of Dermatology and [1]Pathology, PSG Institute of Medical Sciences and Research, Coimbatore, Tamil Nadu, India

Sir,

Pirfenidone is a novel drug with anti-fibrotic and anti-inflammatory properties used in the treatment of idiopathic lung fibrosis.[1] Herein, we report a case of pirfenidone-induced phototoxicity.

A 70-year-old male presented with hyperpigmented itchy skin lesions involving the face, forearms, and thighs for 10 days. His skin lesions were associated with photosensitivity, swelling of face, redness, and watering of eyes. History revealed that he was a recently diagnosed case of idiopathic pulmonary fibrosis and was started on treatment with pirfenidone 200mg two tablets thrice daily. Two months later the dose of pirfenidone was stepped-up to 200 mg three tablets thrice daily. One month after dose increment, the patient started developing itching and redness involving the photoexposed areas.

Cutaneous examination revealed hyperpigmentation with erythematous borders involving the face, "v"area of neck, forearms, dorsum of hands, upper back, thighs, and legs. There was a clear cut demarcation between the photoexposed and nonphotoexposed areas [Figures 1 and 2]. Examination of palms, soles, oral cavity, and genitalia did not reveal any abnormality. Routine hematological and biochemical investigations were within normal limits. Antinuclear antibody by immunofluorescence method was negative. Histopathological examination revealed epidermis exhibiting hyperkeratosis, parakeratosis, and large subcorneal clefting with extensive epidermal necrosis. There was also subepidermal blister formation containing fibrin and mixed inflammatory infiltrate. Dermis showed lichenoidinfiltrate composed of lymphocytes, plasma cells, occasional eosinophils, and neutrophils [Figures 3 and 4]. Naranjo algorithm showed a score of 6 with probable association of drug with the reaction. A diagnosis of pirfenidone-induced phototoxic drug reaction was entertained based on the distinct photodistributed skin lesions and extensive epidermal necrosis with dermal inflammatory infiltrate in histopthology.

Photosensitivity following drug intake occurs in two different patterns: phototoxicity and photoallergy. Phototoxicity is a nonimmunologic reaction following absorption of ultraviolet radiation by drug metabolites. On the contrary, photoallergic reaction is a cell-mediated immune reaction occurring in a sensitized host. Clinically phototoxic reaction mimics sunburn with sharp delineation to the sun exposed areas, whereas photoallergic reaction mimics eczema and it involves nonphotoexposed skin as well. Other patterns described in drug-induced photosensitivity include lichenoid skin lesions, pseudoporphyria, pellagra reaction, and photoonycholysis.[2]

Pirfenidone is an anti-fibrotic agent approved for treatment of idiopathic lung fibrosis. It inhibits transforming growth factor (TGF) -β stimulated collagen production by reducing fibroblast proliferation and production of fibrogenic mediators. Anti-inflammatory action is attributed to its inhibition of inflammatory cytokines like tumor necrosis factor-α, interleukin-1, and production of anti-inflammatory cytokine interleukin-10.[1]

In a study by Taniguchi *et al.* photosensitivity was the major adverse event observed in 51% of the patients in the high-dose group and 53% in low-dose group.[3] Apart from phototoxicity; pirfenidone-induced photoallergy and photoleucomelanoderma have been reported.[1,4]

Seto *et al.* in their study assessed the photosafety of pirfenidone and concluded that there was production of singlet oxygen and superoxide radicals from drug metabolites of pirfenidone on exposure to sunlight pointing to its phototoxic potential. The study also showed that phototoxicity testing using high doses of pirfenidone in rats caused photosensitivity compared to low doses, pointing to the factthat phototoxic reaction parallels concentration of drug levels in skin.[5] Likewise in the present case skin lesions appeared after increment of the dose.

Diagnosis in drug induced photosensitivity can be established with histopathological examination, phototesting in case of phototoxic reaction, and photopatch testing in photoallergic reaction. Guillén *et al.* reported a similar case, where they conducted phototesting which showed a reduced minimal erythema dose and an aberrant response to ultraviolet A starting from 2 J/cm^2.[6] In our case, histopathology revealed a picture consistent with phototoxic reaction, however phototesting was not done.

Treatment options include photoprotection, broad spectrum sunscreens, short course of steroids, and dose reduction

[Downloaded free from http://www.idoj.in on Monday, November 9, 2020, IP: 103.196.30.41]

or stopping of drug. With resolution of skin lesions reintroduction of the drug can be attempted with low doses. However in photoallergic reactions drug reintroduction should be avoided.[7,8] The present case was treated with short course of steroids, sunscreens, and stopping of the drug with improvement of skin lesions. The present case is highlighted for the distinct side effect profile of a new therapeutic agent.

CASE REPORT

Thrombocytopenia induced by intermittent therapy with Rifampicin – A case report

REENA RAI* & JANANI ADITYAN*
**PSG Institute of Medical Sciences and Research, Coimbatore, Tamil Nadu, India*

Accepted for publication 2 May 2018

Introduction

Rifampicin is one of the most widely used and effective antituberculosis/antileprosy drugs. Adverse effects are uncommon, except for occasional hepatotoxicity, skin-rash, gastrointestinal upsets, and flu-like syndrome.[1] It is rarely allergic, and other autoimmune manifestations including thrombocytopenia are seen especially with intermittent treatment.[2] Here we report a case of thrombocytopenia caused by intermittent administration of rifampicin in view of its rare occurrence.

Case Report

A 50 year old male diagnosed with Hansen's disease was administered with multibacillary multidrug therapy (MB-MDT) in August 2017. After a month when he took the second dose of monthly MB-MDT he developed a few purpuric lesions over the inner aspect of his lower lip, left arm and right leg associated with fever, myalgia and cough with hemoptysis.

On Investigation it was discovered that he had thrombocytopenia (8000), other essential baseline investigations were normal including Prothrombin time and INR.

With the differential diagnosis of viral fever induced thrombocytopenia or rifampicin induced thrombocytopenia, the patient was admitted and evaluated. Dengue (rapid card test) and antiplatelet antibody test for rifampicin (Ranbaxy lab) was negative. Six units of platelets were transfused. Since he had hemoptysis sputum culture & sensitivity, chest X ray and HRCT lung was normal. Post transfusion his platelets improved to 1,01,000 hence he was discharged and advised to continue MB MDT after 1 week.

A month later he presented to the emergency room, with severe body pain, chills, sweating, nausea, and one episode of vomiting after taking rifampicin.

Correspondence to: Reena Rai, PSG Institute of Medical Sciences and Research, Coimbatore, Tamil Nadu, India (e-mail: drreena_rai@yahoo.co.in)

 0305-7518/18/064053+03 $1.00 © Lepra

On examination he had hypotension, tachycardia, ECG was in sinus rhythm. On investigation he again had severe thrombocytopenia (4000) and mild hyperbilirubinemia without any purpuric lesions. He was admitted in intermediate care and was started on platelet transfusion (4 units). On day 2 his platelet count further dropped to 3000. He developed numerous purpuric lesions over hand and legs, along with hemoptysis. He was treated with short course of steroids. After 17 units of platelets transfusion platelets improved to 84,000. The patient improved symptomatically. Hence he was diagnosed as Rifampicin induced thrombocytopenia. Clarithromycin was replaced in the place of rifampicin in MB MDT and the patient was discharged. On follow-up his platelet count was normal and he had no bleeding manifestations.

Discussion

Rifampicin is a semisynthetic derivative of rifamycin B which is an antibiotic produced by Streptomyces meditteranei. It is a potent bactericidal drug which has broad antibacterial spectrum including mycobacterium species. It has a rapid action on *Mycobacterium leprae* by inhibiting DNA dependent RNA polymerase.

Rifampicin is commonly known to cause discoloration of body fluids like tears and urine to an orange or red colour. The most serious complications are hepatotoxicity, cutaneous syndrome, abdominal syndrome, respiratory syndrome, and flu like symptoms. Thrombocytopenia is rarely seen.

Rifampicin induced thrombocytopenia is an uncommon but life threatening complication. Only one case has been reported with anti-leprosy treatment.[3] Rifampicin binds non-covalently to specific membrane glycoprotein IX present on the platelets and induces conformational changes thereby activating the complement pathway which leads to destruction of the platelets.

Rifampicin-induced thrombocytopenia is more common in intermittent therapy than in continuous therapy because in continuous therapy there is neutralisation of antibodies, and antigen – antibody complex is being continuously removed without causing an allergic reaction, whereas intermittent therapy allows a sufficient quantity of antibody to be built up during the drug free interval.

Drug induced throbocytopenia is assessed by using standard criteria to define three levels of severity of bleeding.[4]

1. Major bleeding – defined as intracranial or retroperitoneal bleed or overt bleed with decrease in haemoglobin by more than 2 gm% or require two or more units of blood transfusion.
2. Minor bleeding – Overt bleeding that does not meet the criteria of major bleeding (Malena, gross hemoturia epistaxis, gingival bleeding that is prolonged for 30 mins or requires medical intervention) excessive menstrual bleeding or vaginal bleeding other than menses.
3. Trivial bleeding – Petechiae, purpurae, brief epistaxis or gingival bleed, guaic test positive stool or microscopic hematuria.

The direct assay for measurement of platelet bound antibodies can be performed but its sensitivity is 49–66% and specificity is 78–92%. In our case this test was negative so we

restarted Rifampicin again and the patient had a severe episode of thrombocytopenia. Hence confirming our diagnosis of rifampicin induced thrombocytopenia. So the negative test cannot be used to rule out the diagnosis.

In these patients Rifampicin should be stopped. Platelet counts should be monitored regularly, and most of the patients recover with platelet transfusion. Occasionally patients with severe thrombocytopenia and hemorrhagic manifestations may require temporary support with corticosteroids.[5] Plasmapheresis can be helpful in some cases. The offending drug should not be reused as only minute quantities of the drug are needed to set up a subsequent immune reaction. Even death has been reported.

Analysis of Hypersensitivity in Fragrance Series by Patch Testing

Mohan Kumar Periyasamy, Shanmuga C. Sekar, Reena Rai

Department of Dermatology, PSG Hospitals, Coimbatore, Tamil Nadu, India

Abstract

Introduction: Allergic contact dermatitis (ACD) is an inflammatory disorder, which occurs as a result of repeated contact with an allergen. Fragrances are the products obtained naturally or produced synthetically. The purpose of this study is to detect the fragrance allergens producing ACD. **Materials and Methods:** This is an open-label prospective observational study. Patients of age above 18 years with history of using cosmetic products with dermatitis lesions over face, neck, axilla and hands were included. Patch testing was done with fragrance series by using the standard technique. The results were interpreted on day 2 and day 4 as recommended by International Contact Dermatitis Research Group criteria. **Results:** Totally 27 patients were included in this study. Of them, 12 were males and 15 were females; the mean age was 43 years. The mean duration of symptoms was 12.5 months. The most common site of involvement was hands. Housewives and office workers were the most commonly affected occupational groups. The most commonly used category of cosmetic product was talcum powders by 13 (48.1%) patients. In this study, 85.18% patients showed at least one fragrance antigen positivity. Fragrance mix II is the most frequent allergen in this study. **Discussion:** We conclude that the fragrance mix II is an important marker to find out fragrance allergy. Hand dermatitis is the most common presentation in patients with fragrance allergy. Perfumed talcum powders, soaps and perfumes are the leading sources of sensitization to fragrance allergens.

Keywords: *Allergic contact dermatitis, cosmetics, fragrances, hand dermatitis, patch testing*

Introduction

Allergic contact dermatitis (ACD) is an inflammatory disorder, which occurs as a result of repeated contact with an allergen, leading to the rapid activation of T cells and further release of cytokines.[1] In the sixth century, Aetius Amidenus, a physician to the Byzantine court first used the word "eczema". Eczema may present clinically as scaling, clustered papulovesicles, associated with erythema, pruritus and fissuring. It is caused by a different variety of external and internal factors.[2] Patch testing is considered as the gold standard and only reliable method to identify the contact allergens.[3]

Cosmetics is defined as the substances which are intended to be poured, rubbed, sprinkled or sprayed on skin, applied to a normal or previously sensitized skin for cleansing, promoting attractiveness, beautifying, or to alter the appearance of the human skin or body.[4] Cosmetics and toiletries are being used by most of the people for hygiene and personal care of the body to enhance the attractiveness of consumers, get pleasant smell, protection and masking the defects present in the skin.[5] Cosmetics are complex mixtures made up of preservatives, perfumes, emulsifiers, stabilizing agents, various types of lipids, alcohols and so on.[6]

Fragrances are the products obtained naturally or produced synthetically. Natural fragrances, such as balsams, concretes, essential oils and absolutes are available, with a few animal products such as musk, civet and ambergris, which also can be manufactured synthetically.[7] Masking fragrances are used mainly in topical medicaments and cosmetic products by labeling them as "fragrance free". But they contain original fragrances.[8] The purpose of this study is to detect all the fragrance allergens which cause ACD.

Materials and Methods

This is an open-label prospective observational study conducted from March 2017 to July 2018 in a tertiary care hospital. All patients of age above 18 years who

attended our dermatology outpatient department with the history of using various topical cosmetic products such as perfumes, detergent soap, after shave lotion, moisturizers, facial makeup creams, with dermatitis lesions over face, neck, axilla and hands were included in the study. Age below 18 years, who have not used any cosmetic products, who are on systemic corticosteroids, immunosuppressants, pregnant, lactating females, were excluded from the study.

The study was reviewed and approved by an institutional ethical committee, and all patients gave their voluntary informed consent to participate in this study. Detailed history regarding duration, occupation, systemic illness was obtained and recorded [Table 1]. Patch testing with fragrance series [Figure 1] was done by using the standard technique, that is, 0.1 ml of each antigen was placed in an aluminum Finn chamber, mounted on an adhesive tape [Figure 2], which was applied over the back of all the patients [Figure 3]. A total of 42 patch test antigens [Table 2] are present in the fragrance series obtained from chemotechnique diagnostics, AB Sweden. The results were interpreted on days 2 and 4 as recommended by International Contact Dermatitis Research Group (ICDRG) criteria [Table 3].

Results

A total of 27 patients were included in this study and patch testing was done with fragrance series. Of them, 12 (44.4%) were males and 15 (55.5%) were females; the mean age was 43 years (range 18-68 years). The mean duration of symptoms was 12.5 months (range 1-24 months). The most common site of involvement was hands [Figure 4], which

Figure 5: Erythema and scaling seen over the neck

was observed in 19 (70.3%) patients [Table 4], followed by neck [Figure 5] in 12 (44.4%) patients.

The most commonly seen occupational groups with dermatitis features were housewives 6 (22.2%) and office workers 6 (22.2%) patients [Table 5]. The most commonly used category of cosmetic products by these patients were talcum powders by 13 (48.1%) patients [Table 6] followed by scented soaps in 12 (44.4%) patients.

Out of the 27 patients, 8 (29.6%) were atopic individuals and 19 (70.3%) were non-atopic individuals. Of the 27 patients, 23 (85.18%) patients showed at least one antigen positivity, and 4 (14.8%) patients were negative to all antigens. The most frequent allergen to become positive in this study is fragrance mix II [Figure 6] in eight (29.6%) patients [Table 7], followed by cinnamic aldehyde and cinnamic alcohol in seven (25.9%) patients each [Figure 7].

Discussion

ACD is one of the commonest examples of type IV hypersensitivity reaction which usually affects the previously sensitized persons. The contact allergens are very small molecules which are able to penetrate deeper layers of the skin and produce sensitization.[2] Fragrances are the most common cause of allergic reactions to

cosmetics. Fragrances can enter into the body through nose into lungs, upper airways, ingestion, skin, and it can cause irritation of eyes, throat and nose, headaches, dizziness, forgetfulness and easy fatigability.[9]

In our study, females outnumbered males in fragrance hypersensitivity reactions by nearly 10%. The fact that there is a high prevalence of fragrance allergy in women than men could be due to the frequent use of skin care, personal hygiene and face care products by the female population.

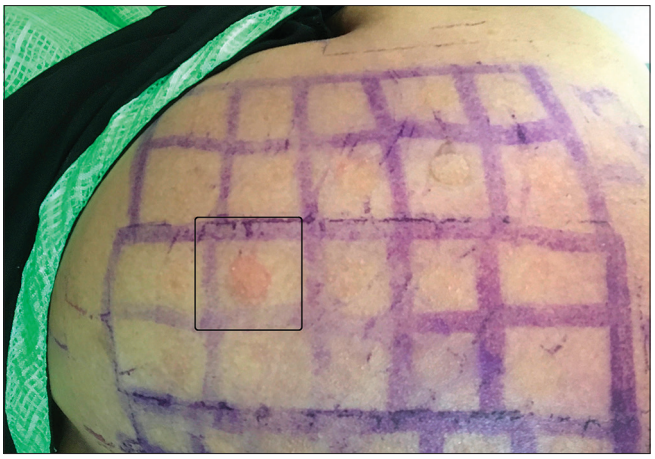

Figure 6: Patch test: Same patient shown in Figure 4, showed positive reaction to fragrance mix II

In this study, housewives and office workers are the occupational groups who developed fragrance allergy most frequently, which is seen in six (22.2%) patients in each occupational group. DeGroot *et al*.[7] found that fragrance allergy from perfumes, deodorants and aftershave lotions is commonly encountered in Swedish college students.

In this study, most commonly 19 (70.3%) patients had lesions over the hands, and next frequent site was over the neck in 12 (44.4%) patients. Our findings correlate well with the studies conducted by Santucci and Malten;[7] they found that hand dermatitis was the most common presentation with 41% and 52% positivity, respectively, because of frequent contact of the fragrance products such as soaps, fairness creams, shampoos and topical medications with hands before application at various sites of the body.[7]

In this study, the most common category of cosmetic products used were talcum powders by 13 (48.1%) patients and scented soaps by 12 (44.4%) patients. An observational study found that the skin care products such as lotions, creams were the cosmetic categories which were blamed for the positive reactions in patch testing in 37% of patients; 30% of positive cases had used personal care products and 13% used deodorants and antiperspirants.[5] According to Cornelis *et al*., soaps were used by 87% of the people, 82% people used toothpaste, shampoos were used by 80%, deodorants and antiperspirants by 61%, talcum powder and body spray were used by nearly 45% of the study population.[5]

In this study, we found that the most frequent allergen to show positivity was fragrance mix II in eight (29.6%) patients. The second most common allergens were cinnamic aldehyde and cinnamic alcohol in seven (25.9%) patients, which is followed by Geranium oil Bourbon and Lavender absolute in five (18.5%) patients. Our observations are similar to a study conducted by Johansen *et al*.: who stated that the most common allergens are fragrance mix II and

Table 3: Interpretation of Patch Test Results (ICDRG Criteria)

Notation	Description
Negative	No changes in the tested skin area
?+	Non-palpable faint erythema
1+	Palpable erythema with moderate edema or infiltrate, no papules or vesicles
2+	Strong infiltrate and erythema, numerous papules or vesicles
3+	Many vesicles coalesced to form bulla or ulceration
NT	Not tested
IR	Inflammation is sharply limited to an exposed area, lack of infiltrate, small petechiae, pustules with papules and vesicles

ICDRG=International Contact Dermatitis Research Group

Table 4: Location of dermatitis lesions

Location	Number of patients	Percentage
Neck	12	44.4
Face	11	40.7
Hands	19	70.3
Axilla	5	18.5

Table 5: Various occupational groups presented with dermatitis

Occupation	Number of patients	Percentage
Housewife	6	22.2
Navy man	1	3.7
Office worker	6	22.2
Painter	3	11.1
Business	2	7.4
Textile laborer	1	3.7
Agriculture	5	18.5
Cement worker	2	7.4
Machine operator	1	3.7

Table 6: Categories of the cosmetic products used by the patients

Category	Number of patients	Percentage
Perfumes	9	33.3
Soaps	12	44.4
Detergents	5	18.5
Moisturizers	5	18.5
Talcum powders	13	48.1
Fairness creams	5	18.5
Sunscreens	3	11.1
Shampoo	2	7.4
Aftershave lotion	1	3.7

balsam of peru.[10] Santucci *et al*. identified 54 out of 92 patients were sensitive to fragrance mix II.[7]

Various studies have been conducted in various countries to know the incidence of fragrance allergy, but only a few studies are available for our Indian skin type. This

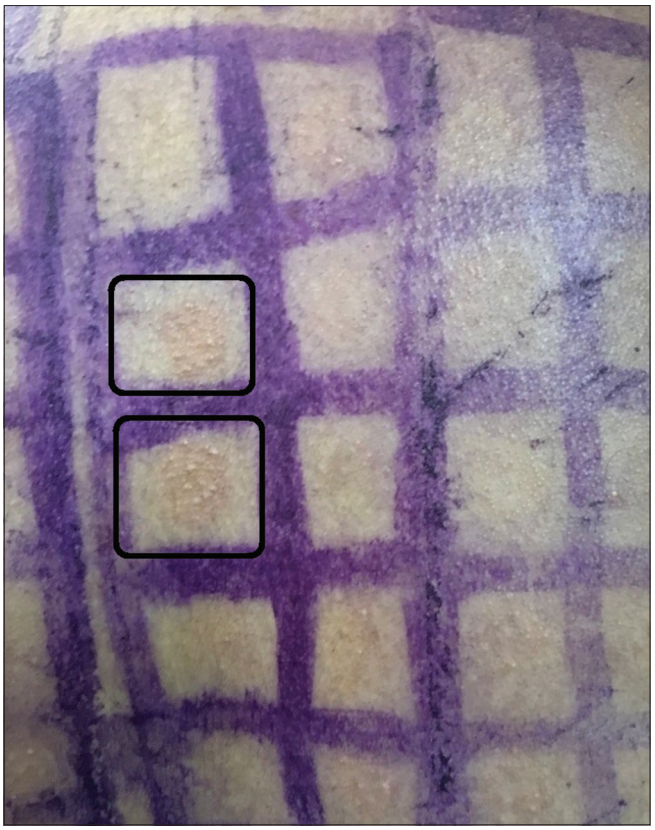

Figure 7: Patch test: Same patient shown in Figure 5, showed positive reaction to cinnamic alcohol and cinnamic aldehyde

is because the fragrance allergy is usually not reported to the dermatologists by the patients. In USA, the most frequent sensitizer was fragrance mix II. In Netherlands, isoeugenol is followed by oak moss absolute. In a European study, they found that oak moss absolute is the most frequently positive fragrance allergen followed by isoeugenol.[10]

In this study, a total of 27 patients were included with dermatitis. Of them, 8 (29.6%) patients were known atopic and 19 (70.3%) patients were non-atopic individuals. But Katsarma *et al*.[10] stated that more than 50% of ACD patients were with atopic diathesis in their study. Caress and Maria *et al*.[11] also concluded that the fragrance-induced ACD is most commonly seen in atopic eczema cases.

In this study, we did not experience any adverse events or intolerability to patch testing. All the 27 patients came for regular follow-up and also for the readings taken on day 2 and day 4. Once the patient is diagnosed as a case of ACD by patch testing, pamphlets were issued regarding the awareness of how to avoid contact with the particular allergens. Cosmetics are not very safe as claimed by the manufacturing companies, and it may contain many fragrance allergens. ACD induced by cosmetics was more prevalent in urban people than rural because of the health awareness and attitude towards cosmetics in urban people.[12]

[Downloaded free from http://www.idoj.in on Thursday, December 16, 2021, IP: 103.224.34.2]

Table 7: Frequency of fragrance allergen positivity

Antigens	Number of patients showed positivity	Percentage
Cinnamic aldehyde	7	25.9
Cinnamic alcohol	7	25.9
Isoeugenol	4	14.8
Oakmoss absolute	4	14.8
Lavender absolute	5	18.5
Geranium oil Bourbon	5	18.5
Fragrance mix II	8	29.6
Benzyl cinnamate	4	14.8

Conclusion

Patch testing is a simple method to diagnose the causative agent of ACD. It shortens the time lapse from the first visit to final diagnosis and increases the period of remission, which in turn reduces the cost of treatment. We conclude that fragrance mix II is an important marker to find out fragrance allergy. Hand dermatitis is the most common presentation in patients with fragrance allergy. Perfumed talcum powders, soaps and perfumes are the leading source of sensitization to fragrance allergens producing fragrance allergy.

Comparative Analysis of BIOCHIP Mosaic-Based Indirect Immunofluorescence with Direct Immunofluorescence in Diagnosis of Autoimmune Bullous Diseases: A Cross-Sectional Study

P. Arunprasath, Reena Rai*, Chaitra Venkataswamy[1,*]

Departments of Dermatology and [1]Pathology, PSG Institute of Medical Sciences and Research, Coimbatore, Tamil Nadu, India

**Both authors have contributed equally in this study.*

Abstract

Background: Autoimmune bullous diseases (AIBD) are a heterogeneous group of diseases characterized by autoantibodies against desmosomal proteins in the pemphigus group of disorders and adhesion molecules of the dermal-epidermal junction in pemphigoid group of diseases. Direct immunofluorescence (DIF) establishes the diagnosis of AIBD by demonstrating intercellular deposits of IgG and C3 in case of pemphigus and linear deposits of IgG and C3 along the basement membrane zone (BMZ) in bullous pemphigoid (BP). BIOCHIP mosaic-based indirect immunofluorescence (IIF), a novel diagnostic approach employs detection of characteristic staining pattern and target antigens in a single miniature incubation field. **Aim:** To compare the BIOCHIP mosaic-based IIF with DIF in the diagnosis of AIBD. **Materials and Methods:** A total of 40 patients of AIBD in the active phase of the disease were included in the study. Skin biopsy was done in these patients for DIF study and serum was subjected to BIOCHIP mosaic-based IIF assay. The results were then compared. **Results:** DIF revealed a diagnosis of Pemphigus in 18 patients and BP in 22 patients. BIOCHIP showed a diagnosis of pemphigus in 18 patients, BP in 18 patients and floor pattern staining in four patients, which could be attributed to any of the floor pattern staining subepidermal blistering disease. **Limitations:** Small sample size, lack of control group and no comparison made with ELISA. **Conclusion:** This study concludes that the result of BIOCHIP showed a significant correlation with the DIF and can be used as a first line-screening tool in the diagnosis of AIBD.

Keywords: *Autoimmune bullous skin diseases, BIOCHIP mosaic, direct immunofluorescence, indirect immunofluorescence*

Introduction

Autoimmune bullous diseases (AIBD) include diverse group of skin diseases characterized by autoantibodies against desmosomal proteins in case of pemphigus group of diseases and components of basement membrane zone (BMZ) in pemphigoid diseases. Diagnosis of AIBD is based on the combination of characteristic clinical features, histopathological findings, direct immunofluorescence (DIF), indirect immunofluorescence (IIF) or enzyme-linked immunosorbent assay (ELISA) for target antigens. BIOCHIP mosaic, a novel diagnostic technique employs detection of target antigens and characteristic-staining pattern, in a single miniature incubation field.[1]

Materials and Methods

The present study was a cross-sectional study conducted during September 2018-July 2019 in the department of dermatology and pathology in a tertiary care hospital. Institutional ethics committee approval was obtained prior to the commencement of the study. A total of 40 patients with suspected AIBD were included in the study. AIBD patients under treatment and clinical remission were excluded from the study. All the participants were informed regarding the study and samples were collected after written consent. Skin biopsy was obtained from uninvolved perilesional skin for DIF and 5 ml of blood was obtained for BIOCHIP mosaic evaluation. Subsequently, the results of DIF and BIOCHIP mosaic were compared.

BIOCHIP mosaic

Procedure

The Dermatology mosaic 7 BIOCHIP (Euroimmun, Germany) was
